In general relativity theory the geometric properties of space are determined by the gravitational field alone, without any effect of the electromagnetic field on the geometry of space. After creating the general theory of relativity Einstein posed the problem of constructing a geometry of four-dimensional spacetime determined by the electromagnetic as well as the gravitational field. The first attempt of construction of a unified field theory was made by Hermann Weyl in his paper *Gravitation and electricity* (Gravitation und Elektrizität. Leipzig, 1918) *[340, pp. 200–216]*. Besides the metric quadratic form

$$ds^2 = \sum_{\mu,\nu} g_{\mu\nu} dx^\mu dx_\nu \tag{2}$$

Weyl considers also the linear form

$$d\phi = \sum_{\mu} \phi_\mu dx_\mu \tag{7}$$

and writes that

> *The internal metrical connexion of space thus depends on a linear form* (7) *besides the quadratic form* (2)—which is determined except as to an arbitrary factor of proportionality *[340, p. 206]*.

The vector ϕ_μ is the *vector-potential* of the electromagnetic field $F_{\mu\nu}$ given by

$$F_{\mu\nu} = \partial\phi_\mu/\partial x_\nu - \partial\phi_\nu/\partial x_\mu.$$

The geometry constructed by Weyl is called the *Weyl connection*. Weyl expounded this theory also in his *Space, Time and Matter* (1918) *[626]*.

Einstein himself devoted the last 35 years of his life to the search for a unified field theory. Of other attempts at constructing a unified field theory we note, first of all, the paper of Theodor Kaluza (1885–1954) *On the unicity problem of physics* (Zum Unitätsproblem der Physik. Berlin, 1921) *[259]*. To increase the number of relevant parameters Kaluza went in the direction of increasing the number of dimensions of his space and assumed that in addition to the four dimensions of physical spacetime there is a fifth dimension without a direct physical sense. Proceeding from Kaluza's idea the mathematician Veblen and the physicist Pauli proposed in 1930–1933 a unified field theory in which five coordinates are viewed as the projective coordinates of particles in a four-dimensional space.

A detailed history of unified field theories in the first third of the 20th century is given by Vladimir Pavlovič Vizgin in the book *Unified field theories in the first third of the 20th century* (Edinye teorii polya v pervoĭ treti XX veka. Moscow, 1985) *[615]*.

We note that when Einstein posed the question of a unified field theory he assumed that the theories of interactions of the gravitational and electromagnetic fields exhaust all forms of physical interactions. The discovery, in the last few decades, of "strong" and "weak" interactions that do not coincide with these interactions deprived the problem posed by Einstein of the importance he attached to it. In his "Remarks to the Einsteinian sketch of a unified field theory" the famous German physicist Werner Heisenberg (1901–1976) wrote:

> This attempt, grandiose in its conception, failed from the very beginning. At the time when Einstein concerned himself with the unified field theory new elementary particles were continuously discovered and with them their associated new fields. This meant that there existed no hard, solid, empirical basis for the implementation of the Einsteinian program and Einstein's attempts produced no conclusive results whatever. However, the failure that dogged the Einsteinian program also had deeper foundations than the uncertainty of empirical facts; these foundations have to do with the relations of Einstein's field-theoretic view of quantum theory. Einstein proceeded from the classical nonlinear field theory of matter for the metric tensor of the field that defined his geometry.

> Einstein hoped that in the end it will be possible to think of atoms and elementary particles in such a theory as singular solutions of the nonlinear equations of the field. In reality, however, the element of discreteness that expresses the existence of elementary particles has a far wider character. It becomes dominant as soon as we go over to the domain of atoms and elementary particles; which is why their description by means of a field theory of the classical type is out of the question. Conversely, we now know that there operate here quantum-mechanical laws whose structure was understood in the twenties. Since Einstein could not come to terms with such a structure, he did not make an attempt to approach the unified field theory using quantum laws.
>
> Nevertheless, experiments with elementary particles carried out in connection with quantum theory contain very many arguments in favor of Einstein's program.
>
> In the last ten years many elementary particles have been discovered and thus also many new fields. Also, it became clear that elementary particles can change into one another. If two elementary particles with very high kinetic energy collide in some way then there can arise new particles, and the laws that govern the coming into existence and the disappearance of elementary particles can, apparently, be formulated by means of relatively simple selection rules and the corresponding quantum numbers. It follows that all elementary particles "consist," so to say, of one and the same substance that can be simply called "energy" or "matter"; their structure and their ability to go over into one another should follow from a simple law for matter.
>
> Thus, by the nature of things, a satisfactory theory of elementary particles must, at the same time, be a unified field theory of matter *[221a, pp. 120 - 125]*.

An attempt to create such a unified theory of elementary particles was made by Heisenberg himself.

Spaces with Affine Connection

Although the problem of a unified field theory has not yielded any substantial results for physics, it has been remarkably fruitful for geometry. Weyl's theory was further developed by Schouten, who introduced the general notion of a space with an affine connection in the paper *On different forms of connection that can be laid at the foundation of a differential geometry* (Über die verschiedenen Arten der Übertragung die einer Differentialgeometrie zugrunde gelegt werden können. Berlin, 1922) *[511]*. A detailed exposition of Schouten's theory is found in his *Ricci calculus*. A space with an affine connection is defined as a manifold of points with coordinates x^i at each of whose points there is given a point function $\Gamma^i_{jk} = \Gamma^i_{kj}$ that is not expressible in the general case in terms of the point functions g_{ij}. Because of this last condition it is not possible, in the general case, to define in a space with an affine connection the length of lines, but it *is* possible to define parallel displacement of vectors by formula (8.14). In a space with an affine connection geodesics are defined. They are solutions of the equations (8.11). For each arc of a geodesic there is defined its midpoint. In such a space one can define reflections in points along geodesics. Just as in a Riemannian space, the geometric sense of parallel displacement of vectors is that it is determined by a mapping of a neighborhood of a point of the space onto a neighborhood of an infinitely near point that is the result of two reflections in two points along geodesics. The name *affine connection* is due to the fact that the mapping of vectors at a point of space onto vectors at an infinitely near point of this space is an affine transformation of vector spaces.

It is clear that Riemannian and pseudo-Riemannian spaces are special cases of spaces with an affine connection. In such spaces the mapping of vectors at one point onto vectors at an infinitely close point under parallel displacement is an isometry of Euclidean and pseudo-Euclidean spaces, respectively.

The space introduced by Weyl in his unified field theory is also a space with an affine connection. In this space the mapping of vectors at one point onto vectors at an infinitely close point under parallel displacement is a similarity transformation.

Even more general spaces were introduced by the French mathematician Élie Cartan (1869–1951). In the papers *On manifolds with an affine connection and the generalized relativity theory* (Sur les variétés à connexion affine et la théorie de la relativité généralisée. Paris, 1923) *[96, part 3, pp. 659–746, 798–825, 921–992]*, *Spaces with a conformal connection* (Les espaces à connexion conforme. Paris, 1923) *[96, part 3, pp. 747–797]* and *On manifolds with a projective connection* (Sur les variétés à connexion projective. Paris, 1924) *[96, part 3, pp. 825–861]* Cartan introduced the notion of a *space with a homogeneous connection*. Whereas in the case of a space with an affine connection there is associated to every point a vector space that can be regarded as an affine space, and under parallel displacement of vectors the space at one point is mapped by an affine transformation onto the space at an infinitely near point, in the case of a space with a homogeneous connection there corresponds to every point of the space a homogeneous space with a definite group of transformations. Also, for every pair of infinitely near points there is specified a transformation of the spaces associated with these points that preserves their geometry. In addition to spaces with an affine connection and special cases of such spaces noted above, the most important spaces with a homogeneous connection are *spaces with a projective* and *conformal connection*, respectively. To each point of these spaces there is associated, respectively, a projective or conformal space, and for each pair of infinitely near points of a space with a connection there is specified, respectively, a projective or conformal mapping of one of the spaces associated with these points onto the other.

Differentiable Manifolds

The spaces introduced by Riemann and the groups introduced by Lie, bearing the names of their respective inventors, as well as pseudo-Riemannian spaces, Weyl spaces, and the more general spaces with an affine or other homogeneous connection were defined only locally—in the domain of a certain coordinate system. The introduction of topological manifolds made possible the study of differential-geometric spaces in the large. In every n-dimensional topological manifold one can define a homeomorphic mapping of a neighborhood U of every point onto some domain of n-dimensional Euclidean space, and the coordinate system in the Euclidean space provides coordinates for the neighborhood U. This system of coordinates in the neighborhood U is now called a *system of local coordinates* or a *local map* of the manifold, and the totality of local maps is called the *atlas* of the manifold. A manifold is called *differentiable of class* v if (1) the domains of the maps of the atlas cover the whole manifold; and (2) if U and U' are two domains of maps of the atlas with nonempty intersection and a point x in the intersection has coordinates x^i and $x^{i'}$ in the two maps then the functions $x^{i'} = f(x^1, \ldots, x^n)$ have continuous partial derivatives up to and including order v, and the jacobian $\det\left(\frac{\partial x^{i'}}{\partial x^j}\right)$ is different from zero throughout the intersection of the domains. The manifold is called *analytic* if the functions in (2) are analytic.

The definitions of a differentiable manifold and of an analytic manifold were formulated by Oswald Veblen (1880–1960) and by John Henry Constantine Whitehead (1904–1960) in *The foundations of differential geometry* (Cambridge, 1932) *[612]*.

With every point of a differentiable manifold there is associated a vector space with vectors $\{dx^i\}$ whose coordinates are the differentials of the coordinates x^i; these spaces are called the *tangent spaces* of the differentiable manifold. Under coordinate transformations $x^i \to x^{i'}$ the coordinates of the vectors and tensors of the tangent spaces transform according to the rules (8.7)–(8.9), and so on. If in every tangent space of a differentiable manifold there is given a metric tensor g_{ij} that determines an inner product in the Euclidean or pseudo-Euclidean space then the differentiable manifold is called, respectively, a *Riemannian* or *pseudo-Riemannian space in the large*. If in each of the tangent spaces of a differentiable manifold there is given an object Γ^i_{jk} that transforms under coordinate transformations according to the same rule as the coefficients Γ^i_{jk} of Riemannian spaces then the differentiable space is called a *space with an affine connection in the large*.

Fibrations

Spaces with connections are special cases of fiber spaces. Unlike spaces with Schouten-Cartan connections, fiber spaces are considered in the large. The initial form of the theory of fiber spaces in the large was the theory of "sphere-spaces," that is, fiber spaces whose "fibers" are spheres. This theory arose in connection with the solution of the problem of continuous mapping of an n-dimensional sphere onto an m-dimensional one for, if $n > m$, then to every point of the m-dimensional sphere there corresponds an $(n - m)$-dimensional manifold of the n-dimensional sphere, so that the latter "stratifies" or "fibrates" into these manifolds; the resulting fibres are also called *spheres*. The theory of such spaces was constructed by the American mathematician Hassler Whitney (b. 1907) in the paper *Sphere-spaces* (Boston, 1935) *[632]*. In the paper *On the theory of sphere bundles* (Boston, 1940) *[633]* Whitney calls these spaces *sphere-bundles*. The most complete account of Whitney's theory is contained in his lectures *On the topology of differentiable manifolds* (Ann Arbor, 1941) *[634]*. Together with *sphere-bundles* Whitney also considered *plane-bundles*. Whitney associated to every differentiable manifold a *tangent plane-bundle* consisting of the tangent spaces of the manifold and *tangent sphere-bundle* consisting of spheres in these tangent spaces with centers at the points of tangency, with one sphere in each tangent space. In the first case, the points of the *fibers* characterize the vectors of the differentiable manifold; in the second, they characterize the directions issuing from a point of the manifold.

Soon Whitney's *sphere-bundles* were replaced by arbitrary manifolds. Then there arose the more general concept of a *fiber bundle* or a *fiber space*. The general theory of such spaces was set forth by the American mathematician Norman Steenrod (1910–1971) in the monograph *The topology of fiber bundles* (Princeton, 1951) *[560]*, which completed the development of this theory.

The simplest fiber space is the *direct product* of two topological spaces S and T, that is, the totality of pairs (s, t) of elements s in S and t in T where the closed sets of the topological product are sets of pairs (s, t) in which both elements s and t vary over closed sets in the spaces S and T, respectively. In this case one may view the set of pairs (s, t_0) with fixed t_0 as a *fiber* and the space T of all possible elements t_0 as a basis of the fiber space. One can also view the set of pairs (s_0, t) with fixed s_0 as a *fiber* and the space S as a basis of the same fiber space. In this case the fibration is called *trivial*.

In more complicated cases, a fibre space is not simply the direct product of a *fiber* by a *basis* but also consists of homeomorphic fibers, and, if the latter are viewed as points of some new space, then this space can be regarded as a basis of the fiber space. The simplest fiber space of this kind is a *Möbius strip* obtained from the lateral surface of a right circular cylinder by identification of pairs of points that are symmetric with respect to its center, or from a rectangle (which may be thought of as the application of half of the preceding cylinder to a plane) by gluing the points of a pair of its opposite sides that are symmetric with respect to its center. (Hence the name *skew products* for general fibrations of a space used in the Russian translation of N. Steenrod's book *[560]*). One usually considers also the group of topological mappings of a fiber onto itself that preserves a certain structure of these fibers and mappings of fibers, one onto another, that preserve this structure.

The most important fiber spaces are the *tangent plane-bundles* defined by Whitney for differentiable manifolds. Now they are called simply *tangent bundles* of differentiable manifolds. The bases of these fiber spaces are the differentiable manifolds, and the fibres are their tangent spaces. To the class of fiber spaces there belong Riemannian spaces, pseudo-Riemannian spaces, and spaces with an affine connection in the large together with their tangent spaces that are, respectively, Euclidean, pseudo-Euclidean, and affine, as well as spaces with a projective, conformal, and arbitrary homogeneous connection together with the corresponding homogeneous spaces that also form *fibers*. The groups of transformations of the *fibers* of these spaces are, respectively, the groups of Euclidean and pseudo-Euclidean motions, of affine, projective, conformal, and other transformations.

Exterior Forms, Curvature and Betti Numbers

The field of a skew-symmetric covariant tensor $a_{i_1 i_2 \dots i_k}$ in a domain of a differentiable manifold defines at every point of this domain an exterior differential form

$$\omega_k = \sum_{i_1} \dots \sum_{i_k} a_{i_1 i_2 \dots i_k} dx^{i_1} \wedge dx^{i_2} \wedge \cdots \wedge dx^{i_k},$$

where $\wedge$ denotes exterior multiplication. The form is invariant under even permutations of the dx^{i_a} and changes sign under odd permutations of the dx^{i_a} (in virtue of the skew symmetry of $a_{i_1 \dots i_k}$ the ordinary differential form $\sum_{i_1} \dots \sum_{i_k} a_{i_1 i_2 \dots i_k} dx^{i_1} dx^{i_2} \dots dx^{i_k}$ is equal to zero). For exterior forms we define the operations of exterior multiplication

$$\omega_{k+l} = \omega_k \wedge \omega_l$$

and exterior differentiation

$$\omega_{k+1} = \mathscr{D}\omega_k = \sum_{i_1} \dots \sum_{i_k} da_{i_1 \dots i_k} \wedge dx^{i_1} \wedge \cdots \wedge dx^{i_k}.$$

The differential forms in multiple integrals defining areas and volumes are exterior forms, and the Ostrogradskiĭ formula in the beginning of chapter 7 can be written as

$$\int_{\partial M} \omega = \int_M \mathscr{D}\omega,$$

where M is a bounded domain and ∂M is its boundary.

The theory of exterior forms was founded by É. Cartan in the paper *On certain differential expressions and the Pfaff problem* (Sur certaines expressions différentielles et le problème de Pfaff. Paris, 1899) *[96, part 2, pp. 303–396]*. It was extensively developed by É. Cartan (see his book *Exterior differential systems and their geometrical applications* (Les systèmes différentiels extérieurs et leurs applications géométriques. Paris, 1945) *[97]*, by the Soviet geometer Sergeĭ Pavlovič Finikov (1883–1964), and by their students.

If a moving orthonormal frame $\{\mathbf{e}_i\}$ is associated with every point of a curve or surface in the space R_n or with every figure of a family of figures in this space, then the differentials of the radius vector $\mathbf{x}$ and of the vectors $\mathbf{e}_i$ of the frame can be written as

$$d\mathbf{x} = \mathbf{e}_i\omega^i, \qquad d\mathbf{e}_i = \mathbf{e}_j\omega_i^j, \tag{8.16}$$

where

$$\omega_j^i = -\omega_i^j, \tag{8.17}$$

and the exterior differentials of the forms ω^i and ω_j^i satisfy the *equations of structure*

$$\mathscr{D}\omega^i = \sum_k \omega^k \wedge \omega_k^i, \qquad \mathscr{D}\omega_j^i = \sum_k \omega_j^k \wedge \omega_k^i. \tag{8.18}$$

A curve, surface or family of figures is defined by a system of Pfaff equations $\theta^1 = \theta^2 = \cdots = \theta^r = 0$, where the forms θ^A are linear combinations of the forms ω^i, ω_j^i. For a curve with arc length s and tangent vector $\mathbf{e}_1$ these equations are $\omega^2 = \cdots = \omega^n = 0$ and for a hypersurface with normal vector $\mathbf{e}_n$ the equation is $\omega^n = 0$. If for the curve we put $d\mathbf{e}_1/ds = k_1\mathbf{e}_2$ and choose vectors $\mathbf{e}_3, \ldots, \mathbf{e}_n$ so that $d\mathbf{e}_i/ds$ is a linear combination of $\mathbf{e}_1, \ldots, \mathbf{e}_{i+1}$, then $\omega_i^{i+1}/ds = -\omega_{i+1}^i/ds = k_i$ are curvatures of the curve and the remaining ω_j^i are zeros. In this way we obtain the *Frenet formulas*

$$\begin{aligned} &d\mathbf{e}_1/ds = k_1\mathbf{e}_2,\\ &d\mathbf{e}_2/ds = -k_1\mathbf{e}_1 + k_2\mathbf{e}_3, \ldots,\\ &\quad d\mathbf{e}_i/ds = -k_{i-1}\mathbf{e}_{i-1} + k_i\mathbf{e}_{i+1}, \ldots, d\mathbf{e}_n/ds = -k_{n-1}\mathbf{e}_{n-1} \end{aligned}$$

discovered for R_3 in 1847 by Frederic Frenet (1816–1900) and for R_n in 1874 by C. Jordan. The curvatures k_i define the curve up to a motion of R_n.

For a hypersurface we direct the vectors $\mathbf{e}_1, \ldots, \mathbf{e}_{n-1}$ along curvature lines of the hypersurface and the vector $\mathbf{e}_n$ along its normal. Exterior differentiation of the Pfaff equation $\omega^n = 0$ gives, in view of (8.18), $\mathscr{D}\omega^n = \sum_k \omega^k \wedge \omega_k^n = 0$. Hence $\omega_\alpha^n = \sum_\beta b_{\alpha\beta}\omega^\beta$ $(\alpha, \beta = 1, 2, \ldots, n-1)$. We note that the analogues of Gauss's quadratic forms for surfaces in R_3 and for hypersurfaces in R_n are

$$d\mathbf{x}^2 = \sum_\alpha (\omega^\alpha)^2,$$

$$\mathbf{e}_n d^2\mathbf{x} = -d\mathbf{e}_n d\mathbf{x} = -\left(-\sum_\alpha \omega_\alpha^n \mathbf{e}_\alpha\right)\left(\sum_\beta \omega^\beta \mathbf{e}_\beta\right) = \sum_\alpha \sum_\beta b_{\alpha\beta}\omega^\alpha\omega^\beta.$$

In our basis $b_{\alpha\beta} = b_\alpha\delta_{\alpha\beta}$, $-b_\alpha = k_\alpha$ are main curvatures of the hypersurface; they are differential invariants of the hypersurface. Exterior differentiation of other forms yields a complete system of differential invariants of the hypersurface which defines it up to a motion of the space R_n.

Formulas (8.16) and (8.18) also hold in the affine space E_n and in the pseudo-Euclidean space ${}^lR_n$. In the case of E_n the forms ω_j^i are not connected by any condition. In the case of ${}^lR_n$ with scalar square of a vector $\mathbf{x}^2 = \sum_i \varepsilon_i (x^i)^2$ the conditions (8.17) become

$$\varepsilon_i \omega^i_j = -\varepsilon_j \omega^j_i. \tag{8.19}$$

In the spaces P_n, S_n and ${}^lS_n$ the points are represented by vectors of the spaces E_{n+1}, R_{n+1} and ${}^lR_{n+1}$, respectively. In these spaces the role of the radius vector $\mathbf{x}$ is played by e_0. In these spaces hold the second formulas (8.16) and (8.18). In P_n the forms ω^i_j are connected by the condition $\sum_i \omega^i_i = 0$, in S_n by the condition (8.17), and in ${}^lR_n$ by the condition (8.19).

Analogous methods can be applied in all homogeneous spaces.

These methods can also be applied in spaces with affine connection and in Riemannian and pseudo-Riemannian spaces. In these spaces the vectors $\mathbf{e}_i$ are vectors of the tangent spaces of E_n, R_n and ${}^lR_n$ respectively. In these spaces hold formulas (8.16) and in Riemannian and pseudo-Riemannian spaces formulas (8.17) and (8.19), respectively. The equations of structure there have the form

$$\mathscr{D}\omega^i = \sum_k \omega^k \wedge \omega^i_k + \sum_j \sum_k S^i_{jk} \omega^j \wedge \omega^k,$$
$$\mathscr{D}\omega^i_j = \sum \omega^k_j \wedge \omega^i_k + \sum_k \sum_h R_{jkh}{}^{\cdots i} \omega^k \wedge \omega^h$$

where S^i_{jk} is the *torsion tensor* (equal to zero in spaces without torsion, in particular, in Riemannian and pseudo-Riemannian spaces), $R_{jkh}{}^{\cdots i}$ is the *curvature tensor* (in Riemannian spaces $R_{ijkl} = g_{hl} R^h{}_{ijk}$ is the Riemann tensor).

An exterior differential form ω is called *closed* if $\mathscr{D}\omega = 0$ and *exact* if $\omega = \mathscr{D}\omega'$. Every exact form is closed since $\mathscr{D}(\mathscr{D}\omega) = 0$. Exterior differentiation is similar to the taking of a boundary, except that in the latter case the dimension of a manifold decreases and in the former case the "order" of a form increases. This analogy was made use of in the paper *On analysis situs* [i.e. topology] *of n-dimensional manifolds* (Sur l'analysis situs des variétés à n-dimensions. Paris, 1931) *[452]* by the Belgian mathematician Georges de Rham (1903–1969). In this paper de Rham defined the *cohomology groups*, in a certain sense dual to Betti's *homology groups*, and applied exterior differential forms for the calculation of Betti numbers. The integral of a closed form is said to be homologous to zero, and h integrals of closed forms on a p-dimensional submanifold which are independent in the usual topological sense are said to be homologically independent if no linear combination of these integrals with constant coefficients not all zero is homologous to zero. De Rham has shown that the Betti number b_p is equal to the number of homologically independent integrals of exact differential forms of order p. This method of calculation of Betti numbers was applied by Cartan in his *Topology of compact homogeneous spaces* (La topologie des espaces homogènes clos. Moscow, 1937) *[96, part 1, pp. 1331–1338]* and by his student Charles Ehresmann in the paper *On the topology of certain homogeneous spaces* (Sur la topologie de certains espaces homogènes. Princeton, 1934) *[164]*.

The Betti numbers are connected with the Gaussian curvature of a surface: if the Gaussian integral curvature $\int K d\sigma$ is taken over a closed compact surface in R_3, then this integral is equal to $4\pi\left(1-\frac{b_1}{2}\right)$, where b_1 is the first Betti number of the surface. This number is equal to double the number of handles of the surface ($b_1 = 0$ for a sphere and $= 2$ for a torus). About this problem see the book of Kentaro Yano and Salomon Bochner *Curvature and Betti numbers* (Princeton, 1953) *[645]*.

The Curvature of Space

Curvature and Intrinsic Geometry of a Surface in the Works of Euler

$$K = \frac{d\alpha}{ds} = \lim_{\Delta s \to 0} \frac{\Delta \alpha}{\Delta s}$$

K is also the reciprocal of the radius of curvature at the point in question, that is, the radius of the OSCULATING circle at that point.

(The osculating circle at a point P of a curve is defined as the limit of circles determined by three points on the curve as they tend to P.)

The concepts of the curvature of a curve and of the osculating circle were already know to Leibniz.

Théorème de Newton

Figure 3.7 Le théorème de Newton projectif

3e Cas. *On emploie un volume auxiliaire, afin d'étudier les propriétés d'une figure plane, que l'on peut considérer comme étant une section du solide.*

Exercice.

174. Théorème. *Sur une sécante quelconque, l'hyperbole et ses asymptotes interceptent des segments égaux.*

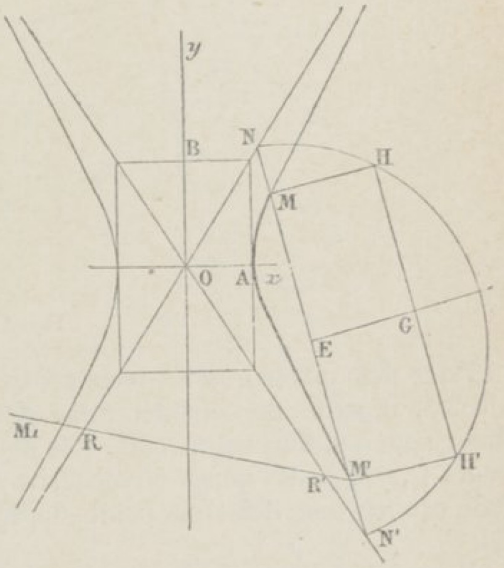

Fig. 110.

Considérons le cône formé par la rotation de ON autour de Ox. Un plan sécant perpendiculaire au méridien principal, et dont la trace serait NN', couperait le cône suivant une ellipse, puisque toutes les génératrices de la même nappe seraient rencontrées. (G., n° 844.)

Soit NHN' le rabattement de la moitié de l'ellipse : le plan qui donne l'hyperbole est éloigné de l'axe du cône de la longueur OB ; donc sa trace sur l'ellipse est une corde HH' parallèle à NN' et telle que $EG = OB$. Mais, NN' étant le grand axe de l'ellipse, la perpendiculaire élevée au milieu de NN' divise toute corde parallèle en deux parties égales : ainsi $GH = GH'$; donc $MN = M'N'$.

Si la sécante coupait les deux branches, la section serait une hyperbole dont RR' serait l'axe transverse ; $M'M_1$ serait la projection d'une corde parallèle ; donc encore, $M_1R = M'R'$.

Application. A l'aide de la propriété démontrée, on construit très facilement une hyperbole lorsqu'on connaît les asymptotes et un point de la courbe.

175. Corollaire. *Toute tangente limitée aux asymptotes est divisée en deux parties égales par le point de contact*[*].

Exercice.

176. Théorème de d'Alembert[*]. *Trois circonférences, considérées deux à deux, ont six centres de similitude ; les trois centres extérieurs sont*

---

[*] On trouve facilement la plupart des propriétés de l'ellipse lorsqu'on la considère comme étant obtenue par la section oblique d'un cône de révolution. MAC-LAURIN, dès 1742, en donne de nombreux exemples dans son *Traité des fluxions*, tome II, chap. XIV, page 96.

[*] D'ALEMBERT, né à Paris en 1717, mort en 1783. On lui doit un *Traité de dynamique*, le *Traité de l'équilibre et du mouvement des fluides*, et un grand nombre d'autres écrits.

en ligne droite ; il en est de même de deux centres intérieurs et d'un centre extérieur.

Démonstration de Monge *. Considérons des sphères ayant pour grands cercles les cercles donnés A, B, C. Les cônes, circonscrits à ces sphères prises deux à deux, ont respectivement pour sommets les centres de similitude.

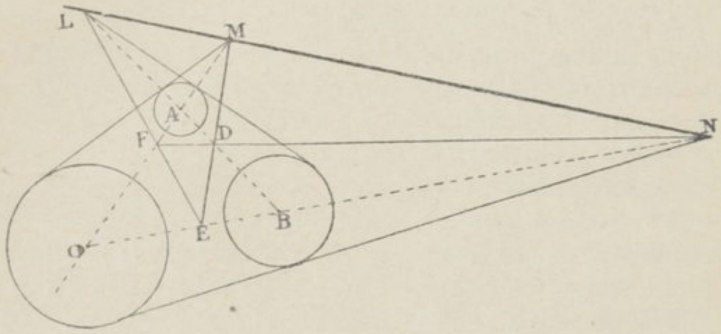

Fig. 111.

Pour démontrer que les trois centres extérieurs L, M, N sont en ligne droite, il suffit de considérer les deux plans tangents qui laissent les trois sphères d'un même côté. Ces deux plans contiennent les trois sommets L, M, N des cônes circonscrits ; or deux plans se coupent suivant une droite ; donc les trois points L, M, N sont en ligne droite.

Remarque. Pour F, D, N, on considère les deux plans tangents qui laissent les sphères B et C d'un même côté, tandis que la sphère A est de l'autre côté, etc.

Exercice.

177 *a.* **Théorème de Desargues** **. *Lorsque les côtés de deux triangles* ABC, abc *se coupent deux à deux en trois points situés en ligne droite, les droites* Aa, Bb, Cc, *qui joignent les sommets correspondants, se coupent au même point.*

Admettons que *abc* soit la base d'un prisme triangulaire, dont A'B'C' serait la section par un plan mené par la droite LMN.

Les droites AB, A'B' concourent au point L, car LA'B' est l'intersection du plan sécant et du plan conduit par L*ab*.

Il est évident que les droites AA', BB', CC' concourent en un même point S ; car si par les lignes concourantes LAB, LA'B' on fait passer un premier plan, puis un second par MAC, MA′C′, un troisième par NBC, NB′C′, les trois plans se coupent en un même point S.

---

* Monge, né à Beaune en 1746, mort en 1818, élève, puis répétiteur à l'école militaire de Mézières, est le principal créateur de la *géométrie descriptive*. Après avoir accompagné Bonaparte en Égypte, il eut à son retour la direction de l'École polytechnique.

** Desargues, né à Lyon en 1593, mort en 1662, s'occupa surtout de la partie pratique des mathématiques. Pascal, Descartes, Fermat, La Hire, ont profité des idées de cet auteur. On doit à Desargues le théorème relatif à deux triangles dont les sommets sont deux à deux sur trois droites concourantes, théorème que Poncelet a pris pour base de sa théorie des figures homologiques.

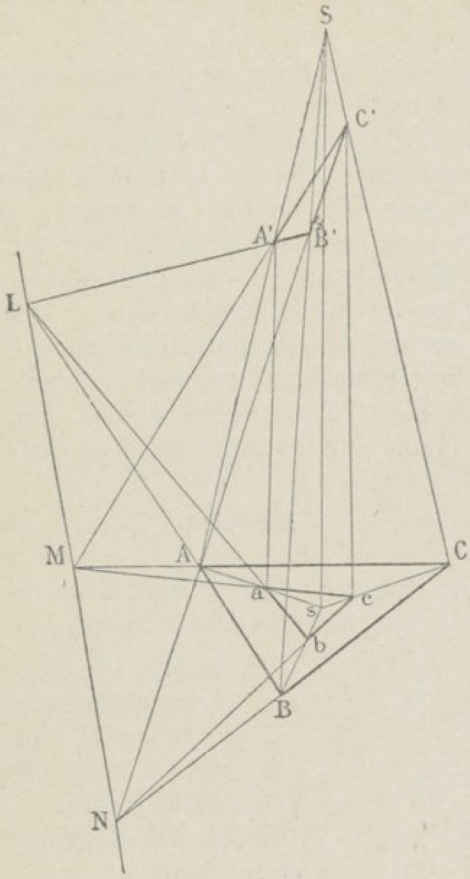

Fig. 112.

Donc les trois droites A*a*, B*b*, C*c* concourent en un même point *s*, projection du sommet S de la pyramide sur la base ABC.

Exercice.

177 *b*. Théorème réciproque. *Lorsque les sommets de deux triangles* ABC, abc *sont deux à deux sur trois droites qui concourent en un même point* s, *les côtés des triangles se coupent deux à deux, en trois points* L, M, N *situés en ligne droite.*

Considérons une pyramide dont *sa*A, *sb*B, *sc*C seraient les projections des arêtes latérales. Les projetantes qui correspondent aux sommets *a*, *b*, *c* donneraient A′, B′, C′, sur les arêtes correspondantes.

Or le plan de la section A′B′C′ coupe celui de la base suivant une certaine droite, et les côtés correspondants AB, A′B′ se coupent sur cette droite, en L, par exemple; donc *ab* passe aussi par ce point, car *ab* est la projection de A′B′.

Remarque. Les deux théorèmes de *Desargues* sont fondamentaux dans la théorie de l'*homologie* *.

---

* L'***homologie***, comme corps de doctrine et procédé général de transformation des figures,

§ VI. — Projections ou Sections.

178. La méthode des projections ou des sections est, en quelque sorte, la contre-partie de la méthode qui emploie des surfaces ou des volumes auxiliaires pour étudier des questions de géométrie plane. En effet, par la méthode des projections, on se propose d'obtenir une figure plus simple que la figure proposée, ou bien on ramène une question de géométrie dans l'espace à un exercice plan, se bornant à étudier la section obtenue en coupant le solide par un plan convenablement choisi.

Nous ne considérons ici que la *projection cylindrique,* c'est-à-dire la projection obtenue par des droites parallèles entre elles, mais dans une direction d'ailleurs quelconque par rapport au plan de la section. Ainsi, étudier la projection plane d'une figure donnée revient à considérer la section du cylindre formé par les projetantes de cette figure donnée.

Exercice.

179. Théorème. *La bissectrice de l'angle d'un triangle divise le côté opposé en segments proportionnels aux côtés adjacents.*

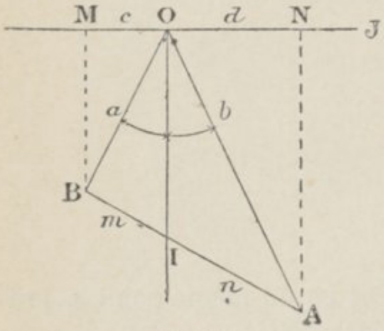

Fig. 113.

Projetons les sommets A et B sur la bissectrice extérieure OJ.

Les côtés a et b étant également inclinés sur OI sont proportionnels à leurs projections c et d.

Il en est de même des segments m et n; donc

$$\frac{a}{b}=\frac{c}{d}=\frac{m}{n} \quad C.\ Q.\ F.\ D.$$

Remarque. Pour les segments déterminés par la bissectrice extérieure, on projette ces segments et les côtés adjacents sur la bissectrice intérieure. La démonstration est tout aussi simple que la précédente.

Exercice.

180. Théorème de Ménélaüs. *Lorsqu'une transversale coupe les trois côtés d'un triangle, le produit de trois segments, n'ayant pas d'extrémité commune, égale le produit des trois autres segments* (n° 166).

---

est due à Poncelet. Pour se rendre compte de la fécondité de cette méthode et de l'esprit investigateur du créateur de l'homologie, il faut lire son *Traité des propriétés projectives des figures*, et les *Applications d'analyse et de géométrie*, du même auteur.

Traité des propriétés projectives des figures, 2 vol. in-4°. La première édition est de 1822, et la seconde de 1865. Les premières recherches datent de 1813, pendant la captivité de l'auteur en Russie; elles furent communiquées dès 1814 à MM. François et Servois, professeurs aux écoles d'artillerie et du génie à Metz.

Quelques fragments de ces recherches ont été publiés en 1817-1818 dans le tome VIII des *Annales de Gergonne.*

Sur une droite quelconque, projetons les trois sommets du triangle par des lignes Aa, Bb, Cc parallèles à la transversale. Le point o est la projection des trois points L, M, N.

On sait que les parallèles divisent les sécantes en parties proportionnelles; on peut donc remplacer le rapport $\frac{AL}{BL}$ par $\frac{ao}{bo}$, etc.

Mais $AL.BM.CN = BL.CM.AN$ ou $\frac{AL}{BL} \cdot \frac{BM}{CM} \cdot \frac{CN}{AN} = 1$ peut être remplacé par

$$\frac{ao}{bo} \cdot \frac{bo}{co} \cdot \frac{co}{ao} = 1$$

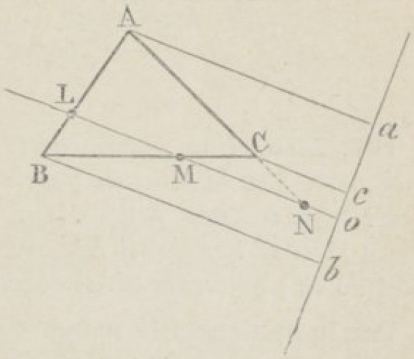

Fig. 114.

Or cette dernière égalité est évidente; la relation demandée est par suite démontrée.

Exercice.

181. Théorème de Carnot *. *Lorsqu'une transversale coupe les côtés d'un polygone plan, chaque côté est divisé en deux segments; le produit de tous les segments, n'ayant pas d'extrémité commune, égale le produit de tous les autres segments.*

Soit, par exemple, un pentagone ABCDE dont les côtés successifs AB, BC,... sont coupés par une transversale en des points H, K, L, M, N.

Projetons la figure sur une droite quelconque xy située dans son plan, par des droites parallèles à la transversale, et soit O le point où cette ligne rencontre xy.

Il faut prouver qu'on a :

$$\frac{AH}{BH} \cdot \frac{BK}{CK} \cdot \frac{CL}{DL} \cdot \frac{DM}{EM} \cdot \frac{EN}{AN} = 1$$

ou

$$\frac{ao}{bo} \cdot \frac{bo}{co} \cdot \frac{co}{do} \cdot \frac{do}{eo} \cdot \frac{eo}{ao} = 1$$

Or cette dernière relation est évidente. La première est donc démontrée.

Remarque. On démontre aussi d'une manière fort simple la généralisation suivante :

Lorsqu'un plan coupe les côtés d'un polygogne gauche, chaque côté est divisé en deux segments; le produit de tous les segments; n'ayant pas d'extrémité commune, égale le produit de tous les autres segments.

---

* CARNOT, né à Nolay (Côte-d'Or) en 1753, mort à Magdebourg en 1823, élève de MONGE à l'école de Mézières, publia un *Essai sur les transversales, De la corrélation dans les figures de géométrie*, la *Géométrie de position*.

On ne cite généralement que la *Géométrie de position*, publiée en 1803; mais le théorème ci-dessus, ainsi que son extension à un polygone gauche, se trouve déjà dans l'ouvrage publié en 1801 : *De la corrélation des figures de géométrie*, n^{os} 220 et 221, page 162.

Il suffit de projeter la figure sur un plan non parallèle au plan sécant, en recourant à des droites parallèles à ce même plan sécant; car on retombe sur le *théorème de Carnot.*

Exercice.

182. Lieu. *Une pyramide triangulaire* SABC *est coupée par un plan qui rencontre le plan de base suivant* LMN, *et détermine dans la pyramide une section* A'B'C'. *On fait tourner la section* A'B'C' *autour de l'axe* MN, *et l'on joint* AA', BB', CC'; *quel est le lieu décrit par le sommet de la pyramide ainsi obtenue* * ?

Par la hauteur SH menons un plan SHOR perpendiculaire à l'axe de rotation; ce plan détermine deux droites DE, D'E' dont il suffit d'étudier la position respective, car elles sont invariablement liées à la base et à la section. Le problème revient donc à une question connue de géométrie plane. *On demande le lieu décrit par le point de concours* S *des droites* DD', EE' (nº 84).

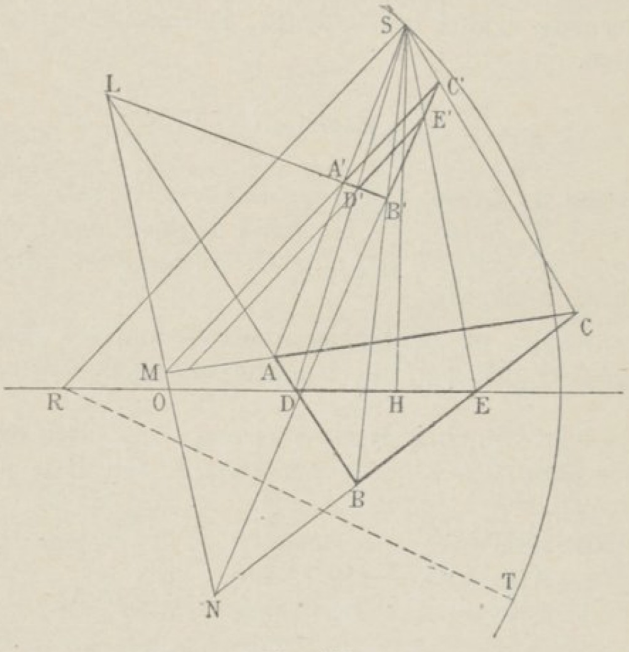

Fig. 115.

Le sommet S décrit une circonférence dont le plan est perpendiculaire à MN; R en est le centre et RS le rayon.

---

* Ce théorème a été indiqué par Poncelet dans l'étude de l'homologie; mais il est attribué ordinairement à Steiner, qui l'a formulé explicitement dans le *Journal de Crelle.*

La démonstration que nous donnons est très simple; néanmoins on lira avec fruit celle de A. Amiot, *Leçons nouvelles de géométrie élémentaire*, 2ᵉ édition, page 570.

A. Amiot, ancien professeur de mathématiques spéciales au lycée Saint-Louis, est surtout connu par les nombreux élèves qu'il a préparés pour l'École normale supérieure et pour l'École polytechnique. On lui doit divers ouvrages classiques, entre autres des *Eléments de géométrie* et les *Leçons nouvelles de géométrie descriptive.*

9 ./01. . .+ . 7 2 H 7 !
2 & -2 2!) "

3.6.3 Application : le théorème de Newton

3.6.5 Théorème. *Soit* a, b, c, d *un repère et soient* e *et* f *les intersections de* $(ab), (cd)$ *et* $(ad), (bc)$ *respectivement (voir fig. 3.7). Soit* D *une droite et* p, q, r *les intersections de* D *avec* (ca)*,* (bd) *et* (ef)*. On appelle* i, j, k *les conjugués harmoniques de* p, q, r *par rapport à* c, a *;* b, d *et* e, f*. Alors* i, j, k *sont alignés.*

Démonstration. On note u, v, w les intersections de $(bd), (ef)$; $(ef), (ac)$ et $(ac), (bd)$ respectivement et on applique la partie réciproque de 3.6.3 au triangle uvw. Il s'agit donc de montrer qu'on a :

$$\llbracket v, w, p, i \rrbracket \, \llbracket w, u, q, j \rrbracket \, \llbracket u, v, r, k \rrbracket = 1,$$

ou encore, en permutant les termes :

$$\llbracket i, p, w, v \rrbracket \, \llbracket j, q, u, w \rrbracket \, \llbracket k, r, v, u \rrbracket = 1.$$

Mais, on a le lemme suivant :

3.6.6 Lemme. *On a* $\llbracket i, p, w, v \rrbracket = \llbracket p, a, v, w \rrbracket^2 = \llbracket p, c, v, w \rrbracket^2$ *et les égalités analogues sur les droites* (bd) *et* (ef)*.*

Ce lemme implique le théorème car on a $\llbracket p, a, v, w \rrbracket \, \llbracket q, d, w, u \rrbracket \, \llbracket r, f, u, v \rrbracket = 1$ par application du sens direct de 3.6.3 au triangle uvw et aux points alignés p, q, r d'une part et a, d, f d'autre part.

Démonstration. (du lemme) On a $\llbracket a, c, p, i \rrbracket = -1$ par définition de i. Par ailleurs, la polaire de w par rapport aux droites (ad) et (bc) n'est autre que (fe) par construction de la polaire et on en déduit $\llbracket a, c, v, w \rrbracket = -1$. L'unique involution φ de (ac) admettant a et c pour points fixes (voir 3.5.13) échange donc i, p (resp. v, w) (c'est d'ailleurs l'involution de Desargues de (ac) associée au quadrilatère $jkqr$). L'application de φ donne l'égalité $\llbracket i, p, w, v \rrbracket = \llbracket p, i, v, w \rrbracket$. On en déduit, avec le lemme des trois birapports 3.6.1, $\llbracket i, p, w, v \rrbracket = \llbracket p, a, v, w \rrbracket \, \llbracket a, i, v, w \rrbracket = \llbracket p, a, v, w \rrbracket \, \llbracket a, p, w, v \rrbracket$ par application de φ et le lemme en résulte par permutation.

Le théorème originel de Newton correspond au cas où D est la droite de l'infini (voir fig. 3.8) :

3.6.7 Corollaire. (Newton) *Soit* a, b, c, d *quatre points du plan affine non trois à trois alignés. Soient* e *et* f *les intersections de* $(ab), (cd)$ *et* $(ad), (bc)$ *respectivement. Alors les milieux* i, j, k *de* c, a *;* b, d *et* e, f *respectivement, sont alignés.*

Nous reviendrons sur ce théorème dans les Parties II et III. Le lecteur qui voudrait en voir d'autres preuves pourra se reporter au livre de Jean-Louis Ayme (voir [Aym03]) où il en trouvera une trentaine !

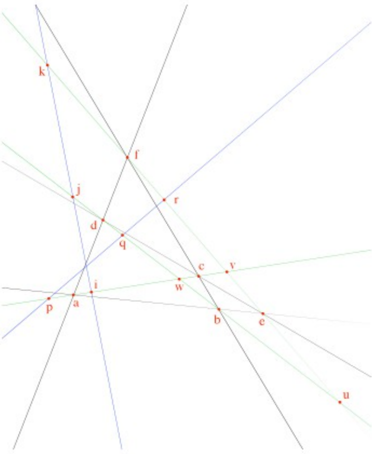

FIGURE 3.7 – Le théorème de Newton projectif

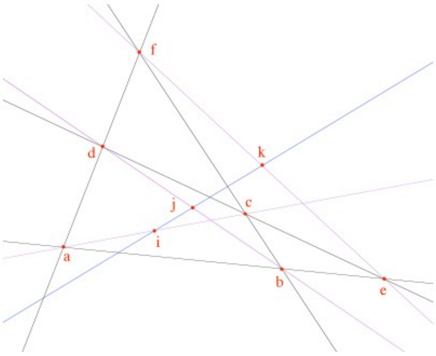

FIGURE 3.8 – Le théorème de Newton affine

3.6.4 Involutions et birapports

3.6.8 Lemme. *Soit D une droite projective et soient α, β, γ, α', β', γ' six points distincts de D. Soit $f : D \to D$ l'homographie définie par $f(\alpha) = \alpha'$, $f(\beta) = \beta'$, $f(\gamma) = \gamma'$. Alors f est une involution si et seulement si on a la relation suivante entre birapports :*

$$(*) \qquad [\![\alpha, \beta, \gamma, \gamma']\!]\, [\![\beta, \gamma, \alpha, \alpha']\!]\, [\![\gamma, \alpha, \beta, \beta']\!] = -1.$$

Démonstration. On vérifie que la relation $(*)$ équivaut à

$$\frac{\overline{\gamma'\beta}}{\overline{\gamma'\alpha}} \times \frac{\overline{\alpha'\gamma}}{\overline{\alpha'\beta}} \times \frac{\overline{\beta'\alpha}}{\overline{\beta'\gamma}} = 1,$$

ce qui, en multipliant haut et bas par $\overline{\gamma'\gamma}$, conduit à :

$$[\![\gamma', \alpha', \beta, \gamma]\!] = [\![\gamma', \beta', \gamma, \alpha]\!]^{-1} = [\![\gamma', \beta', \alpha, \gamma]\!] = [\![\gamma, \alpha, \beta', \gamma']\!].$$

Il en résulte que l'homographie qui envoie γ' sur γ, α' sur α, β sur β' envoie aussi γ sur γ'. C'est donc une involution. Mais alors elle envoie α sur α', donc cette involution n'est autre que f.

3.6.9 *Remarque.* On peut affaiblir l'hypothèse que les six points sont distincts. Il faut bien entendu supposer α, β, γ distincts, ainsi que α', β', γ' et supposer aussi que l'un des couples homologues par f est non trivial (par exemple $\gamma \neq \gamma'$), sinon on a $f = \mathrm{Id}$. Sous ces hypothèses, le résultat reste vrai avec la convention que si l'un des birapports est infini (par exemple si $\gamma' = \alpha$) alors l'un des autres est nul (et ici on a nécessairement $\alpha' = \gamma$).

3.6.5 Involutions et concours

3.6.10 Théorème. *Soient a, b, c trois points non alignés de $\mathbf{P}(E)$ et soient a', b', c' des points de (bc), (ca) et (ab) respectivement, distincts de a, b, c. Soit D une droite ne passant ni par les points a, b, c, a', b', c', ni par les points d'intersections de (aa'), (bb'), (cc'). La droite D coupe respectivement (bc), (ca), (ab), (aa'), (bb'), (cc') en des points $\alpha, \beta, \gamma, \alpha', \beta', \gamma'$.*
Alors les droites (aa'), (bb') et (cc') sont concourantes si et seulement si l'homographie de D qui envoie α sur α', β sur β', γ sur γ' est une involution.

Démonstration. Supposons (aa'), (bb'), (cc') concourantes en d. Alors le résultat n'est rien d'autre que le théorème de Desargues, cf. 3.5.6, appliqué au repère a, b, c, d.

Pour la réciproque on appelle d le point d'intersection de (aa') et (bb') et γ'' celui de D et de (cd). On applique encore Desargues au repère $abcd$. On en déduit une involution de D qui échange α et α', β et β' et γ et γ''. C'est nécessairement l'homographie de l'énoncé et on a $\gamma' = \gamma''$, ce qui signifie que d est sur (cc').

3.6.11 *Remarque.* C'est cet argument qui a été utilisé en 3.5.9 pour prouver le concours des hauteurs d'un triangle.

3.6.12 Corollaire. *Avec les notations ci-dessus, les droites (aa'), (bb') et (cc') sont concourantes si et seulement si on a la relation*

$$(*) \qquad \llbracket \alpha, \beta, \gamma, \gamma' \rrbracket \, \llbracket \beta, \gamma, \alpha, \alpha' \rrbracket \, \llbracket \gamma, \alpha, \beta, \beta' \rrbracket = -1,$$

ou encore la relation $(**)$: $\llbracket b, a, \gamma, c' \rrbracket \, \llbracket c, b, \alpha, a' \rrbracket \, \llbracket a, c, \beta, b' \rrbracket = -1$.

Démonstration. Le premier point vient de 3.6.8 (car les six points $\alpha, \beta, \gamma, \alpha', \beta', \gamma'$ sont distincts). Pour le second on montre successivement les égalités $\llbracket \alpha, \beta, \gamma, \gamma' \rrbracket = \llbracket b, a, \gamma, c' \rrbracket$, $\llbracket \beta, \gamma, \alpha, \alpha' \rrbracket = \llbracket c, b, \alpha, a' \rrbracket$ et $\llbracket \gamma, \alpha, \beta, \beta' \rrbracket = \llbracket a, c, \beta, b' \rrbracket$ en utilisant les perspectives de centres c, a, b.

Figure 3.8 Le Théorème de Newton affine.

Affine Adjetivo: allowing for or preserving parallel relationship

"still to be implemented are geometric primitives and affine transformation of image".

The simplest way to see why this assertion is true is to observe that any triangle in the plane can be mapped by an invertible affine transformation to an equilateral triangle.

Using parallelograms ~~from the previous~~ to define affine transformations may be a mixed blessing.

It can be obtained from the previous description by applying affine transformation to keep the polygon bounded as it degenerates.

Our interest is in the space of affine equivalence classes of equal-area polygons.

A twisted cubic curve → subjects of Atiyah's first paper.

Michael Atiyah and Friedrich Hirzebruch, the creators of topological K-theory.

September 2018, at the 2018 Heidelberg Laureate Forum, he claimed a simple proof of the Riemann hypothesis, one of the most important and challenging problems in mathematics.

His claims have been met with skepticism by the mathematical community.

data 08.02.2020

Twisted cubic is a smooth, rational curve C of degree three in projective 3-space. P^3.

It is a fundamental example of a skew curve.

It is essentially unique, up to projective transformation.

L'équation de la tangente sera

$$\frac{yy'}{b^2}+\frac{xx'}{a^2}=1.$$

Étant donnée une circonférence de grand cercle $y=\mathrm{A}x+\mathrm{B}$, si on demande la condition pour qu'elle soit tangente à l'ellipse, on écrira que les deux équations sont identiques, ce qui conduira à la condition

$$\mathrm{B}=\pm\sqrt{\mathrm{A}^2a^2+b^2}.$$

L'équation d'une tangente pourra donc se représenter par la formule

$$y=\mathrm{A}x\pm\sqrt{\mathrm{A}^2a^2+\mathrm{B}^2}.$$

Si on cherche la rencontre des deux lignes ainsi représentées, on trouvera qu'elle a lieu à 90 degrés de l'origine ou du centre en un point dont la latitude a pour tangente

A (*voyez* la tangente au cercle). Le signe + se rapporte à la tangente LC située au-dessus du diamètre LO, et le signe — à la tangente LD au-dessous de LO; LO a pour équation

$$y = mx.$$

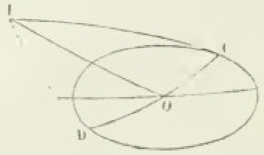
Si on mène un rayon au point de contact C, et qu'on désigne par A′ le coefficient angulaire de ce rayon, on aura

$$A' = \frac{y'}{x'};$$

donc entre ce coefficient et celui A de la tangente on a la relation

$$AA' = -\frac{b^2}{a^2}.$$

Fig. 1.



Soit OL le conjugué de OC et A″ son coefficient, on a aussi

$$A'A'' = -\frac{b^2}{a^2},$$

donc

$$A = A'';$$

d'où il résulte que la tangente et le diamètre OL se rencontrent à 90 degrés du centre en un point dont la latitude a pour tangente

$$A = -\frac{b^2 x'}{a^2 y'}.$$

On pourrait donc mener une tangente en C en menant le diamètre OC, déterminant son conjugué (nous avons vu le moyen plus haut), prenant sur ce conjugué OL un arc égal à 90 degrés, et joignant le point obtenu au point C.

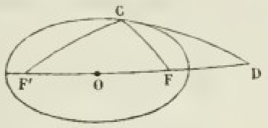
On peut aussi se servir de la relation

$$X x' = a^2,$$

X étant la tangente du segment déterminé par la rencontre de la tangente avec l'axe.

Théorème. *La tangente divise en parties égales l'angle formé par un rayon vecteur mené du foyer au point de contact et le prolongement de l'autre rayon vecteur.*

Fig. 2.



Il suffit pour cela de démontrer qu'on a la relation

$$\frac{\sin F'C}{\sin FC} = \frac{\sin F'D}{\sin FD}.$$

Or, nous avons trouvé précédemment

$$\operatorname{tang}\left(\frac{F'C + FC}{2}\right) = a \quad \text{et} \quad \operatorname{tang}\left(\frac{F'C - FC}{2}\right) = \frac{Cx'}{a}.$$

Ajoutant et soustrayant membre à membre, puis divisant, on trouve

$$\frac{\sin F'C}{\sin FC} = \frac{a^2 + Cx'}{a^2 - Cx'};$$

d'autre part nous avons trouvé

$$\operatorname{tang} OD = \frac{a^2}{x'};$$

on a d'ailleurs

$$\text{tang OF} = C;$$

opérant sur ces équations comme sur les précédentes, on a

$$\frac{\sin F'D}{\sin FD} = \frac{a^2 + Cx'}{a^2 - Cx'};$$

donc

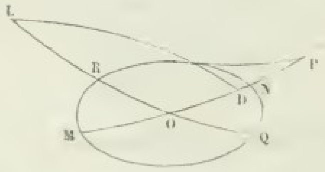
$$\frac{\sin F'C}{\sin FC} = \frac{\sin F'D}{\sin FD}. \qquad \text{C. Q. F. D.}$$

Cela donne le moyen de mener par un point quelconque une tangente à l'ellipse, comme sur un plan.

Quand la courbe est rapportée à deux diamètres conjugués, l'équation de la tangente ne change pas de forme, c'est toujours

$$\frac{yy'}{b_{,}^2} + \frac{xx'}{a_{,}^2} = 1.$$

Fig. 3.



Si on cherche l'intersection de la tangente avec l'axe des x, on trouve

$$xx' = a_{,}^2;$$

d'où l'on voit que si l'on prolonge une tangente jusqu'à la rencontre d'un diamètre quelconque en P, et qu'on joigne le point du conjugué à 90 degrés de l'origine au point de contact, qu'on prolonge l'arc obtenu jusqu'au premier diamètre en D, on aura

$$\text{tang ON tang OP} = \text{tang}^2\,\text{ON}.$$

on a d'ailleurs

$$\text{tang}\,\text{OF} = \text{C};$$

opérant sur ces équations comme sur les précédentes, on a

$$\frac{\sin \text{F}'\text{D}}{\sin \text{FD}} = \frac{a^2 + \text{C}x'}{a^2 - \text{C}x'};$$

donc

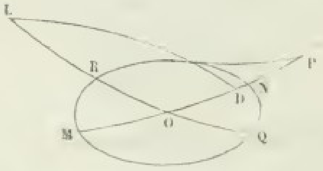
$$\frac{\sin \text{F}'\text{C}}{\sin \text{FC}} = \frac{\sin \text{F}'\text{D}}{\sin \text{FD}}. \qquad \text{C. Q. F. D.}$$

Cela donne le moyen de mener par un point quelconque une tangente à l'ellipse, comme sur un plan.

Quand la courbe est rapportée à deux diamètres conjugués, l'équation de la tangente ne change pas de forme, c'est toujours

$$\frac{yy'}{b_{\prime}^2} + \frac{xx'}{a_{\prime}^2} = 1.$$

Fig. 3.



Si on cherche l'intersection de la tangente avec l'axe des x, on trouve

$$xx' = a_{\prime}^2;$$

d'où l'on voit que si l'on prolonge une tangente jusqu'à la rencontre d'un diamètre quelconque en P, et qu'on joigne le point du conjugué à 90 degrés de l'origine au point de contact, qu'on prolonge l'arc obtenu jusqu'au premier diamètre en D, on aura

$$\text{tang}\,\text{ON}\;\text{tang}\,\text{OP} = \text{tang}^2\,\text{ON}.$$

Prenons OCM $= 90°$. Joignons MA par un arc qui coupe en D l'arc OP. Nous aurons par le théorème précédent

$$\operatorname{tang} \mathrm{OD} \operatorname{tang} \mathrm{OP} = b_{,}^{2}.$$

Soit mené l'arc DS perperdiculaire sur OP, nous aurons

$$\frac{\operatorname{tang} \mathrm{OD}}{\operatorname{tang} \mathrm{OS}} = \frac{\operatorname{tang} \mathrm{OA}}{\operatorname{tang} \mathrm{OP}};$$

d'où

$$\operatorname{tang} \mathrm{OS} \operatorname{tang} \mathrm{OA} = \operatorname{tang} \mathrm{OD} \operatorname{tang} \mathrm{OP} = b_{,}^{2}.$$

On a donc

$$\operatorname{tang} \mathrm{OS} = \frac{b_{,}^{2}}{a},$$

ce qui détermine le point S.

Mais le lieu des sommets des triangles rectangles ayant pour hypoténuse OS est une ellipse dont nous avons déjà déterminé les axes. OS est l'un des axes et l'autre β se trouve par la formule

$$\sin \beta = \operatorname{tang} \frac{\mathrm{OS}}{2}:$$

la question revient donc à trouver la rencontre d'un grand cercle MA avec une ellipse dont on connaît les axes. (Problème déjà résolu.)

Discussion. Pour que le problème soit possible, il faut que le cercle MAD coupe l'ellipse. Or celle-ci a pour équation (résultat déjà trouvé)

$$x^2 + y^2 - \mathrm{A}x = 0,$$

A étant la tangente de OS$= \frac{b_{,}^{2}}{a}$. Le cercle MA passant par un point M de latitude α et par le point A a pour équation

$$y = \alpha'(x - a), \quad (\alpha' = \operatorname{tang} \alpha);$$

combinant ces deux équations, on trouve par l'élimination de y,

$$(\alpha_,^2 + 1)\, x^2 - (2a\alpha_,^2 + \mathrm{A})\, x + a^2\alpha_,^2 = 0.$$

Pour que les racines soient réelles, il faut avoir

$$\mathrm{A} > 2a \operatorname{tang}\left(45^\circ - \frac{\alpha}{2}\right);$$

d'où

$$b_,^2 > 2a^2 \operatorname{tang}\left(45^\circ - \frac{\alpha}{2}\right).$$

Ce qui donne le minimum de b'. Si on suppose pour b' sa valeur minimum, les racines sont égales et on trouve

$$x = a \sin\alpha';$$

d'où

$$y = -\alpha' a (1 - \sin\alpha').$$

Si on divise y par x, on aura la tangente de l'angle AOZ compris entre la direction du diamètre b' et l'axe de la courbe a. On trouve que cet angle $\mathrm{AOZ} = \frac{\alpha' + 90^\circ}{2} + 90^\circ$. Ce qui démontre que la direction du diamètre b', dans le cas du minimum, est bissectrice de l'angle formé par l'axe des y et OM′ prolongement de OM. De là résulte ce théorème :

Parmi toutes les ellipses qu'on peut construire sur un axe donné, il y en a une pour laquelle le conjugué d'un diamètre OM *de direction connue est minimum, et dans cette ellipse, la direction de ce conjugué divise en parties égales l'angle formé par le second axe et le prolongement du diamètre donné* OM.

Le même théorème a lieu sur un plan.

Théorème a démontrer. *Si aux extrémités* AB *d'un* *axe, on mène deux tangentes et qu'on les coupe par une troisième aux points* M *et* N, *qu'on projette* AM *et* BN *sur l'autre axe, le produit des tangentes des deux projections est égal à la tangente carrée de la moitié de cet axe, et si on multiplie* tang AM *par* tang BN, *on trouve la tangente carrée de ce même demi-axe multipliée par le cosinus carré du premier.*

La première partie de l'énoncé est encore vraie, quand on remplace les axes par un système de diamètres conjugués.

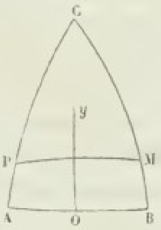
Ce théorème peut servir à résoudre le problème suivant :

On donne un des axes d'une ellipse et une tangente, trouver l'autre axe.

On peut aussi en tirer le corollaire :

Étant donné un triangle bi-rectangle ABC, si on coupe par un arc les côtés en M et P, de manière que le produit des tangentes des segments à partir de la base soit constante $= \tang^2 \varphi$, la courbe enveloppe de l'arc sécant est une ellipse sphérique, dont un axe est AB et dont l'autre s'obtient en prenant $AP = BM = \varphi$, et joignant PM, l'intersection de cet arc avec la perpendiculaire Oy donne l'extrémité du second axe.

Fig. 6.



Théorème à démontrer. *Si on mène en un point* A *d'une ellipse une tangente, qu'on la prolonge jusqu'à la rencontre en M, N de deux diamètres conjugués pris pour axes, qu'on construise le demi-diamètre conjugué de celui qui passe au point A, la tangente carrée de la projection de ce demi-diamètre sur un des deux premiers égale le produit des tangentes des projections des deux segments de la tangente (il s'agit ici de projections obliques).*

Si au lieu de deux diamètres on prend les axes, et qu'on appelle b' la tangente du diamètre conjugué de celui qui passe au point de contact, le produit des tangentes trigonométriques des deux segments de la tangente égalera

$$b'^2 \cos^2 a \cos^2 b + \sin^2 a \sin^2 b.$$

Cette relation sert à résoudre le problème suivant :

Étant donnés les axes d'une ellipse non construite, lui mener une tangente telle, que le produit des tangentes des deux segments interceptés entre le point de contact et les axes soit égal à une quantité donnée P.

La relation donnera b'^2. Connaissant a, b et b', on pourra par une construction déjà faite trouver la direction du diamètre b', ainsi que la direction et la grandeur OA de son conjugué; il suffira alors de joindre le point A à un point pris sur b' à 90 degrés de l'origine.

Discussion. Pour que le problème soit possible, il ne suffit pas qu'on trouve pour b'^2 une valeur positive, il faut qu'on la trouve comprise entre a^2 et b^2. Ce qui conduit aux conditions

$$P < \sin^2 \alpha, \quad P > \sin^2 \beta,$$

α et β désignant les demi-axes. Dans le cas du maximum, la tangente sera menée par l'extrémité du petit axe et réciproquement.

Théorème. *Si des deux foyers d'une ellipse on abaisse des arcs perpendiculaires sur une tangente, le produit des sinus de ces arcs est constant et égal à* $\sin^2 \beta \cos^2 \gamma$, *$\gamma$ étant la distance du centre au foyer, et β le demi-axe perpendiculaire à l'axe des foyers.*

On sait qu'une tangente quelconque peut se représenter par l'équation

$$y = mx + \sqrt{a^2 m^2 + b^2}.$$

La distance δ du foyer à cette tangente est donnée d'après une formule ci-dessus démontrée par l'équation

$$\sin \delta = \frac{\sqrt{a^2 m^2 + b^2} + mc}{\sqrt{1 + b^2 + m^2 (1 + a^2)} \sqrt{1 + c^2}},$$

l'autre distance est donnée par l'équation

$$\sin \delta' = \frac{\sqrt{a^2 m^2 + b^2} - mc}{\sqrt{1 + b^2 + m^2 (1 + a^2)} \sqrt{1 + c^2}};$$

multipliant membre à membre et observant que

$$\cos a' = \cos b \cos \gamma,$$

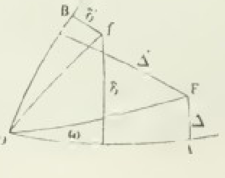
on trouve

$$\sin \delta . \sin \delta' = \sin^2 b \cos^2 c.$$

Ce théorème peut servir à trouver l'axe β, connaissant les foyers et une tangente.

Application. On donne un foyer et deux tangentes,

Fig. 7.



trouver le lieu du second foyer. Soient F le foyer donné, Δ et Δ' ses sinus distances aux deux tangentes OA, OB, f l'autre foyer, δ et δ' les sinus des deux distances.

On aura, par le théorème précédent,

$$\frac{\delta}{\delta'} = \frac{\Delta'}{\Delta};$$

mais

$$\frac{\delta}{\delta'} = \frac{\sin f\mathrm{OA}}{\sin(\theta - f\mathrm{OA})};$$

soit

$$f\mathrm{OA} = \alpha,$$

on aura

$$\frac{\delta}{\delta'} = \frac{\sin\alpha}{\sin(\theta - \alpha)};$$

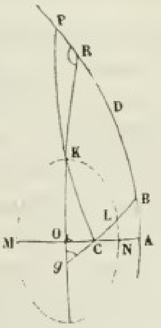
soit β l'angle FOB, on aura de même

$$\frac{\Delta'}{\Delta} = \frac{\sin\beta}{\sin(\theta - \beta)}.$$

D'où on conclut aisément $\alpha = \beta$; donc le lieu du point f est une circonférence de grand cercle passant à l'origine et par un point symétrique de F relativement à la bissectrice.

Corollaire. Si d'un point O on mène deux tangentes à

Fig. 8.



une ellipse et qu'on joigne le point O aux deux foyers par deux arcs de grands cercles, ces arcs feront avec les deux tangentes, des angles égaux. Si on demandait le lieu du centre qui sur un plan est une ligne droite parallèle au lieu du foyer, je dis qu'on trouverait une ellipse sphérique. Cela revient à faire voir que le lieu du milieu de l'arc variable CB terminé d'une part à un point fixe C, et d'autre part à sa rencontre B avec une circonférence AD, est une ellipse.

Posons

$$\mathrm{CB} = 2\rho, \quad \operatorname{tang} \mathrm{CA} = p \quad \text{et} \quad \mathrm{BCA} = \omega,$$

nous avons dans le triangle ABC,

$$p = \operatorname{tang} 2\rho \cos\omega \quad \text{ou} \quad 2 \operatorname{tang}\rho \cos\omega = p(1 - \operatorname{tang}\rho),$$

ou passant aux coordonnées rectangles,

$$1 - \frac{2x}{p} = y^2 + x^2.$$

C'est une ellipse dont on pourrait trouver les axes par son équation, mais on les obtient plus aisément par la géométrie. Soit N le point milieu de CA, N sera l'extrémité d'un axe. Prenons $\mathrm{NM} = \frac{\pi}{2}$, M sera l'autre extrémité, OK perpendiculaire sur MN sera la direction du second axe. Pour en avoir l'extrémité, construisons le le triangle OCg, de manière que l'angle $g = \mathrm{R}$. Soit K le milieu de gR, joignez CK, prolongez l'arc CK jusqu'en P, K sera, par suite d'une égalité de triangles, le milieu de CKP, donc K est un point du lieu, c'est un sommet. La courbe est alors facile à construire.

On voit donc que *quand on donne deux tangentes et un foyer, le lieu du centre est une ellipse.*

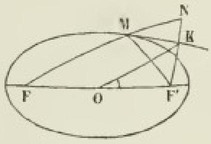
Problème. *Trouver le lieu des projections du foyer sur les tangentes.*

On peut prendre l'équation générale des tangentes

$$y = mx + \sqrt{a^2 m^2 + b^2},$$

et celle d'une perpendiculaire abaissée du foyer sur cette tangente, puis éliminer m entre ces deux équations ; mais le calcul est long et compliqué : on arrive beaucoup plus simplement au résultat par le moyen suivant : Soit MK une tangente en M ; joignons le point M aux foyers par les

Fig. 9.



arcs MF, MF', prenons sur FM prolongé MN = MF', joignons NF' par un arc qui coupe la tangente en K. K est un point du lieu ; j'appelle ρ la distance OK, ω l'angle KOF', et p la distance F'K ou KN dans le triangle KOF', nous aurons

$$(1) \qquad \cos p = \cos c \cos \rho + \sin c \sin \rho \cos \omega,$$

et dans le triangle NFF',

$$(2) \qquad \cos 2\alpha = \cos 2c \cos 2\rho + \sin 2c \sin 2p \cos F' ;$$

on a encore dans ORF'

$$\cos F' = \frac{\cos \rho - \cos p \cos c}{\sin p \sin c}.$$

Je remplace $\cos F'$ par cette expression dans l'équation (2), puis j'élimine $\cos p$ par l'équation (1), on trouve ainsi l'équation

$$\sin^2 \rho (\cos^2 c + \sin^2 c \cos^2 \omega) = \sin^2 \alpha,$$

et passant aux coordonnées rectangles

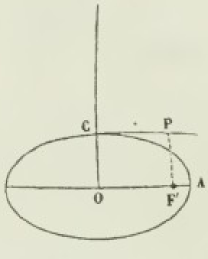
$$\frac{y^2(\cos^2 c - \sin^2\alpha)}{\sin^2\alpha} + \frac{x^2}{a^2} = 1.$$

Le lieu demandé est donc une ellipse concentrique à la première ayant un axe commun 2α ; l'autre axe 2β est donné par la formule

$$\operatorname{tang}^2\beta = \frac{\sin^2\alpha}{\cos^2 e - \sin^2\alpha}.$$

Si le rayon de la sphère est infini, on trouve un cercle, car $\beta = \alpha$.

Fig. 10.



Quand on a reconnu que la courbe est du second degré, on peut trouver les axes sur la figure. Il est d'abord évident que OA est un axe de la courbe. Pour avoir l'autre, au sommet C menons une tangente CP et projetons le foyer F' sur cette tangente ; l'arc F'P projetant ira couper l'axe des y en un point D à $\frac{\pi}{2} + \beta$ de l'origine ($\beta =$ OC).

Donc on a pour le point P, $y' = -\frac{1}{b}$, l'équation de l'arc F'P sera donc

$$\frac{y}{-\frac{1}{b}} + \frac{x}{c} = 1$$

(c étant la tangente de OF'). Si dans cette équation nous faisons $y = b$, nous aurons les coordonnées du point D. Mais ces coordonnées doivent vérifier l'équation du lieu

$$\frac{y^2}{\beta'^2} + \frac{x^2}{a^2} = 1,$$

il est donc facile d'avoir β ou $\text{tang}\,\beta$; on trouve comme par l'autre méthode

$$\text{tang}^2\beta = \frac{\sin^2\alpha}{\cos^2 c - \sin^2\alpha}.$$

Si d'un point A, pris hors d'une ellipse sphérique, on mène deux tangentes et qu'on divise en parties égales les angles qu'elles font entre elles, les deux bissectrices viennent couper l'axe en deux points tels, que le produit des tangentes de leurs distances au centre est une constante c^2 égale au carré de la demi-distance des foyers. Les tangentes ont pour équations

$$y = mx + \sqrt{a^2 m^2 + b^2}, \quad y = m'x + \sqrt{a^2 m_1^2 + \beta^2}.$$

Les bissectrices ont pour équations

$$\frac{y - mx - \sqrt{a^2 m^2 + b^2}}{\sqrt{1 + b^2 + m^2(1 + a^2)}} = \frac{y - m'x - \sqrt{a^2 m_1^2 + b^2}}{\pm\sqrt{1 + b^2 + m_1^2(1 + a^2)}},$$

ou

$$r(y - mx - s) = r'(y - m'x - s'),$$

en appelant r et r' les inverses des dénominateurs et s, s', les deux radicaux du numérateur. Faisant $y = 0$, on trouve

$$x = \frac{rs - r's'}{m'r' - mr};$$

pour l'autre bissectrice, il faut changer le signe de r', ce qui donne

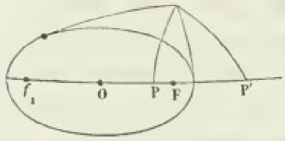
$$X = -\frac{rs + r's'}{m'r' + mr};$$

d'où on tire

$$
\begin{aligned}
\mathrm{X}x &= \frac{r_{,}^{2}s_{,}^{2} - r^{2}s^{2}}{m_{,}^{2}r_{,}^{2} - m^{2}r^{2}} = \frac{r_{,}^{2}(a^{2}m_{,}^{2} + b^{2}) - r^{2}(a^{2}m_{,}^{2} + b^{2})}{m_{,}^{2}r_{,}^{2} - m^{2}r^{2}} \\
&= a^{2} + \frac{b^{2}(r_{,}^{2} - r^{2})}{m_{,}^{2}r_{,}^{2} - m^{2}r^{2}} = a^{2} + \frac{b^{2}(1 + a^{2})(m^{2} - m_{,}^{2})}{m_{,}^{2}(1 + b^{2}) - m^{2}(1 + b^{2})} \\
&= a^{2} - \frac{\sin^{2}\beta}{\cos^{2}\alpha} = \frac{\sin^{2}\alpha - \sin^{2}\beta}{\cos^{2}\beta} = \mathrm{C}^{2},
\end{aligned}
$$

C désignant la tangente de la demi-distance des foyers.

FIG. 11.



Il suit de là que si avec 2 C comme arc diamétral on traçait un cercle, les deux points P et P' seraient tels, que la polaire de l'un relative à ce cercle passerait par l'autre, donc les points de rencontre des bissectrices avec l'axe et les deux foyers sont quatre points harmoniques. Ce théorème peut servir à construire une ellipse connaissant le centre, la direction de l'axe et deux tangentes. On peut encore en conclure que si on donne deux tangentes et un foyer, le lieu de l'autre foyer est une circonférence de grand cercle.

PROBLÈME. *Trouver le lieu des sommets d'angles droits dont les côtés sont tangents à une ellipse.*

Soient $x'y'$, $x''y''$ les tangentes des coordonnées des points de contact, les deux tangentes en ces points auront pour équations

$$a^{2}yy' + b^{2}xx' = a^{2}b^{2},$$
$$a^{2}yy'' + b^{2}xx'' = a^{2}b^{2},$$

on a aussi

$$a^2 y_{,}^2 + b^2 x_{,}^2 = a^2 b^2,$$
$$a^2 y_{,,}^2 + b^2 x_{,,}^2 = a^2 b^2,$$

et pour que les deux tangentes soient rectangulaires, on a la condition connue

$$a'' y' y'' + b'' x' x'' + a'' b'' = 0,$$

il faut éliminer x', x'', y', y'' entre ces quatre équations. L'élimination se fait comme pour l'ellipse plane, et on trouve pour équation du lieu

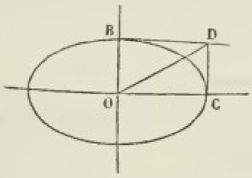
$$(1 - a^2) y^2 + (1 - b^2) x^2 = a^2 + b^2.$$

Premier cas.

$$a^2 < 1, \quad b^2 < 1,$$

on a uneellipse sphérique. Si par les points C et B, sommets de la courbe donnée, on mène deux tangentes se coupant en D, le cercle concentrique à l'ellipse et passant en D aura pour équation

Fig. 12.



$$x^2 + y^2 = a^2 + b^2,$$

et comme dans la courbe trouvée on a

$$x^2 + y^2 > a^2 + b^2,$$

tous les points de cette courbe sont extérieurs au cercle (OD), par suite ils sont extérieurs à l'ellipse; on pourra donc par chacun d'eux mener deux tangentes, qui se couperont à angle droit.

Deuxième cas. Si on a

$$a^2 > 1 \quad \text{et} \quad b^2 > 1,$$

l'équation trouvée ne sera satisfaite par aucune valeur réelle de y et de x, en sorte que le problème de mener à l'ellipse deux tangentes rectangulaires sera dans ce cas impossible.

Troisième cas.

$$a^2 > 1, \quad b^2 < 1.$$

L'équation trouvée pourra s'écrire ainsi :

$$(a^2 - 1)y^2 - (1 - b^2)x^2 = -(a^2 + b^2),$$

on pourra l'appeler une *hyperbole sphérique*, et tous ses points conviendront encore à la question.

Quatrième cas.

$$a = 1, \quad b < 1.$$

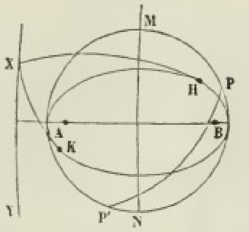
La courbe donnée est une *parabole sphérique*, le lieu trouvé a pour équation

$$x = \pm\sqrt{\frac{1 + b^2}{1 - b^2}} = \pm\sqrt{\frac{1}{\cos 2\hat{c}}},$$

$2\hat{c}$ représentant le petit axe de la courbe donnée; cette équation représente deux circonférences perpendiculaires à l'axe de 90 degrés : il est aisé de reconnaître que ces circonférences sont les deux directrices de la parabole. Ainsi les directrices d'une parabole sphérique ont, comme sur le plan, la propriété de contenir tous les sommets des angles droits circonscrits à la courbe.

Si on construit une courbe dont les points soient les pôles des tangentes de la courbe donnée, on trouve une

FIG. 13.



ellipse qu'on nomme ellipse *supplémentaire* de la première; elle a avec elle l'axe commun AB; le second axe MN est plus grand que AB. Cela posé, si par un point X de la directrice on mène les tangentes XH, XK, leurs pôles seront deux points P et P_1 de la courbe supplémentaire, l'arc PP' passera donc par le pôle de la directrice XY qui est le foyer de la parabole donnée, et il sera supplémentaire de l'angle X, c'est-à-dire de 90 degrés. On voit donc que si un ellipse a son petit axe de 90 degrés, tous les arcs de même longueur $\frac{\pi}{2}$, inscrits à la courbe, passeront par un point fixe qui sera le foyer de la parabole supplémentaire. (BORGNET.)

On résout, d'une manière analogue, le problème suivant : Trouver le lieu des intersections des tangentes menées par les extrémités de deux diamètres conjugués. L'équation est la même que sur le plan, savoir :

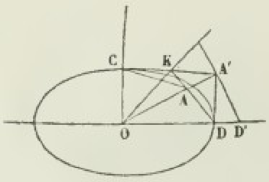
$$\frac{y^2}{(b\sqrt{2})^2}+\frac{x^2}{(a\sqrt{2})^2}=1.$$

Si par le centre O on mène une sécante coupant les deux courbes aux points A' et A, on aura

$$\operatorname{tang} OA' = \operatorname{tang} OA \,.\, \sqrt{2}.$$

De là résulte un moyen simple d'obtenir les axes. Menons

Fig. 14.



aux sommets D et C les tangentes DA', CA'; A' sera un point du lieu; joignons AD, et abaissons OK perpendiculaire sur AD, puis de A' abaissons aussi une perpendiculaire sur OK, cette perpendiculaire viendra couper OD en un point D' qui sera l'extrémité d'un des axes; l'autre sommet C' se trouve de même.

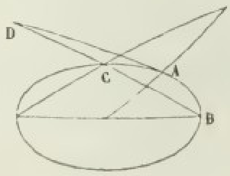
Propriétés des cordes supplémentaires.

Leur définition et la relation entre leurs coefficients angulaires sont comme pour l'ellipse plane. Ainsi en appelant ces coefficients α, α', on aura

$$\alpha\alpha' = -\frac{b^2}{a^2} \quad \text{ou} \quad -\frac{b_{\prime}^2}{a_{\prime}^2},$$

selon que la courbe sera rapportée à ses axes ou à un système de diamètres conjugués. Or on a la même relation entre les coefficients angulaires β, β' d'une tangente et du

Fig. 15.



rayon mené au point de contact; si donc $\alpha = \beta$, on aura

$$\alpha' = \beta',$$

ce qui démontre que quand une tangente rencontre une corde CB à 90 degrés du centre, la corde supplémentaire de CB rencontre aussi à 90 degrés du centre le rayon mené au point de contact.

Cela donne un moyen facile de mener une tangente par un point donné sur la courbe ou par un point situé à 90 degrés du centre.

Si on appelle γ le coefficient angulaire d'un grand cercle et γ' le coefficient du rayon qui joint son pôle au centre, on a aussi

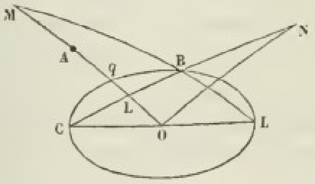
$$\gamma\gamma' = -\frac{b^2}{a^2}.$$

Si donc $\alpha = \gamma$, on aura

$$\alpha' = \gamma',$$

c'est-à-dire que si une corde CB rencontre à 90 degrés du centre un grand cercle, la corde supplémentaire de CB rencontrera aussi à 90 degrés du centre l'arc allant du centre au pôle de ce cercle. Si donc on veut construire la polaire d'un point A, on joindra OA, on prendra sur OA prolongée $OM = 90^\circ$, on joindra M à l'extrémité L de l'axe ou d'un autre diamètre par un arc coupant l'ellipse en B. On mènera CB corde supplémentaire de BL, on prendra sur CB un point N à 90 degrés du centre, et le point N

Fig. 16.



sera un point de la polaire de A. Il sera facile d'en trouver un second par la relation connue

$$\text{tang}^2\, \text{O}q = \text{tang OA}\,.\,\text{tang OL}.$$

On démontrera aussi facilement que si un diamètre et une corde se coupent à 90 degrés du centre, le conjugué et la corde supplémentaire se coupent à la même distance du centre, ce qui servira à construire deux diamètres conjugués dont l'un passe par un point donné.

SUR L'INTERPOLATION (*);

PAR M. EUGÈNE ROUCHÉ,
Professeur au lycée Charlemagne, Docteur ès Sciences mathematiques.

I.

1. Dans l'un de ses intéressants articles sur divers points du Cours de Mathématiques spéciales, M. Gerono a indiqué un moyen de déduire la formule d'interpolation de Newton de celle de Lagrange.

Je me propose de donner de ce même problème une solution assez facile et assez courte pour être introduite dans les Éléments. Toutefois, je ne serais peut-être pas revenu sur cette question, sans une circonstance particulière, qui se présente d'ailleurs assez fréquemment en mathématiques.

Lorsqu'on aborde le problème dont je viens de parler, il suffit d'un coup d'œil pour voir que la formule de Lagrange, dans sa forme habituelle, ne se prête pas aisément à la transformation demandée. Une préparation préalable est nécessaire pour éviter de longs calculs. En cherchant à grouper convenablement les termes, j'ai été

MATHÉMATIQUES.

MÉTHODE ÉLÉMENTAIRE POUR CALCULER LE RAPPORT DE LA CIRCONFÉRENCE AU DIAMÈTRE;

PAR M. L. MALEYX.

En étudiant la méthode inventée par Archimède pour déterminer une valeur approchée du rapport de la circonférence au diamètre, j'ai été conduit à faire deux remarques principales.

La première consiste en ce que Archimède, en doublant le nombre des côtés d'un polygone régulier, fait varier à la fois le périmètre du polygone et les diamètres des cercles inscrit et circonscrit; ce fait distingue sa méthode de celle dite *des périmètres*, où l'on suppose que, le périmètre du polygone variant, le rayon du cercle circonscrit reste fixe, et de celle dite *des polygones isopérimètres*, où l'on suppose que le périmètre reste fixe. S'il existe une constante dans sa méthode, cette constante est le côté du polygone, et encore ne l'est-elle pas d'une manière absolue.

La deuxième remarque consiste en ce que l'application de ses principes peut être rendue plus simple que celle des principes des deux autres méthodes que je viens de citer.

J'ai fondé sur ces remarques une étude que je me propose de publier ultérieurement. et dont j'extrais ce qui suit.

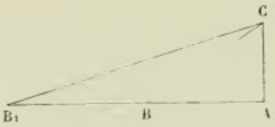
I. *Un côté de l'angle droit d'un triangle rectangle est représenté par* 1, *son hypoténuse par* D *et le second côté par* d, *l'angle opposé au premier côté l'étant par* α; *on se propose de calculer le second côté de l'angle droit* d_1 *et l'hypoténuse* D_1 *d'un second triangle rectangle dont le premier côté est aussi représenté par* 1, *et opposé à un angle égal à* $\frac{\alpha}{2}$.

Soit (*fig.* 1) ABC le premier triangle rectangle dans lequel on a

$$A = 1^{\text{dt}}, \quad ABC = \alpha, \quad AC = 1, \quad BC = D, \quad AB = d.$$

Pour construire le second, il suffira de prolonger AB de la longueur $BB_1 = BC = D$, et d'unir par une ligne droite le point B_1 au point C; car, le triangle CBB_1 étant isoscèle par construction, on a

Fig. 1.



$$BB_1C = BCB_1 = \tfrac{1}{2}ABC.$$

On a du reste évidemment

$$AB_1 = d_1 = D + d$$

et, d'après le théorème de Pythagore,

$$B_1C = D_1 = \sqrt{d_1^2 + 1}.$$

II. *Extraction de la racine carrée d'un nombre donné sous la forme* $a^2 + R$, *d'après les données* a *et* R, *et sans effectuer le carré* a^2.

Prenons a pour valeur approchée par défaut de la racine cherchée, et soit $\frac{b}{10^\alpha}$ la valeur aussi approchée par défaut, et à moins de $\frac{1}{10^\alpha}$ de la partie complémentaire de la racine, on a

$$\left(a+\frac{b}{10^\alpha}\right)^2 \leq (a^2+\mathrm{R}):$$

développant le premier membre et réduisant,

$$2a\times\frac{b}{10^\alpha}+\frac{b^2}{10^{2\alpha}}\leq\mathrm{R},$$

d'où

$$\frac{b}{10^\alpha}\leq\frac{\mathrm{R}}{2a}.$$

Nous pouvons développer le quotient $\frac{\mathrm{R}}{2a}$ en fraction décimale, à moins de $\frac{1}{10^\alpha}$ par défaut, et, si $\frac{q}{10^\alpha}$ représente ce développement, R_1 étant le reste de la division, nous aurons

$$\mathrm{R}=2a\times\frac{q}{10^\alpha}+\mathrm{R}_1$$

et, en conséquence,

$$\frac{b}{10^\alpha}\leq\frac{q}{10^\alpha}+\frac{\mathrm{R}_1}{2a},\qquad\frac{\mathrm{R}_1}{2a}<\frac{1}{10^\alpha}.$$

$\frac{b}{10^\alpha}$, étant un multiple de $\frac{1}{10^\alpha}$ contenu dans le second membre de l'inégalité précédente, ne peut surpasser $\frac{q}{10^\alpha}$, qui est le plus grand multiple de $\frac{1}{10^\alpha}$ contenu dans le même nombre ; $\frac{q}{10^\alpha}$ ne peut donc être que supérieur ou égal à $\frac{b}{10^\alpha}$, et, pour qu'il ne lui soit pas supérieur, il suffit que du nombre donné, $a^2+\mathrm{R}$, on puisse retrancher le carré de $a+\frac{q}{10^\alpha}$, c'est-à-dire qu'on ait l'inégalité

$$\left(a+\frac{q}{10^\alpha}\right)^2\leq a^2+\mathrm{R}$$

ou

$$2a \times \frac{q}{10^{\alpha}} + \frac{q^2}{10^{2\alpha}} \leq R$$

ou encore

$$\frac{q^2}{10^{2\alpha}} \leq R_1.$$

Si donc on développe le quotient de la division de R par $2a$ en décimales, tant que le carré de la partie trouvée au quotient ne surpassera pas le reste de la division, cette partie sera égale à la partie complémentaire de la racine, à moins d'une unité du dernier ordre, et par défaut.

Supposons que nous nous arrêtions dans la division de R par $2a$ à la partie $\frac{q}{10^{\alpha}}$ du quotient, $\frac{q^2}{10^{2\alpha}}$ ne surpassant pas le reste R_1 de la division, et désignons par R_2 l'excès de R_1 sur $\frac{q^2}{10^{2\alpha}}$; nous aurons successivement

$$\frac{q^2}{10^{2\alpha}} + R_2 = R_1,$$

$$\frac{q^2}{10^{2\alpha}} + R_2 = R - 2a \times \frac{q}{10^{\alpha}};$$

d'où, ajoutant aux deux membres $a^2 + 2a \times \frac{q}{10^{\alpha}}$,

$$\left(a + \frac{q}{10^{\alpha}}\right)^2 + R_2 = a^2 + R.$$

On pourra alors reprendre le calcul précédent en traitant $a + \frac{q}{10^{\alpha}}$ et R_2 de la même manière que a et R, et continuer ainsi jusqu'à ce que l'on ait obtenu une valeur suffisamment approchée de la racine cherchée.

Observations. — On pourra encore abréger le calcul en ne conservant que la partie utile des produits qu'on devra successivement retrancher dans les divisions qu'on aura à faire, à condition de tenir compte à la fin du calcul des erreurs commises sur ces produits.

III. Pour ne rien laisser à désirer, donnons un exemple de ce calcul : soit à extraire la racine carrée de la somme $(3,732050807568 + \alpha)^2 + 1$, α étant un nombre positif inconnu, mais moindre que $\frac{1}{10^{12}}$. Agissons comme si α était nul, nous en tiendrons compte ultérieurement; commençons la division de 1 par le double de la partie entre parenthèses diminuée de α, ne conservant dans chaque produit que la partie représentant des unités de l'ordre $\frac{1}{10^{13}}$:

```
1,0000000000000000 | 7,464101615136
   7464101815136    |---------------
 ----------------   | 0,13
   2535898384864o
   2239230484540 8
   --------------
    29666790032 32
```

Retranchons du second reste le carré de la partie trouvée au quotient $(0,13)^2 = 0,0169$, puis divisons le résultat de cette soustraction par la somme du diviseur précédent et du double de la partie trouvée au quotient, 0,26 :

```
0,0296667900323 2
0,0169
---------
0,01276679003232o | 7,724101615136
     7724101615136 |---------------
    -------------- | 0,001652
     5042688417184
     4634460969078
     -------------
      408227448106
      386205080755
      ------------
       22022367351
       15448203230
       -----------
        6574164121
```

Opérons sur le nouveau quotient comme sur le précédent, modifions de même le diviseur et poursuivons :

$$
\begin{array}{r|l}
0{,}000006574164121 & \\
(0{,}001652)^2 = 0{,}000002729104 & \\
\hline
3845060121 & 7{,}727405615136 \\
\cline{2-2}
3090962244 & 0{,}000000497587 \\
\hline
754097877 & \\
695466504 & \\
\hline
58631373 & \\
54091835 & \\
\hline
4539538 & \\
3863700 & \\
\hline
675838 & \\
618192 & \\
\hline
57646 & \\
54089 & \\
\hline
3557 &
\end{array}
$$

Dans les opérations que nous venons d'exécuter, les produits que nous avons successivement retranchés du dividende initial sont trop faibles : il en résulte que le reste final est trop grand de la somme des parties négligées dans chaque produit ; il est facile de former une limite supérieure de la somme de ces parties négligées.

Nous avons d'abord négligé le produit de 2α (partie complémentaire du diviseur) par le nombre formé des trois premiers chiffres des quotients obtenus, soit $0{,}131$; cette première partie négligée a une valeur moindre que $0{,}131 \times \frac{2}{10^{12}} = \frac{131 \times 2}{10^{15}}$.

En second lieu, dans chacun des produits suivants, la partie négligée n'atteint pas un nombre d'unités de l'ordre $\frac{1}{10^{15}}$ marqué par le chiffre employé au multiplicateur ; donc la somme des parties négligées n'atteint pas le produit

$$\frac{1}{10^{15}} \times (131 \times 2 + 6 + 5 + 2 + 4 + 9 + 7 + 5 + 8 + 7),$$

et, si nous désignons cette somme par E, nous aurons

$$E < \frac{315}{10^{15}}.$$

De là résulte que, si nous désignons par R le reste final exact, nous avons les inégalités

$$\frac{3557 - 315}{10^{15}} = \frac{3242}{10^{15}} < R < \frac{3557}{10^{15}}.$$

Le dernier quotient trouvé ne pourrait être que trop grand, puisque nous avons opéré sur des dividendes trop grands, et il ne l'est pas, en tant que quotient, puisque son produit par le diviseur retranché du dividende fournit le reste R qui est positif; il n'est pas trop grand non plus, en tant que partie complémentaire de la racine, puisque son carré est inférieur à $\frac{25}{10^{14}}$ qui est lui-même certainement inférieur à R.

Donc la partie complémentaire de la racine carrée cherchée est, à moins de $\frac{1}{10^{12}}$ par défaut,

$$0,131652497587,$$

et la racine carrée est elle-même :

$$3,863703305155,$$

à moins de $\frac{2}{10^{12}}$ par défaut.

IV. L'exemple sur lequel nous venons d'appliquer le procédé d'extraction de la racine carrée exposé au n° II n'a pas été pris au hasard; si dans le triangle rectangle ABC, considéré au n° I, nous supposons

$$BC = D = 2,$$

nous aurons

$$AB = d = \sqrt{3} \quad \text{et} \quad \alpha = 30^\circ.$$

Or $\sqrt{3}$ est égale à 1,732050807568, à moins de $\frac{1}{10^{12}}$ par défaut; dès lors, et par application des formules du n° I, nous aurons, en partant des données,

$$\begin{array}{llll}
D = 2, & & & \\
d = \sqrt{3} = 1,732050807568 & \text{à moins de} & \frac{1}{10^{12}} & \text{par défaut}, \\
d_1 = \quad 3,732050807568 & \text{»} & \frac{1}{10^{12}} & \text{»} \\
D_1 = \quad 3,863703305155 & \text{»} & \frac{2}{10^{12}} & \text{»}
\end{array}$$

l'angle compris entre D_1 et d_1 étant de 15°.

On voit du reste immédiatement, en unissant le point A au point milieu de BC, ou à celui de B_1C, que D et d sont les diamètres des cercles circonscrit ou inscrit à l'hexagone régulier dont le côté est 1, et que D_1 et d_1 sont les diamètres des cercles circonscrit et inscrit au dodécagone régulier ayant aussi pour côté 1.

Reprenant deux fois le même calcul à partir de D_1 et d_1, nous nous procurerons de même les diamètres D_2 et d_2, D_3 et d_3, des cercles circonscrit et inscrit aux polygones réguliers de vingt-quatre et quarante-huit côtés, respectivement, et ayant chacun pour côté 1.

V. Les détails dans lesquels nous sommes entrés à l'occasion de ces calculs, dans le n° III, doivent nous dispenser de les rapporter *in extenso :* nous n'en donnerons donc que les résultats.

Toutefois, avant de les inscrire, nous ferons la remarque suivante, qui nous conduira à une notation utile : on voit que, dans chaque calcul, tel que celui du n° III, on ne fait que déterminer la différence qui existe entre les diamètres des cercles circonscrit et inscrit à un même polygone régulier dont le côté est 1; nous désignerons donc, d'une façon générale, par D_k et d_k les diamètres des cercles circonscrit et inscrit au polygone régulier dont le côté est 1, et dont le nombre des côtés est 6×2^k, et par Δ_k la différence $D_k - d_k$.

Cela posé, les résultats trouvés sont caractérisés par les égalités suivantes :

$$d_2 = D_1 + d_1 = 7{,}595754112723 \quad \text{à moins de} \quad \frac{3}{10^{12}} \quad \text{par défaut.}$$

$$\Delta_2 = 0{,}065543462815 \quad \text{»} \quad \frac{1}{10^{12}} \quad \text{»}$$

$$D_2 = d_2 + \Delta_2 = 7{,}661297575538 \quad \text{»} \quad \frac{1}{10^{12}} \quad \text{»}$$

$$d_3 = D_2 + d_2 = 15{,}257051688261 \quad \text{»} \quad \frac{7}{10^{12}} \quad \text{»}$$

$$\Delta_3 = 0{,}032736610412 \quad \text{»} \quad \frac{1}{10^{12}} \quad \text{»}$$

$$D_3 = d_3 + \Delta_3 = 15{,}289788298673 \quad \text{»} \quad \frac{8}{10^{12}} \quad \text{»}$$

VI. La partie la plus pénible de ces calculs est évidemment la détermination des nombres Δ : aussi est-on conduit à rechercher s'il n'existe pas quelque propriété géométrique de la figure qui nous permette d'atteindre plus facilement ce résultat.

Reprenons la figure du n° I et ajoutons y la circonférence décrite de B comme centre avec $BC = D$ pour rayon, elle coupe AB en B_1 et en E, joignons CE par une ligne droite; conservant les notations des numéros précédents, nous aurons

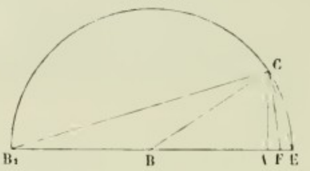
$$BE - BA = D - d = AE = \Delta.$$

Dans le triangle ACE (*fig.* 2), l'angle ACE est égal à l'angle

$$BB_1C = \frac{\alpha}{2},$$

car ils ont leurs côtés respectivement perpendiculaires et sont tous les deux aigus ; donc, pour avoir la différence $AE = \Delta$, il suffira de construire CE faisant avec CA l'angle $ACE = \frac{1}{2}ABC$; de même, pour avoir la différence

Fig. 2.



$$AF = B_1C - B_1A = D_1 - d_1 = \Delta_1,$$

il suffira de construire la droite CF faisant avec CA l'angle $ACF = \frac{1}{2}AB_1C$. On conclut de cette construction que CF est bissectrice de l'angle ACE et de la propriété connue de cette droite, l'égalité de rapports

$$\frac{\Delta - \Delta_1}{\Delta_1} = \frac{CE}{CA} = \sqrt{\Delta^2 + 1}.$$

Élevons les deux membres au carré et ramenons à la forme entière

$$\Delta^2 - 2\Delta\Delta_1 + \Delta_1^2 = \Delta_1^2(\Delta^2 + 1).$$

Réduisant et transposant,

$$\Delta\Delta_1^2 + 2\Delta_1 - \Delta = 0.$$

Cette équation du second degré définit Δ_1 au moyen de Δ par sa racine positive ; mais, comme Δ a généralement une petite valeur, on peut calculer Δ_1 au moyen d'une suite d'inégalités que nous allons déduire de l'équation même, et sans extraction de racine carrée.

Nous pouvons donner à l'équation précédente la forme

$$\Delta_1 = \tfrac{1}{2}\Delta - \tfrac{1}{2}\Delta\Delta_1^2 : \tag{1}$$

d'où l'inégalité évidente

$$\Delta_1 < \tfrac{1}{2}\Delta.$$

Remplaçons dans l'équation (1), et au second membre seulement, Δ_1 par le nombre plus grand $\frac{1}{2}\Delta$; nous aurons

$$\Delta_1 > \tfrac{1}{2}\Delta - \tfrac{1}{8}\Delta^3.$$

Ainsi, en prenant pour valeur approchée par excès de Δ_1 la valeur $\frac{1}{2}\Delta$, l'erreur commise a pour limite supérieure $\frac{1}{8}\Delta^3$.

Si nous remplaçons maintenant au second membre de l'équation (1) Δ_1 par le nombre plus petit $\frac{1}{2}\Delta - \frac{1}{8}\Delta^3$, nous aurons, en négligeant un terme soustractif, ce qui ne fait qu'augmenter l'inégalité,

$$\Delta_1 < \tfrac{1}{2}\Delta - \tfrac{1}{8}\Delta^3 + \tfrac{1}{16}\Delta^5.$$

Dès lors, en prenant pour valeur approchée par défaut de Δ_1 la différence $\frac{1}{2}\Delta - \frac{1}{8}\Delta^3$, l'erreur commise sera inférieure à $\frac{1}{16}\Delta^5$.

Enfin, en substituant à Δ_1 dans le second membre de l'équation (1) la valeur trop grande $\frac{1}{2}\Delta - \frac{1}{8}\Delta^3 + \frac{1}{16}\Delta^5$, nous aurons, en négligeant des termes dont la somme est certainement positive,

$$\Delta_1 > \tfrac{1}{2}\Delta - \tfrac{1}{8}\Delta^3 + \tfrac{1}{16}\Delta^5 - \tfrac{5}{16}\Delta^7 ;$$

d'où l'on conclut que si, dans la suite

$$\tfrac{1}{2}\Delta - \tfrac{1}{8}\Delta^3 + \tfrac{1}{16}\Delta^5 - \tfrac{5}{16}\Delta^7.$$

on prend un, deux ou trois termes comme valeur approchée de Δ_1, cette valeur est approchée par excès ou par défaut suivant qu'on s'arrête à un terme affecté du signe + ou du signe —, et que, dans tous les cas, la valeur absolue du premier terme négligé est limite supérieure de l'erreur commise.

Ces inégalités permettent de calculer un des nombres Δ au moyen du précédent avec une assez grande approximation : on pourrait même l'obtenir avec une approximation illimitée par l'emploi de l'égalité (1) et par la méthode des approximations successives ; mais leur emploi est encore pénible, eu égard aux multiplications à faire : aussi ne ferons-nous usage dans ce qui suit que des inégalités

$$\tfrac{1}{2}\Delta - \tfrac{1}{8}\Delta^3 < \Delta_1 < \tfrac{1}{2}\Delta,$$

et nous allons nous occuper d'établir des formules se déduisant de l'équation (1) et permettant d'arriver au même résultat au moyen d'opérations plus simples.

VII. Reprenons l'égalité initiale réduite du n° VI

$$\Delta - 2\Delta_1 - \Delta\Delta_1^2 = 0, \tag{1}$$

d'où

$$\Delta = \frac{2\Delta_1}{1 - \Delta_1^2}. \tag{1'}$$

Appliquons-la aux différences d'ordre supérieur de une unité

$$\Delta_1 - 2\Delta_2 - \Delta_1\Delta_2^2 = 0, \tag{2}$$

d'où

$$\Delta_1 = \frac{2\Delta_2}{1 - \Delta_2^2}. \tag{2'}$$

Δ étant peu différent de $2\Delta_1$, et Δ_1 l'étant peu de $2\Delta_2$, la valeur numérique du dernier terme du premier membre de l'égalité (1) est sensiblement égale à huit fois celle du terme correspondant de l'égalité (2); retranchant les égalités (1) et (2) membre à membre après avoir multiplié la seconde par 8, on a

$$\Delta - 10\Delta_1 + 16\Delta_2 - \Delta_1(\Delta\Delta_1 - 8\Delta_2^2) = 0. \tag{3}$$

Transformons le dernier terme du premier membre de l'égalité (3); si nous multiplions membre à membre l'égalité (1)' et l'égalité obtenue en élevant au carré les deux membres de l'égalité (2)', nous aurons

$$\Delta\Delta_1 = \frac{8\Delta_2^2}{(1-\Delta_1^2)(1-\Delta_2^2)^2}.$$

Remplaçons au dénominateur Δ_1 par sa valeur tirée de l'égalité (2)'

$$\Delta\Delta_1 = \frac{8\Delta_2^2}{(1-\Delta_2^2)^2 - 4\Delta_2^2}.$$

De là on déduit

$$\begin{aligned}\Delta\Delta_1 - 8\Delta_2^2 &= 8\Delta_2^2\left[\frac{1}{(1-\Delta_2^2)^2 - 4\Delta_2^2} - 1\right]\\ &= 8\Delta_2^2 \times \frac{6\Delta_2^2 - \Delta_2^4}{(1-\Delta_2^2)^2 - 4\Delta_2^2}.\end{aligned}$$

En substituant au dénominateur $\frac{2\Delta_2}{\Delta_1}$ à $1 - \Delta_2^2$ qui lui est égal, d'après l'égalité (2)',

$$\Delta\Delta_1 - 8\Delta_2^2 = 8\Delta_2^2 \times \frac{6\Delta_2^2 - \Delta_2^4}{\frac{4\Delta_2^2}{\Delta_1^2} - 4\Delta_2^2} = 8\Delta_2^2\Delta_1^2 \times \frac{6-\Delta_2^2}{4(1-\Delta_1^2)}.$$

Remplaçons enfin au dénominateur de la dernière fraction $1 - \Delta_1^2$ par sa valeur $\frac{2\Delta_1}{\Delta}$ déduite de l'égalité (1)', on a, après réduction,

$$\Delta\Delta_1 - 8\Delta_2^2 = \Delta\Delta_1\Delta_2^2(6 - \Delta_2^2):$$

d'où, reportant dans l'égalité (3), on a

$$\Delta - 10\Delta_1 + 16\Delta_2 - \Delta\Delta_1^2\Delta_2^2(6 - \Delta_2^2) = 0. \tag{α}$$

De l'égalité (*a*) on peut déduire

$$\Delta_2 = \frac{1}{16}(10\Delta_1 - \Delta) + \frac{(6-\Delta_2^2)\Delta\Delta_1^2\Delta_2^2}{16}.$$

Le premier terme du second membre fournit une valeur approchée par défaut de Δ_2, et le second terme qui représente l'erreur est moindre que

$$\frac{6\Delta\left(\frac{\Delta}{2}\right)^2\left(\frac{\Delta}{4}\right)^2}{16} = \frac{3}{512}\Delta^5 < \frac{\Delta^5}{170}.$$

VIII. Reprenons encore l'égalité (*a*) du numéro précédent, et appliquons-la aux différences d'indice supérieur d'une unité :

$$(a) \qquad \Delta - 10\Delta_1 + 16\Delta_2 - \Delta\Delta_1^2\Delta_2^2(6-\Delta_1^2) = 0.$$

$$(b) \qquad \Delta_1 - 10\Delta_2 + 16\Delta_3 - \Delta_1\Delta_2^2\Delta_3^2(6-\Delta_3^2) = 0.$$

Retranchons membre à membre de l'égalité (*a*) l'égalité (*b*) dont les deux membres ont été précédemment multipliés par 32; on en déduit

$$(c) \qquad \left\{\begin{aligned} &\Delta - 42\Delta_1 + 336\Delta_2 - 512\Delta_3 \\ &\quad - \Delta_1\Delta_2^2[\Delta\Delta_1(6-\Delta_2^2) - 32\Delta_3^2(6-\Delta_3^2)] = 0. \end{aligned}\right.$$

Nous allons réduire la parenthèse du dernier terme de l'égalité (*c*) en l'exprimant d'abord au moyen de Δ_3; nous avons trouvé dans le numéro précédent l'expression du produit $\Delta\Delta_1$ au moyen de Δ_2; on en déduit, en tenant compte de l'égalité $\Delta_2 = \frac{2\Delta_3}{1-\Delta_3^2}$,

$$\begin{aligned} \Delta\Delta_1(6-\Delta_2^2) &= \frac{8\Delta_2^2(6-\Delta_2^2)}{(1-\Delta_2^2)^2 - 4\Delta_2^2} \\ &= \frac{\dfrac{32\Delta_3^2}{(1-\Delta_3^2)^2}\left[6 - \dfrac{4\Delta_3^2}{(1-\Delta_3^2)^2}\right]}{\left[1 - \dfrac{4\Delta_3^2}{(1-\Delta_3^2)^2}\right]^2 - \dfrac{16\Delta_3^2}{(1-\Delta_3^2)^2}} \\ &= \frac{32\Delta_3^2[6(1-\Delta_3^2)^2 - 4\Delta_3^2]}{[(1-\Delta_3^2)^2 - 4\Delta_3^2]^2 - 16\Delta_3^2(1-\Delta_3^2)^2}. \end{aligned}$$

La parenthèse du dernier terme de l'égalité (c) peut alors, par substitution de la valeur précédente, s'écrire sous la forme

$$\frac{32\Delta_3^2}{[(1-\Delta_3^2)^2-4\Delta_3^2]^2-16\Delta_3^2(1-\Delta_3^2)^2} \times \{6(1-\Delta_3^2)^2-4\Delta_3^2-(6-\Delta_3^2)\{[(1-\Delta_3^2)^2-4\Delta_3^2]^2-16\Delta_3^2(1-\Delta_3^2)^2\}\}$$

Effectuons les calculs indiqués dans la parenthèse; l'expression précédente devient

$$\frac{32\Delta_3^2}{[(1-\Delta_3^2)^2-4\Delta_3^2]^2-16\Delta_3^2(1-\Delta_3^2)^2} \times \Delta_3^2(153-442\Delta_3^2+238\Delta_3^4-34\Delta_3^6+\Delta_3^8).$$

Transformons actuellement le facteur fractionnaire en remplaçant dans son dénominateur $(1-\Delta_3^2)$ par la quantité égale $\frac{2\Delta_3}{\Delta_2}$, on trouve

$$\begin{aligned}\frac{32\Delta_3^2}{[(1-\Delta_3^2)^2-4\Delta_3^2]^2-16\Delta_3^2(1-\Delta_3^2)^2} &= \frac{32\Delta_3^2}{\left(\frac{4\Delta_3^2}{\Delta_2^2}-4\Delta_3^2\right)^2-16\Delta_3^2\times\frac{4\Delta_3^2}{\Delta_2^2}} \\ &= \frac{2\Delta_2^4}{\Delta_3^2[(1-\Delta_2^2)^2-4\Delta_2^2]}.\end{aligned}$$

Remplaçons de nouveau $(1-\Delta_2^2)$ par la fraction égale $\frac{2\Delta_2}{\Delta_1}$; nous trouvons, pour valeur du facteur fractionnaire,

$$\frac{2\Delta_2^4}{\Delta_3^2[(1-\Delta_2^2)^2-4\Delta_2^2]} = \frac{2\Delta_2^4}{\Delta_3^2\left(\frac{4\Delta_2^2}{\Delta_1^2}-4\Delta_2^2\right)} = \frac{\Delta_2^2\times\Delta_1^2}{2\Delta_3^2(1-\Delta_1^2)}.$$

Substituons enfin à $1-\Delta_1^2$ la valeur égale $\frac{2\Delta_1}{\Delta}$

$$\frac{\Delta_2^2\times\Delta_1^2}{2\Delta_3^2(1-\Delta_1^2)} = \frac{\Delta\Delta_1\Delta_2^2}{4\Delta_3^2}.$$

Il en résulte que la parenthèse du dernier terme de l'égalité (c) peut s'écrire

$$\frac{\Delta\Delta_1\Delta_2^2}{4}(153 - 442\Delta_3^2 + 238\Delta_3^4 - 34\Delta_3^6 + \Delta_3^8),$$

et qu'enfin l'égalité (c) peut prendre la forme

$$(d)\quad \left\{ \begin{aligned} &\Delta - 42\Delta_1 + 336\Delta_2 - 512\Delta_3 \\ &\quad - \frac{\Delta\Delta_1^2\Delta_2^4}{4}(153 - 442\Delta_3^2 + 238\Delta_3^4 - 34\Delta_3^6 + \Delta_3^8) = 0; \end{aligned} \right.$$

d'où l'on déduit

$$\begin{aligned} \Delta_3 = {} & \frac{1}{512}[(8\Delta_2 - \Delta_1) \times 42 + \Delta] \\ & - \frac{\Delta\Delta_1^2\Delta_2^4}{2048}(153 - 442\Delta_3^2 + 238\Delta_3^4 - 34\Delta_3^6 + \Delta_3^8). \end{aligned}$$

Comme la parenthèse du second terme du second membre est évidemment positive pour les valeurs de Δ_3 qui ne surpassent pas $\sqrt{\frac{153}{442}}$ et à plus forte raison $\frac{1}{2} < \sqrt{\frac{153}{442}}$; que de plus, pour les mêmes valeurs de Δ_3, cette parenthèse a une valeur inférieure à 153, il en résulte que le premier terme du second membre peut être pris comme valeur approchée par excès de Δ_3, et que l'erreur commise est moindre que la fraction $\frac{153\Delta\Delta_1^2\Delta_2^4}{2048}$, qui admet elle-même, comme limite supérieure, $\frac{153\Delta^7}{2048 \times 2^{10}} = \frac{153\Delta^7}{2^{21}}$.

IX. Les formules établies aux n^os VI, VII et VIII, prises sous les formes

$$\begin{aligned} \Delta_1 &= \tfrac{1}{2}\Delta - \tfrac{1}{2}\Delta\Delta_1^2, \\ \Delta_2 &= \frac{1}{16}(10\Delta_1 - \Delta) + \frac{(6 - \Delta_2^2)\Delta.\Delta_1^2.\Delta_2^2}{16}, \\ \Delta_3 &= \frac{1}{512}[(8\Delta_2 - \Delta_1) \times 42 + \Delta] \\ &\quad - \frac{\Delta\Delta_1^2\Delta_2^4}{2048}(153 - 442\Delta_3^2 + 238\Delta_3^4 - 34\Delta_3^6 + \Delta_3^8), \end{aligned}$$

permettent de calculer une des valeurs Δ au moyen de la précédente, ou des deux ou trois précédentes, avec une approximation indéfinie, à l'aide de la méthode des approximations successives, et cela indépendamment des valeurs de D et d.

On pourrait encore les appliquer en suivant des méthodes diverses pour obtenir des valeurs approchées de l'inconnue, mais le procédé qui nous paraît le plus avantageux, et celui que nous allons appliquer, consiste à prendre pour valeur approchée du premier membre le premier terme du second ; nous éviterons ainsi l'emploi des logarithmes, et nous obtiendrons une approximation suffisante, pourvu que Δ soit assez petit.

Nous avons déjà trouvé directement, aux n^{os} III et V, les valeurs

$$\Delta_1 = 0,131652497587\ldots,$$
$$\Delta_2 = 0,065543462815\ldots,$$
$$\Delta_3 = 0,032736610412\ldots,$$

chacune de ces valeurs étant approchée à moins de $\frac{1}{10^{12}}$ par défaut.

En acceptant comme valeur approchée par excès de Δ_4, $\frac{1}{512}[(8\Delta_3 - \Delta_2) \times 42 + \Delta_1]$, l'erreur sera, d'après la fin du n° VIII, inférieure à $\frac{153 \times 132^7}{2^{21} \times 10^{21}}$.

Mais on a évidemment les égalités ou inégalités suivantes :

$$\begin{aligned}\frac{153 \times 132^7}{2^{21} \times 10^{21}} &= \frac{153 \times 33^7}{2^7 \times 10^{21}}\\ &= 153 \times \left(\frac{33}{100}\right)^7 \times \frac{1}{2^7 \times 10^7} < 153 \times \frac{1}{3^7} \times \frac{1}{2^7 \times 10^7}\\ &= \frac{17}{3^5 \times 2^7 \times 10^7} < \frac{55}{10^{12}}.\end{aligned}$$

Si nous faisons le calcul de

$$\frac{1}{512}[(8\Delta_3 - \Delta_2) \times 42 + \Delta_1].$$

en prenant les valeurs approchées que nous avons trouvées pour Δ_1, Δ_2, Δ_3, la première et la dernière par excès, la seconde par défaut, nous aurons pour valeur approchée par excès $0,01636392218 5$, quotient décimal approché à moins de $\frac{1}{10^{12}}$ par excès; du reste, l'erreur commise en remplaçant Δ_1, Δ_2, Δ_3 par leurs valeurs approchées n'atteint pas

$$\frac{1}{10^{12}} \times \frac{1}{512} \times (336 + 42 + 1) < \frac{1}{10^{12}},$$

d'où résulte qu'on peut prendre le quotient

$$0,016363922185$$

comme valeur approchée par excès de Δ_4 à moins de $\frac{57}{10^{12}}$, et le nombre $0,016363922128$ comme valeur approchée par défaut du même nombre, avec la même limite d'erreur.

Si actuellement nous répétons des calculs analogues pour trouver une valeur approchée de Δ_5 au moyen de Δ_2, Δ_3, Δ_4, en observant que la limite supérieure du terme négligé, à savoir $\frac{153\Delta_2\Delta_3^2\Delta_4^4}{2048}$, est moindre que le $\frac{1}{128}$ de celle du terme négligé dans le calcul précédent, puisque Δ_2, Δ_3, Δ_4 sont respectivement moindres que les moitiés de Δ_1, Δ_2, Δ_3, et qu'en conséquence ce terme négligé est moindre que $\frac{55}{10^{14}}$; que, de plus, l'erreur commise en substituant à Δ_2, Δ_3, Δ_4 leurs valeurs approchées, et en développant le quotient en fraction décimale à moins de $\frac{1}{10^{12}}$, par excès, est moindre que

$$\frac{1}{10^{12}} \times \frac{1}{512} \times (336 \times 57 + 42 + 1) + \frac{1}{10^{12}} < \frac{39}{10^{12}},$$

nous en conclurons qu'on peut prendre comme valeur approchée de Δ_5 par excès et à moins de $\frac{40}{10^{12}}$ le nombre $0,0081813437$, et comme valeur approchée de Δ_5 par défaut et avec la même approximation le nombre

$$0,0081814133397;$$

d'où

$$0,016363922128 < \Delta_4 < 0,016363922185,$$
$$0,0081814133397 < \Delta_5 < 0,0081814133437.$$

X. Les valeurs de Δ auxquelles nous sommes actuellement parvenus sont suffisamment petites pour que nous puissions faire usage de la formule établie au n° VII pour obtenir les valeurs consécutives de Δ; nous accepterons donc, comme valeur approchée par défaut de Δ_6, $\frac{1}{16}(10\,\Delta_5 - \Delta_4)$, et nous avons vu à la fin du n° VII que la limite de l'erreur commise était $\frac{\Delta_4^5}{170} < \frac{8}{10^{12}}$. Calculons $\frac{1}{16}(10\Delta_5 - \Delta_4)$, par défaut, en prenant Δ_5 par défaut et Δ_4 par excès; la limite de l'erreur commise sera $\frac{1}{16}(10 \times 40 + 57) \times \frac{1}{10^{12}}$, moindre que $\frac{29}{10^{12}}$. Il résulte de là que la valeur approchée par défaut et à moins de $\frac{1}{10^{12}}$ de

$$\tfrac{1}{16}(0,081814133970 - 0,016363922185)$$

est aussi approchée par défaut de Δ_6 à moins de $\frac{38}{10^{12}}$; d'où

$$0,004090638236 < \Delta_6 < 0,004090638274.$$

On trouve de même, par l'emploi réitéré de la même formule et en prenant les mêmes précautions relatives à l'approximation,

$$0,002045310557 < \Delta_7 < 0,002045310586,$$
$$0,001022654206 < \Delta_8 < 0,001022654229.$$

Nous avons ainsi trouvé des valeurs approchées de Δ_6 à moins de $\frac{38}{10^{12}}$, de Δ_7 à moins de $\frac{29}{10^{12}}$ et de Δ_8 à moins de $\frac{23}{10^{12}}$.

Δ_8 est assez petit, comme nous allons le voir, pour que nous puissions tirer tout le parti possible des nombres que nous avons calculés, en tenant compte des erreurs qui les affectent.

XI. Nous avons posé au n° V $\Delta_k = D_k - d_k$, nous avons du reste vu, d'après le n° I, que

$$d_{k+1} = D_k + d_k;$$

on en déduit

$$d_{k+1} = 2\,d_k + \Delta_k.$$

Faisant varier k, on trouve

$$\begin{aligned}
d_4 &= 2\,d_3 + \Delta_3,\\
d_5 &= 2\,d_4 + \Delta_4,\\
&\dots\dots\dots\dots\\
d_p &= 2\,d_{p-1} + \Delta_{p-1}.
\end{aligned}$$

Multipliant ces égalités par les puissances décroissantes de 2 à partir de 2^{p-4}, on trouve, en les ajoutant membre à membre,

$$(1) \qquad d_p = 2^{p-3}\,d_3 + 2^{p-4}\,\Delta_3 + 2^{p-5}\,\Delta_4 + \ldots + 2\,\Delta_{p-2} + \Delta_{p-1}.$$

Si nous posons $p = 8$, nous aurons

$$(2) \qquad d_8 = 2^5\,d_3 + 2^4\,\Delta_3 + 2^3\,\Delta_4 + 2^2\,\Delta_5 + 2\,\Delta_6 + \Delta_7.$$

Remplaçons dans cette égalité (2) d_3, Δ_3, Δ_4, …, Δ_7, par les valeurs approchées par défaut que nous en avons trouvées, nous aurons une valeur approchée par défaut de d_8, et la limite supérieure de l'erreur commise sur d_8 s'obtiendra en remplaçant au second membre de l'égalité (2) d_3, Δ_3, ... Δ_7, chacun par la limite supérieure de l'erreur commise sur ce nombre.

Nous rapportons ci-dessous le Tableau de ce calcul, en observant que nous n'écrivons que le numérateur de la limite supérieure de chaque erreur, tous ces nombres ayant pour dénominateur commun 10^{12}.

Sur une ligne horizontale nous écrivons séparément la valeur approchée par défaut de d_3 et le numérateur de la limite de l'erreur commise sur ce nombre. Nous multiplions ces deux nombres par 2; les produits sont placés sur la seconde ligne horizontale. A ces produits nous ajoutons respectivement la valeur approchée par défaut de Δ_3, et le numérateur de la limite de l'erreur commise sur Δ_3; nous multiplions les sommes par 2, et nous continuons de même jusqu'à ce que nous ayons fait l'addition de la valeur approchée par défaut de Δ_7 et du numérateur de la limite de l'erreur correspondante.

$$\begin{array}{rr}
15,257051688261 & 7 \\
30,514103376522 & 14 \\
32736610412 & 1 \\
\hline
30,546839986934 & 15 \\
61,093679973868 & 30 \\
16363922128 & 57 \\
\hline
61,110043895996 & 87 \\
122,220087791992 & 174 \\
8181413397 & 40 \\
\hline
122,228269205389 & 214 \\
244,456538410778 & 428 \\
4090638236 & 38 \\
\hline
244,460629049014 & 466 \\
488,921258098028 & 932 \\
2045310557 & 29 \\
\hline
488,923303408585 & 961
\end{array}$$

De là nous pouvons conclure que d_8 admet pour valeur approchée par défaut 488,923303408585, et que la limite supérieure de l'erreur est $\frac{961}{10^{12}}$.

XII. Par le procédé employé au n° XI, on trouve l'égalité

$$(1)\qquad \left\{\begin{aligned} d_{p+n} = 2^n d_p + 2^{n-1}\Delta_p + 2^{n-2}\Delta_{p+1} + \ldots \\ + 2\Delta_{p+n-2} + \Delta_{p+n-1}. \end{aligned}\right.$$

Si k est le nombre des côtés du polygone admettant pour diamètre du cercle inscrit d_p, d_{p+n} est le diamètre du cercle inscrit dans le polygone dont le nombre des côtés est $k \times 2^n$, et dont le périmètre est aussi représenté par $k \times 2^n$; nous pouvons en conclure, d'après l'égalité des rapports des périmètres de deux polygones réguliers d'un même nombre de côtés à celui des diamètres des cercles qui leur sont respectivement inscrits, que $\frac{d_{p+n}}{2^n}$ est le diamètre du cercle inscrit, dans le polygone régulier dont le nombre des côtés est $k \times 2^n$ et dont le périmètre est k.

Divisant les deux membres de la dernière égalité (1) par 2^n, on en déduit

$$\frac{d_{p+n}}{2^n} = d_p + \frac{1}{2}\Delta_p + \frac{1}{2^2}\Delta_{p+1} + \ldots + \frac{1}{2^n}\Delta_{p+n-1}.$$

On trouve de même, pour le diamètre du cercle circonscrit au même polygone,

$$\frac{\mathrm{D}_{p+n}}{2^n} = d_p + \frac{1}{2}\Delta_p + \frac{1}{2^2}\Delta_{p+1} + \ldots + \frac{1}{2^n}\Delta_{p+n-1} + \frac{1}{2^n}\Delta_{p+n}.$$

On voit facilement, d'après ces égalités, que $\frac{d_{p+n}}{2^n}$ croît avec n, tandis que $\frac{\mathrm{D}_{p+n}}{2^n}$ décroît dans les mêmes circonstances, tout en restant supérieur à $\frac{d_{p+n}}{2^n}$ d'une quantité qui a pour limite zéro quand n augmente indéfiniment; du reste, $\frac{d_{p+n}}{2^n}$ et $\frac{D_{p+n}}{2^n}$ comprennent entre eux le diamètre de la circonférence dont la longueur est k; on peut donc considérer le diamètre de cette circonférence dont la longueur est k comme la limite vers laquelle tend $\frac{d_{p+n}}{2^n}$ quand n augmente au delà de toute limite, et nous poserons

$$\Theta = \lim \frac{d_{p+n}}{2^n}.$$

XIII. D'après les inégalités établies au n° VI, nous pouvons écrire

$$\begin{array}{llll}
 & \Delta_p & = \Delta_p & = \Delta_p, \\
\frac{1}{2}\Delta_p & -\frac{1}{8}\Delta_p^3 & < \Delta_{p+1} & < \frac{1}{2}\Delta_p. \\
\frac{1}{2}\Delta_{p+1} & -\frac{1}{8}\Delta_{p+1}^3 & < \Delta_{p+2} & < \frac{1}{2}\Delta_{p+1}, \\
\frac{1}{2}\Delta_{p+2} & -\frac{1}{8}\Delta_{p+2}^3 & < \Delta_{p+3} & < \frac{1}{2}\Delta_{p+2}, \\
\multicolumn{4}{l}{\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots,} \\
\frac{1}{2}\Delta_{p+n-2} & -\frac{1}{8}\Delta_{p+n-2}^3 & < \Delta_{p+n-1} & < \frac{1}{2}\Delta_{p+n-2}, \\
\frac{1}{2}\Delta_{p+n-1} & -\frac{1}{2}\Delta_{p+n-1} = & 0 & = \frac{1}{2}\Delta_{p+n-1} - \frac{1}{2}\Delta_{p+n-1}.
\end{array}$$

Multiplions les nombres écrits dans chaque ligne horizontale par une puissance de $\frac{1}{2}$ dont l'exposant soit égal au rang de la ligne correspondante, et ajoutons membre à membre ces deux séries d'inégalités; on trouve, en posant, pour abréger,

$$\Sigma = \frac{1}{2}\Delta_p + \frac{1}{2^2}\Delta_{p+1} + \dots + \frac{1}{2^n}\Delta_{p+n-1},$$

$$\Sigma' = \frac{1}{8}\left(\frac{1}{2^2}\Delta_p^3 + \frac{1}{2^3}\Delta_{p+1}^3 + \dots + \frac{1}{2^n}\Delta_{p+n-2}^3\right),$$

$$\frac{1}{2}\Delta_p + \frac{1}{4}\Sigma - \frac{1}{2^{n+2}}\Delta_{p+n-1} - \Sigma' < \Sigma < \frac{1}{2}\Delta + \frac{1}{4}\Sigma - \frac{1}{2^{n+2}}\Delta_{p+n-1}.$$

Observons actuellement que les termes contenus dans la parenthèse qui donne la valeur de Σ' sont, toujours d'après les inégalités du n° VI, respectivement moindres que les termes de même rang de la progression géométrique décroissante

$$\frac{1}{2^2}\Delta_p^3,\quad \frac{1}{2^3}\times\frac{1}{2^3}\Delta_p^3,\quad \frac{1}{2^4}\times\frac{1}{(2^2)^3}\Delta_p^3,$$
$$\frac{1}{2^5}\times\frac{1}{(2^3)^3}\Delta_p^3,\quad \ldots,\quad \frac{1}{2^n}\times\frac{1}{(2^{n-2})^3}\Delta_p^3;$$

il en résultera que Σ' est inférieur au $\frac{1}{8}$ de la limite de la somme des termes de cette progression, soit à

$$\frac{1}{8}\Delta_p^3\times\frac{\frac{1}{2^2}}{1-\frac{1}{2^4}}=\frac{\Delta_p^3}{2(2^4-1)}.$$

Dès lors, remplaçant Σ' par une quantité plus grande, nous aurons

$$\frac{1}{2}\Delta_p+\frac{1}{4}\Sigma-\frac{1}{2^{n+2}}\Delta_{p+n-1}-\frac{\Delta_p^3}{2(2^4-1)}$$
$$<\Sigma<\frac{1}{2}\Delta_p+\frac{1}{4}\Sigma-\frac{1}{2^{n+2}}\Delta_{p+n-1},$$

ou

$$\frac{1}{2}\Delta_p-\frac{1}{2^{n+2}}\Delta_{p+n-1}-\frac{\Delta_p^3}{2(2^4-1)}<\frac{3}{4}\Sigma<\frac{1}{2}\Delta_p-\frac{1}{2^{n+2}}\Delta_{p+n-1}.$$

Ces inégalités, ayant lieu quel que soit n, auront lieu si on le fait croître au de là detoute limite, et comme, dans ces conditions,

$$\lim\Sigma=\Theta-d_p,\qquad \lim\Delta_{p+n-1}=0,$$

nous trouverons par cette hypothèse

$$\frac{1}{2}\Delta_p-\frac{\Delta_p^3}{2\times(2^4-1)}<\frac{3}{4}(\Theta-d_p)<\frac{1}{2}\Delta_p,$$

d'où

$$d_p+\frac{2}{3}\Delta_p-\frac{2}{3}\frac{\Delta_p^3}{15}<\Theta<d_p+\frac{2}{3}\Delta_p.$$

On peut donc accepter comme valeur approchée par excès du diamètre de la circonférence dont la longueur est k

$$d_p + \tfrac{2}{3}\Delta_p,$$

et comme limite de l'erreur commise $\dfrac{2}{3}\,\dfrac{\Delta_p^3}{15}$.

XIV. Nous reportant au n° XI, le nombre des côtés du polygone régulier, dont le cercle inscrit admet pour diamètre d_8, est

$$6 \times 2^8 = 1536,$$

nous pouvons donc déduire du numéro précédent que

$$d_8 + \tfrac{2}{3}\Delta_8$$

représente par excès le diamètre de la circonférence dont la longueur est représentée par 1536.

D'après les valeurs numériques trouvées pour d_8 et Δ_8, et tenant compte des erreurs dont elles sont affectées, on trouve dans ce cas particulier

$$\Theta < 488,923985179032;$$

la limite de l'erreur commise sur Θ est

$$\frac{1037}{10^{12}}.$$

Le quotient à moins de $\frac{1}{10^{12}}$ par défaut de 1536 par

$$488,923985179032$$

est

$$3,141592653585.$$

On peut prendre pour limite de l'erreur commise sur le quotient $\dfrac{3,2 \times 1037}{488,9 \times 10^{12}} < \dfrac{7}{10^{12}}$, d'où

$$3,141592653585 < \pi < 3,141592653593.$$

$3,141592653593$ est donc approché de π à moins de $\frac{5}{10^{12}}$ sans qu'on connaisse le sens de l'approximation.

On trouverait $\frac{1}{\pi}$ en divisant Θ par 1536.

NOTE SUR LA DÉCOMPOSITION D'UNE FORME QUADRATIQUE À m VARIABLES EN UNE SOMME DE $m-n$ CARRÉS;

PAR M. BENOIT.

On sait que, pour exprimer qu'une forme quadratique à m variables peut se décomposer en une somme de $m-n$ carrés, il faut écrire que tous les déterminants mineurs de l'ordre $n-1$ de son discriminant sont nuls; mais les équations ainsi obtenues ne sont pas distinctes : je vais chercher quelles sont celles d'entre elles dont les autres sont des conséquences.

Soit d'abord le déterminant

$$\Delta = \begin{vmatrix} a_1^1 & a_1^2 & \dots & a_1^m \\ a_2^1 & \cdot\cdot & \dots & a_2^m \\ \cdot\cdot & \cdot\cdot & \dots & \cdot\cdot \\ a_m^1 & \cdot\cdot & \dots & a_m^m \end{vmatrix}.$$

Considérons l'un des mineurs de l'ordre n différent de zéro, soit

$$\delta = \begin{vmatrix} a_1^1 & a_1^2 & \dots & a_1^{m-n} \\ a_2^1 & \cdot\cdot & \dots & a_2^{m-n} \\ \cdot\cdot & \cdot\cdot & \dots & \cdot\cdot\cdot\cdot\cdot \\ a_{m-n}^1 & \cdot\cdot & \dots & a_{m-n}^{m-n} \end{vmatrix} \neq 0.$$

DE
MATHÉMATIQUES.

[O¹5n]

SURFACES ENGENDRÉES PAR LE DÉPLACEMENT D'UNE COURBE PLANE AVEC CONE CIRCONSCRIT LE LONG DE LA COURBE;

Par M. E. KERAVAL,
Professeur au lycée Louis-le-Grand.

Pour abréger, j'appelle *surface* Σ toute surface engendrée par le déplacement d'une courbe plane (C), quand il existe un cône circonscrit à la surface tout le long de chaque courbe (C). Je me servirai de coordonnées homogènes x_1, x_2, x_3, x_4 que je supposerai fonctions de deux paramètres u, v. Le paramètre u restera constant sur chaque courbe (C); je supposerai que les courbes obtenues en faisant v constant soient conjuguées des premières.

Je sais que dans ces conditions x_1, x_2, x_3, x_4 sont des solutions d'une même équation de la forme

$$\frac{\partial^2 \theta}{\partial u\, \partial v} + p\frac{\partial \theta}{\partial u} + q\frac{\partial \theta}{\partial v} + r\theta = 0, \tag{1}$$

où p, q, r sont des fonctions de u et de v. Si je désigne par (S) la courbe lieu du sommet des cônes circonscrits à Σ le long des courbes (C), les tangentes aux courbes v

rencontrent la courbe S, donc si l'on désigne par h et k les invariants de (1) savoir

$$h = \frac{\partial p}{\partial u} + pq - r,$$

$$k = \frac{\partial q}{\partial v} + pq - r,$$

l'invariant k est ici nul; nous dirons que l'équation (1) est de rang zéro à gauche. D'autre part, les courbes u étant planes, il existe une relation de la forme

$$(2) \qquad U_1 x_1 + U_2 x_2 + U_3 x_3 + U_4 x_4 \equiv 0,$$

où les coefficients de x_1, x_2, x_3, x_4 ne dépendent que de u. On sait que, dans ce cas, l'équation (1) est au plus de rang deux à droite, c'est-à-dire qu'après avoir appliqué deux fois au plus la transformation de Laplace on aura une nouvelle équation où le nouvel invariant h sera nul. Alors les équations de la surface Σ doivent être de la forme

$$(3) \qquad x_k = \begin{vmatrix} B_k & A_k & A'_k & A''_k \\ \beta_1 & \alpha_1 & \alpha'_1 & \alpha''_1 \\ \beta_2 & \alpha_2 & \alpha'_2 & \alpha''_2 \\ \beta_3 & \alpha_3 & \alpha'_3 & \alpha''_3 \end{vmatrix} \qquad (k = 1, 2, 3, 4).$$

où les fonctions B_k, β_1, β_2, β_3 dépendent de v et A_k, α_1, α_2, α_3 de u. Mais il peut arriver que le plan des courbes u roule sur un cône; nous prendrons le sommet du cône à l'origine

$$x_1 = 0, \qquad x_2 = 0, \qquad x_3 = 0.$$

Alors la relation (2) ne contiendra plus que trois coordonnées et l'équation (1) sera de rang un à droite, donc

$$(4)\qquad x_k = \begin{vmatrix} B_k & A_k & A'_k \\ \beta_1 & \alpha_1 & \alpha'_1 \\ \beta_2 & \alpha_2 & \alpha'_2 \end{vmatrix}.$$

Enfin le plan des courbe u peut passer par une droite fixe. Dans ce cas, ci cette droite a pour équation

$$x_1 = 0, \qquad x_2 = 0$$

la relation (2) ne contient plus que les deux variables x_1, x_2, l'équation (1) est de rang zéro à droite et les équations de la surface prennent la forme

$$(5)\qquad x_k = B_k + A_k.$$

Nous sommes ainsi conduits à ranger les surfaces Σ en trois catégories, nous aurons ainsi les surfaces Σ de troisième, seconde et première espèce. Dans les équations précédentes on suppose toujours qu'il n'existe pas de relation linéaire homogène à coefficients constants soit entre les quantités α, soit entre les β.

Étude des surfaces Σ de troisième espèce.

Les équations de la surface sont de la forme (3), mais il reste à exprimer que les courbes u sont planes. En portant les valeurs de x_1, x_2, x_3, x_4 dans la relation (2), on trouve une relation linéaire en B_1, B_2, B_3, B_4, β_1, β_2, β_3 et homogène. En divisant par un déterminant différent de zéro, cette relation prend la forme

$$U_1 B_1 + U_2 B_2 + U_3 B_3 + U_4 B_4 + \varphi(\beta_1, \beta_2, \beta_3) \equiv 0,$$

φ étant linéaire et homogène en β_1, β_2, β_3. Dans cette relation donnons à u quatre valeurs telles que le déterminant des coefficients de U_1, U_2, U_3, U_4 soit différent de zéro, ce qui est possible, puisque le plan des courbes u ne roule pas sur un cône, nous pourrons tirer pour B_1, B_2, B_3, B_4 des valeurs de la forme

$$B_k = a_k \beta_1 + b_k \beta_2 + c_k \beta_3,$$

les coefficients a_k, b_k, c_k étant des constantes. Alors en changeant la signification de A_k nous pourrons prendre, pour équations de la surface Σ,

$$(A) \qquad x_k = \begin{vmatrix} 0 & A_k & A'_k & A''_k \\ \beta_1 & \alpha_1 & \alpha'_1 & \alpha''_1 \\ \beta_2 & \alpha_2 & \alpha'_2 & \alpha''_2 \\ \beta_3 & \alpha_3 & \alpha'_3 & \alpha''_3 \end{vmatrix}$$

et cette fois les courbes u sont bien planes. La forme de ces équations nous permet d'énoncer le théorème suivant :

THÉORÈME. — *Les courbes planes* $u = \text{const.}$ *qui engendrent la surface sont homographiques, et la correspondance homographique est établie par les courbes conjuguées* $v = \text{const.}$

On peut imaginer par exemple dans un plan P un point de coordonnées homogènes β_1, β_2, β_3 décrivant une courbe (β). Pour chaque valeur de u on a dans un plan P_u une transformation homographique de cette courbe (β). Nous verrons plus loin si cette homographie peut devenir *singulière* pour certaines valeurs de u.

Pour le moment nous allons chercher les plans P_u et la courbe lieu du sommet des cônes circonscrits. On pourrait se servir des méthodes indiquées par M. Darboux pour des questions analogues, je préfère indiquer une méthode ne dépassant pas le cadre de la classe de Mathématiques spéciales.

Équations de la courbe (S).

Les tangentes aux courbes *v* rencontrent cette courbe. L'une des courbes *v* a pour équations

$$y_k = \begin{vmatrix} A_k & A'_k & A''_k \\ \alpha_1 & \alpha'_1 & \alpha''_1 \\ \alpha_2 & \alpha'_2 & \alpha''_2 \end{vmatrix}.$$

Or la théorie des déterminants nous donne l'identité

$$(6)\qquad \begin{vmatrix} A_k & A'_k & A''_k & A'''_k \\ \alpha_1 & \alpha'_1 & \alpha''_1 & \alpha'''_1 \\ \alpha_2 & \alpha'_2 & \alpha''_2 & \alpha'''_2 \\ \alpha_3 & \alpha'_3 & \alpha''_3 & \alpha'''_3 \end{vmatrix} \times (\alpha_1\alpha'_2 - \alpha_2\alpha'_1)$$
$$= \begin{vmatrix} A_k & A'_k & A''_k \\ \alpha_1 & \alpha'_1 & \alpha''_1 \\ \alpha_2 & \alpha'_2 & \alpha''_2 \end{vmatrix} \times \begin{vmatrix} \alpha_1 & \alpha'_1 & \alpha'''_1 \\ \alpha_2 & \alpha'_2 & \alpha'''_2 \\ \alpha_3 & \alpha'_3 & \alpha'''_3 \end{vmatrix}$$
$$- \begin{vmatrix} A_k & A'_k & A'''_k \\ \alpha_1 & \alpha'_1 & \alpha'''_1 \\ \alpha_2 & \alpha'_2 & \alpha'''_2 \end{vmatrix} \times \begin{vmatrix} \alpha_1 & \alpha'_1 & \alpha''_1 \\ \alpha_2 & \alpha'_2 & \alpha''_2 \\ \alpha_3 & \alpha'_3 & \alpha''_3 \end{vmatrix}.$$

Si donc on pose

$$(B)\qquad X_k = \begin{vmatrix} A_k & A'_k & A''_k & A'''_k \\ \alpha_1 & \alpha'_1 & \alpha''_1 & \alpha'''_1 \\ \alpha_2 & \alpha'_2 & \alpha''_2 & \alpha'''_2 \\ \alpha_3 & \alpha'_3 & \alpha''_3 & \alpha'''_3 \end{vmatrix},$$

cette identité prend la forme

$$y_k \times \begin{vmatrix} \alpha_1 & \alpha'_1 & \alpha'''_1 \\ \alpha_2 & \alpha'_2 & \alpha'''_2 \\ \alpha_3 & \alpha'_3 & \alpha'''_3 \end{vmatrix} - y'_k \times \begin{vmatrix} \alpha_1 & \alpha'_1 & \alpha''_1 \\ \alpha_2 & \alpha'_2 & \alpha''_2 \\ \alpha_3 & \alpha'_3 & \alpha''_3 \end{vmatrix} = X_k(\alpha_1\alpha'_2 - \alpha_2\alpha'_1),$$

qui prouve que le point X_1, X_2, X_3, X_4 se trouve bien sur la tangente à la courbe décrite par le point y_1, y_2, y_3, y_4. Il en est de même pour deux autres courbes *v* dont les coordonnées du sommet du cône sont données par les formules (B).

Plan des courbes u.

Le plan P_u d'une courbe u c'est le plan osculateur de la courbe (λ),

$$\lambda_k = A_k.$$

c'est-à-dire de la courbe décrite par le point de coordonnées A_1, A_2, A_3, A_4. Ceci résulte immédiatement de la forme des équations de la surface Σ, le plan osculateur contenant les trois points de coordonnées A_k, A'_k, A''_k.

Enveloppes des courbes u.

Un point d'une courbe u décrivant une enveloppe ne peut être que sur la caractéristique du plan P_u. Pour ces points, u et v sont liés par la relation

$$\begin{vmatrix} \beta_1 & \alpha_1 & \alpha'_1 \\ \beta_2 & \alpha_2 & \alpha'_2 \\ \beta_3 & \alpha_3 & \alpha'_3 \end{vmatrix} = 0,$$

que j'écrirai pour abréger

$$| \beta \alpha \alpha' | = 0.$$

Pour chaque valeur de u cette relation détermine un certain nombre de points situés sur la caractéristique du plan P_u. Soit M l'un de ces points, ses coordonnées sont fonctions de u et v qui sont eux-mêmes liés par la relation précédente. On peut supposer u et v fonctions d'un paramètre t, on aura

$$\frac{dx_k}{dt} = \frac{\partial x_k}{\partial u}\frac{du}{dt} + \frac{\partial x_k}{\partial v}\frac{dv}{dt}.$$

Or pour ce point M, on a

$$x_k = - A_k | \beta \alpha' \alpha'' | + A'_k | \beta \alpha \alpha'' |,$$

$$\frac{\partial x_k}{\partial u} = - A_k | \beta \alpha' \alpha''' | + A'_k | \beta \alpha \alpha''' | + A''_k | \beta \alpha \alpha'' |,$$

$$\frac{\partial x_k}{\partial v} = - A_k | \beta' \alpha' \alpha'' | + A'_k | \beta' \alpha \alpha'' |,$$

donc $\frac{dx_k}{dt}$ est une fonction linéaire et homogène de A_k, A'_k, A''_k. Le point de coordonnées $\frac{dx_1}{dt}$ $\frac{dx_2}{dt}$ $\frac{dx_3}{dt}$ $\frac{dx_4}{dt}$ est donc dans le plan P_u, il en est de même de la tangente à la courbe décrite par le point M, et comme elle est dans le plan tangent à la surface elle coïncide avec la tangente à la courbe u. Donc tous les points M que nous avons définis décrivent des courbes tangentes aux courbes u. Si par exemple, β_1, β_2, β_3 sont des polynomes de degré m en v, c'est-à-dire si les courbes u sont unicursales et de degré m, on aura m enveloppes. Pour $m = 2$, on retrouve les résultats de M. Blutel. (*Annales de l'École Normale*, mai-juin 1890. *Voir* aussi la thèse de M. Lelieuvre 1894 qui s'occupe du cas d'une courbe plane unicursale se déplaçant de telle sorte qu'elle soit divisée homographiquement par ses conjuguées.)

Une transformation par polaires réciproques change une surface Σ en une surface Σ et nous montre que le cône circonscrit à Σ roule sur des développables décrites par les génératrices de contact du cône avec les plans tangents qu'on peut lui mener par la tangente à la courbe que décrit le sommet du cône.

Définition d'une congruence Σ.

Dans les équations (A) traitons β_1, β_2, β_3 comme des constantes et désignons-les par a, b, c ; au lieu de

α_1, α_2, α_3 mettons α, β, γ, nous aurons les équations

$$(C) \qquad x_k = \begin{vmatrix} 0 & A_k & A'_k & A''_k \\ a & \alpha & \alpha' & \alpha'' \\ b & \beta & \beta' & \beta'' \\ c & \gamma & \gamma' & \gamma'' \end{vmatrix} \qquad (k = 1, 2, 3, 4).$$

Dans ces formules, a, b, c sont donc trois constantes arbitraires et A_1, A_2, A_3, A_4, α, β, γ des fonctions de u. Pour chaque valeur de u, les points x_k qui correspondent aux différentes valeurs a, b, c décrivent un plan P_u et les tangentes aux courbes décrites par ces points concourent en un point S

$$(D) \qquad X_k = \begin{vmatrix} A_k & A'_k & A''_k & A'''_k \\ \alpha & \alpha' & \alpha'' & \alpha''' \\ \beta & \beta' & \beta'' & \beta''' \\ \gamma & \gamma' & \gamma'' & \gamma''' \end{vmatrix}.$$

Si a, b, c restent fixes et que u varie, les formules (C) définissent une courbe v, on a donc une congruence de courbes v et les surfaces de cette congruence sont les surfaces Σ. Il est naturel de chercher quelle peut être la surface focale de la congruence Σ. Il est évident que si pour une valeur particulière de u le point S se trouve dans le plan P_u toutes les courbes de la congruence seront tangentes à ce plan qui formera une des nappes de la surface focale. La valeur de X_k est de la forme

$$X_k = \lambda_1 A_k + \lambda_2 A'_k + \lambda_3 A''_k - \Delta A'''_k,$$

où

$$\Delta = \begin{vmatrix} \alpha & \alpha' & \alpha'' \\ \beta & \beta' & \beta'' \\ \gamma & \gamma' & \gamma'' \end{vmatrix}.$$

J'écris que ce point est dans le plan P_u, c'est-à-dire

$$\begin{vmatrix} x_1 & x_2 & x_3 & x_4 \\ A_1 & A_2 & A_3 & A_4 \\ A'_1 & A'_2 & A'_3 & A'_4 \\ A''_1 & A''_2 & A''_3 & A''_4 \end{vmatrix} = 0.$$

Les coefficients de λ_1, λ_2, λ_3 sont nuls et il reste

$$\Delta \times \begin{vmatrix} A_1 & A_2 & A_3 & A_4 \\ A'_1 & A'_2 & A'_3 & A'_4 \\ A''_1 & A''_2 & A''_3 & A''_4 \\ A'''_1 & A'''_2 & A'''_3 & A'''_4 \end{vmatrix} = 0,$$

ce qui donne : 1° les plans P_u stationnaires c'est-à-dire osculateurs stationnaires de la courbe A_k; 2° les plans P_u pour lesquels $\Delta = 0$ qui correspondent aux valeurs de u pour lesquels un point décrivant la courbe plane $x = \alpha$, $y = \beta$, $z = \gamma$ serait un point d'inflexion. Je vais faire voir que pour ces valeurs de u qui rendent Δ nul, toutes les courbes v sont concourantes et concourent au point S correspondant. Il suffit de se reporter à l'identité (6) où l'on tiendra compte du changement de notations. Ainsi la surface focale se compose des points qui correspondent à Δ nul et des plans P_u stationnaires. D'ailleurs il n'existe pas d'autres points focaux, car si F est un point focal et si S n'est pas dans le plan P_u correspondant, le plan tangent en F à la surface de la congruence dépendra évidemment du mode d'assemblage des courbes v.

Cas d'homographie singulière.

Supposons qu'on donne à u une valeur fixe, les formules (C) font correspondre point par point le plan P_u et un plan Q. Dans le premier on a le point x_1, x_2,

x_3, x_4; dans le deuxième, le point de coordonnées a, b, c homogènes. Il faut s'assurer que ces formules (C) permettent de tirer a, b, c en fonction de trois des variables x_k. Désignons par

$$\begin{vmatrix} \alpha_1 & \alpha_2 & \alpha_3 \\ \beta_1 & \beta_2 & \beta_3 \\ \gamma_1 & \gamma_2 & \gamma_3 \end{vmatrix} \text{ l'adjoint de } \begin{vmatrix} \alpha & \alpha' & \alpha'' \\ \beta & \beta' & \beta'' \\ \gamma & \gamma' & \gamma'' \end{vmatrix},$$

les équations (C) s'écriront

$$\begin{aligned} x_k = &- a(A_k\alpha_1 + A'_k\alpha_2 + A''_k\alpha_3) \\ &- b(A_k\beta_1 + A'_k\beta_2 + A''_k\beta_3) \\ &- c(A_k\gamma_1 + A'_k\gamma_2 + A''_k\gamma_3), \end{aligned}$$

ce qui fait quatre équations. Pour qu'on puisse tirer a, b, c des trois premières, par exemple, il faut que

$$\begin{vmatrix} A_1\alpha_1 + A'_1\alpha_2 + A''_1\alpha_3 & A_1\beta_1 + A'_1\beta_2 + A''_1\beta_3 & A_1\gamma_1 + A'_1\gamma_2 + A''_1\gamma_3 \\ A_2\alpha_1 + A'_2\alpha_2 + A''_2\alpha_3 & A_2\beta_1 + A'_2\beta_2 + A''_2\beta_3 & A_2\gamma_1 + A'_2\gamma_2 + A''_2\gamma_3 \\ A_3\alpha_1 + A'_3\alpha_2 + A''_3\alpha_3 & A_3\beta_1 + A'_3\beta_2 + A''_3\beta_3 & A_3\gamma_1 + A'_3\gamma_2 + A''_3\gamma_3 \end{vmatrix} \neq 0$$

ou

$$\begin{vmatrix} A_1 & A'_1 & A''_1 \\ A_2 & A'_2 & A''_2 \\ A_3 & A'_3 & A''_3 \end{vmatrix} \times \begin{vmatrix} \alpha_1 & \alpha_2 & \alpha_3 \\ \beta_1 & \beta_2 & \beta_3 \\ \gamma_1 & \gamma_2 & \gamma_3 \end{vmatrix} = 0.$$

Si le second de ces déterminants est nul, son adjoint Δ l'est aussi et l'homographie est singulière. Pour cette valeur de u nous avons vu que les courbes v concouraient au point S correspondant. Si $\Delta \neq 0$, l'homographie ne sera singulière que si les quatre déterminants à trois lignes du Tableau

$$T : \begin{vmatrix} A_1 & A_2 & A_3 & A_4 \\ A'_1 & A'_2 & A'_3 & A'_4 \\ A''_1 & A''_2 & A''_3 & A''_4 \end{vmatrix}$$

sont nuls à la fois. Or ceci ne peut arriver que pour certaines valeurs particulières de u, car nous supposons évidemment que le point A_1, A_2, A_3, A_4 décrive une courbe gauche.

Conclusion. — Ayant choisi les fonctions A_k telles que le point A_k décrive une courbe gauche, et les fonctions α, β, γ telles qu'il n'existe pas entre elles une relation linéaire et homogène, les équations d'une surface Σ seront données par les formules (C), où a, b, c sont des fonctions arbitraires d'un paramètre v. Cela revient à choisir arbitrairement la courbe décrite par le point a, b, c dans le plan ou encore l'une des courbes u dans le plan P_u correspondant.

DEUXIÈME SOLUTION.

On arrive aux mêmes conclusions en modifiant très légèrement les formules données par M. Blutel pour le cas des coniques. Ces formules sont les suivantes :

$$x = \frac{P_1 v^2 + Q_1 v + R_1}{P\ v^2 + Q\ v + R},$$
$$y = \frac{P_2 v^2 + Q_2 v + R_2}{P\ v^2 + Q\ v + R},$$
$$z = \frac{P_3 v^2 + Q_3 v + R_3}{P\ v^2 + Q\ v + R}.$$

Les fonctions P, Q, R, P_1, ..., R_3, de la variable u étant déterminées par les équations

$$\frac{P'_1}{P'} = \frac{Q'_1}{Q'} = \frac{R'_1}{R'} = X,$$
$$\frac{P'_2}{P'} = \frac{Q'_2}{Q'} = \frac{R'_2}{R'} = Y,$$
$$\frac{P'_3}{P'} = \frac{Q'_3}{Q'} = \frac{R'_3}{R'} = Z.$$

De telle sorte qu'on peut se donner X, Y, Z sommet du cône circonscrit et P, Q, R, on aura alors P_1, ..., R_3 par neuf quadratures. Si je considère les trois courbes P, Q, R

$$\left\{\begin{aligned} x &= \frac{P_1}{P} \\ y &= \frac{P_2}{P} \\ z &= \frac{P_3}{P} \end{aligned}\right. \qquad \left\{\begin{aligned} x &= \frac{Q_1}{Q} \\ y &= \frac{Q_2}{Q} \\ z &= \frac{Q_3}{Q} \end{aligned}\right. \qquad \left\{\begin{aligned} x &= \frac{R_1}{R} \\ y &= \frac{R_2}{R} \\ z &= \frac{R_3}{R} \end{aligned}\right.$$

les tangentes aux points de ces trois courbes, qui correspondent à une même valeur de u, concourent au point X, Y, Z. La congruence Σ peut alors s'écrire

$$(C') \qquad \left\{\begin{aligned} x &= \frac{aP_1 + bQ_1 + cR_1}{aP + bQ + cR}, \\ y &= \frac{aP_2 + bQ_2 + cR_2}{aP + bQ + cR}, \\ z &= \frac{aP_3 + bQ_3 + cR_3}{aP + bQ + cR}. \end{aligned}\right.$$

Si dans ces formules je donne à u une valeur particulière, la tangente au point x, y, z va passer par X, Y, Z quelles que soient les valeurs des constantes a, b, c; en effet en désignant par D l'expression $aP + bQ + cR$, on a

$$\begin{aligned} D^2 \frac{dx}{du} &= D(aP' + bQ' + cR')X \\ &\quad - (aP_1 + bQ_1 + cR_1)(aP' + bQ' + cR'), \\ D^2 \frac{dx}{du} &= (aP' + bQ' + cR')(DX - Dx), \end{aligned}$$

d'où

$$\frac{X - x}{\dfrac{dx}{du}} = \frac{Y - y}{\dfrac{dy}{du}} = \frac{Z - z}{\dfrac{dz}{du}},$$

qui exprime la propriété indiquée. Les formules (C') sont équivalentes aux formules (C). On peut d'ailleurs les identifier. Posons par exemple

$$P_1 = \frac{\begin{vmatrix} A_1 & A'_1 & A''_1 \\ \beta & \beta' & \beta'' \\ \gamma & \gamma' & \gamma'' \end{vmatrix}}{\begin{vmatrix} \alpha & \alpha' & \alpha'' \\ \beta & \beta' & \beta'' \\ \gamma & \gamma' & \gamma'' \end{vmatrix}}, \qquad P = \frac{\begin{vmatrix} A_4 & A'_4 & A''_4 \\ \beta & \beta' & \beta'' \\ \gamma & \gamma' & \gamma'' \end{vmatrix}}{\begin{vmatrix} \alpha & \alpha' & \alpha'' \\ \beta & \beta' & \beta'' \\ \gamma & \gamma' & \gamma'' \end{vmatrix}}.$$

Nous aurons, en vertu d'une identité analogue à l'identité (6),

$$P'_1 = \begin{vmatrix} A_1 & A'_1 & A''_1 & A'''_1 \\ \alpha & \alpha' & \alpha'' & \alpha''' \\ \beta & \beta' & \beta'' & \beta''' \\ \gamma & \gamma' & \gamma'' & \gamma''' \end{vmatrix} \times (\gamma\beta' - \beta\gamma')$$

et

$$P' = \begin{vmatrix} A_4 & A'_4 & A''_4 & A'''_4 \\ \alpha & \alpha' & \alpha'' & \alpha''' \\ \beta & \beta' & \beta'' & \beta''' \\ \gamma & \gamma' & \gamma'' & \gamma''' \end{vmatrix} \times (\gamma\beta' - \beta\gamma').$$

On voit de suite quelles valeurs il faudrait prendre pour P_2, ... et l'on a bien

$$\frac{P'_1}{P'} = X, \qquad \dots \qquad \text{avec} \qquad X = \frac{X_1}{X_4},$$

X_1 et X_4 étant les valeurs de la première solution.

Détermination d'une congruence Σ quand on donne la courbe lieu des sommets S et la développable enveloppe des plans P_u avec la correspondance entre les sommets et les plans.

Voici la solution avec mes formules. Je me donne les fonctions A_k et, en outre, les trois fonctions F_1, F_2,

F_3 de la variables u telles que

$$\frac{X_1}{X_4} = F_1, \qquad \frac{X_2}{X_4} = F_2, \qquad \frac{X_3}{X_4} = F_3.$$

On trouve alors, pour déterminer la fonction α, l'équation différentielle du troisième ordre

$$\begin{vmatrix} \alpha & \alpha' & \alpha'' & \alpha''' \\ A_1 - F_1 A_4 & A'_1 - F_1 A'_4 & A''_1 - F_1 A''_4 & A'''_1 - F_1 A'''_4 \\ A_2 - F_2 A_4 & A'_2 - F_2 A'_4 & A''_2 - F_2 A''_4 & A'''_2 - F_2 A'''_4 \\ A_2 - F_3 A_4 & A'_3 - F_3 A'_4 & A''_3 - F_3 A''_4 & A'''_3 - F_3 A'''_4 \end{vmatrix} = 0;$$

β et γ vérifient la même équation. Je laisse au lecteur le soin de développer cette méthode; voici celle qu'on peut déduire des calculs de M. Blutel. Soit

$$U_x + V_y + W_z + 1 = 0$$

le plan P_u. On se donne U, V, W, X, Y, Z comme des fonctions de u. Il s'agit de déterminer P, Q, R, $P_1, \ldots, R_3$.

Le plan P_u contient le point $\frac{P_1}{P}, \frac{P_2}{P}, \frac{P_3}{P}$; donc

$$P + UP_1 + VP_2 + WP_3 = 0.$$

Dérivons trois fois en u et posons pour abréger

$$\begin{aligned} H &= U\ X + V\ Y + W\ Z, \\ K &= U'X + V'Y + W'Z, \\ L &= U''X + V''Y + W''Z. \end{aligned}$$

Nous aurons

$$\begin{gathered} UP_1 + VP_2 + WP_3 + P = 0, \\ U'P_1 + V'P_2 + W'P_3 + P' + P'H = 0, \\ U''P_1 + V''P_2 + W''P_3 + P'K + P'' + P''H + P'H' = 0, \\ U'''P_1 + V'''P_3 + W'''P_3 + P'L \\ \qquad P''' + P''K + P''' + H + 2P''H' + P'H'' = 0 \end{gathered}$$

L'élimination de P_1, P_2, P_3 entre ces quatre équations donne, pour déterminer P, une équation différentielle du troisième ordre; P une fois connu, les équations précédentes donnent P_1, P_2, P_3. On a des calculs identiques pour Q_1, Q_2, Q_3, R_1, R_2, R_3. L'équation différentielle qui est linéaire et homogène par rapport à la fonction inconnue et à ses trois dérivées est d'ailleurs la même dans les trois cas. Soient donc P, Q, R trois intégrales de cette équation, les valeurs les plus générales de P, Q, R seront

$$\begin{gathered} a_1 P + b_1 Q + c_1 R, \\ a_2 P + b_2 Q + c_2 R, \\ a_3 P + b_3 Q + c_3 R; \end{gathered}$$

d'où, pour P_1,

$$a_1 P_1 + b_1 Q_1 + c_1 R_1; \qquad \ldots,$$

d'où, en remplaçant dans les formules (C'),

$$\begin{aligned} x &= \frac{a(a_1P_1+b_1Q_1+c_1R_1)+b(a_2P_1+b_2Q_1+c_2R_1)+c(a_3P_1+b_3Q_1+c_3R_1)}{a(a_1P\ +b_1Q_1+c_1R\ )+b(a_2P\ +b_2Q\ +c_2R\ )+c(a_3P\ +b_3Q\ +c_3Q\ )}, \\ y &= \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots, \\ z &= \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots, \end{aligned}$$

ou, avec un changement de notations,

$$\begin{aligned} x &= \frac{AP_1 + BQ_1 + CR_1}{AP\ + BQ\ + CR}, \\ y &= \frac{AP_2 + BQ_2 + CR_2}{AP\ + BQ\ + CR}, \\ z &= \frac{AP_3 + BQ_3 + CR_3}{AP\ + BQ\ + CR}, \end{aligned}$$

avec trois constantes A, B, C ou plutôt deux constantes, $\frac{A}{C}$, $\frac{B}{C}$ par exemple. On a donc une seule congruence Σ.

Conclusion. — Il résulte de là que le problème que nous nous sommes proposé conduit exactement aux mêmes calculs que le problème analogue dans le cas des coniques. Toute la difficulté consistera à résoudre l'équation différentielle du troisième ordre.

Remarque. — Dans un article précédent j'avais considéré les surfaces Σ dans le cas où la courbe plane était indéformable, il fallait donc que cette courbe admette un groupe de transformations homographiques; on sait qu'il en est bien ainsi pour les courbes triangulaires que j'ai trouvées.

Surfaces de deuxième espèce.

Je supposerai que le plan P_u roule sur un cône ayant son sommet à l'origine.

On trouve facilement, pour la congruence Σ, les équations

$$(\mathrm{E}) \qquad x_k = \frac{\begin{vmatrix} 0 & A_k & A'_k \\ a & \alpha & \alpha' \\ b & \beta & \beta' \end{vmatrix}}{\begin{vmatrix} 1 & A_4 & A'_4 \\ a & \alpha & \alpha' \\ b & \beta & \beta' \end{vmatrix}} \qquad (k = 1, 2, 3).$$

Le sommet du cône a pour coordonnées

$$X_k = \frac{\begin{vmatrix} A_k & A'_k & A''_k \\ \alpha & \alpha' & \alpha'' \\ \beta & \beta' & \beta'' \end{vmatrix}}{\begin{vmatrix} A_4 & A'_4 & A''_4 \\ \alpha & \alpha' & \alpha'' \\ \beta & \beta' & \beta'' \end{vmatrix}}.$$

Les plans P_u roulent sur un cône ayant pour sommet l'origine des coordonnées et contenant la courbe

$$x_k = A_k \qquad (k = 1, 2, 3).$$

Avec la méthode de M. Blutel, j'adopterai les formules

$$(\mathrm{E}') \qquad \left\{ \begin{aligned} x &= \frac{aP_1 + bQ_1}{aP + bQ + 1}, \\ y &= \frac{aP_2 + bQ_2}{aP + bQ + 1}, \\ z &= \frac{aP_3 + bQ_3}{aP + bQ + 1}, \end{aligned} \right.$$

avec

$$\frac{P'_1}{P'} = \frac{Q'_1}{Q'} = X,$$

$$\frac{P'_2}{P'} = \frac{Q'_2}{Q'} = Y,$$

$$\frac{P'_3}{P'} = \frac{Q'_3}{Q'} = Z.$$

On se donne alors X, Y, Z sommet du cône puis P, Q; on a alors P_1, P_2, P_3, Q_1, Q_2, Q_3 par six quadratures. Le plan P_u passe par l'origine et les deux points de coordonnées P_1, P_2, P_3 et Q_1, Q_2, Q_3.

Les deux points $\frac{P_1}{P}$, $\frac{P_2}{P}$, $\frac{P_3}{P}$ et $\frac{Q_1}{Q}$, $\frac{Q_2}{Q}$, $\frac{O_3}{Q}$ décrivent deux courbes dont les tangentes se coupent au point X, Y, Z.

Avec ces notations on peut reprendre les calculs faits plus haut pour trouver la congruence Σ quand on se donne la courbe lieu des sommets des cônes et la développable enveloppe des plans P_u avec la correspondance entre les sommets et les plans, c'est-à-dire X, Y, Z, U, V, W; le plan P_u ayant pour équation

$$U_x + V_y + W_z = 0.$$

On trouve alors, pour calculer P et Q, une équation du second ordre linéaire et homogène par rapport à la fonction inconnue, et ses deux premières dérivées se ramenant par suite à une équation de Riccati.

Exemple. — On trouve un exemple intéressant en partant des surfaces Σ de révolution. Si le plan P_u roule sur un cône de révolution, S étant lié au plan, on est ramené à une équation différentielle du type suivant (Oz est l'axe du cône) qu'on est certain de pouvoir intégrer

$$y'' - \frac{2\alpha(x-a)}{1+x^2}y' + \frac{2\beta(x^2-2ax+b)}{(1+x^2)^2}y = 0,$$

où α, β, a sont des constantes et y la fonction inconnue de x. On suppose toutefois α, β liées par la relation

$$\alpha^2+\alpha = 2\beta$$

ou

$$\beta = \frac{\alpha(\alpha+1)}{2}.$$

On peut ramener cette équation à la forme

$$\frac{y''}{y} = \frac{K}{(1+x^2)^2},$$

qui s'intègre facilement.

Surfaces de première espèce.

Généralisation des surfaces de translation.

Ces surfaces ont des équations de la forme

$$x_k = A_k + B_k \qquad (k = 1, 2, 3, 4),$$

où les A_k sont des fonctions de u et les B_k de v. Le long des courbes u (ou v) il existe un cône circonscrit à la surface, il resterait à exprimer que les courbes u sont planes. Pour le moment je garderai ces surfaces dans toute leur généralité. On a là une généralisation des surfaces de translation. Les surfaces transformées par polaires réciproques ont été étudiées par M. Darboux au Tome I de la *Théorie des Surfaces*. Ce sont les surfaces pour lesquelles il existe deux familles conjuguées formées exclusivement de courbes planes. Ici les surfaces que j'étudie sont caractérisées par ce fait qu'il existe un cône circonscrit le long de toutes les courbes du système conjugué u, v. Appelons Σ_1 ces nouvelles surfaces, nous allons en donner une définition géométrique.

Définition des surfaces Σ_1. — Donnons-nous deux courbes, l'une A décrite par le point M′

$$x' = A_1, \qquad y' = A_2, \qquad z' = A_3,$$

A_1, A_2, A_3 étant des fonctions quelconques de u. L'autre courbe B sera décrite par le point M″

$$x'' = B_1, \qquad y'' = B_2, \qquad z'' = B_3, \qquad \text{fonctions de U.}$$

Donnons-nous encore deux autres fonctions A_4 et B_4 l'une de u l'autre de v et sur la droite M′M″ marquons le point M déterminé par

$$\frac{\overline{\mathrm{MM'}}}{\overline{\mathrm{MM''}}} = -\frac{A_4}{B_4}.$$

Les coordonnées du point M seront

$$(\Sigma_1) \qquad \left\{ \begin{aligned} x &= \frac{A_1 B_4 + A_4 B_1}{A_4 + B_4}, \\ y &= \frac{A_2 B_4 + A_4 B_2}{A_4 + B_4}, \\ z &= \frac{A_3 B_4 + A_4 B_3}{A_4 + B_4}. \end{aligned} \right.$$

Comme on peut écrire

$$x = \frac{\frac{A_1}{A_4} + \frac{B_1}{B_4}}{\frac{1}{A_4} + \frac{1}{B_4}},$$

on voit qu'on a bien les mêmes surfaces que celles définies plus haut.

Les courbes u se correspondent point par point et cette correspondance est établie au moyen des courbes conjuguées v. Dans les surfaces de translation les droites joignant les points correspondants de deux courbes u sont égales, parallèles et de même sens; retenons cette propriété que les droites joignant les points correspondants des courbes u (ou v) forment un cylindre. Comme généralisation je vais démontrer le théorème suivant :

Théorème. — *Dans les surfaces* Σ_1 *les droites qui joignent les points correspondants de deux courbes* u (*ou* v) *quelconques forment un cône.*

Donnons à u deux valeurs fixes et soient a et a_1 les valeurs correspondantes de la fonction A_4. Soient M' et M'_1 les positions fixes correspondantes du point M'; enfin M'' correspond à une valeur de v qu'on fera varier. On a ainsi deux positions de M : M et M_1 déterminées par

$$\frac{MM'}{MM''} = -\frac{a}{B_4}, \qquad \frac{M_1M'_1}{M_1M''} = -\frac{a_1}{B_4}.$$

Or

$$\frac{MM'}{MM''}\,\frac{M_1M''}{M_1M'_1}\,\frac{PM'_1}{PM'} = +1.$$

Donc

$$\frac{PM'}{PM'_1} = \frac{a}{a_1},$$

qui prouve que le point P est fixe.

Comme on peut écrire

$$x = \frac{\dfrac{A_1}{A_4} + \dfrac{B_1}{B_4}}{\dfrac{1}{A_4} + \dfrac{1}{B_4}},$$

on voit qu'on a bien les mêmes surfaces que celles définies plus haut.

Les courbes u se correspondent point par point et cette correspondance est établie au moyen des courbes conjuguées v. Dans les surfaces de translation les droites joignant les points correspondants de deux courbes u sont égales, parallèles et de même sens; retenons cette propriété que les droites joignant les points correspondants des courbes u (ou v) forment un cylindre. Comme généralisation je vais démontrer le théorème suivant :

Théorème. — *Dans les surfaces Σ_1 les droites qui joignent les points correspondants de deux courbes u (ou v) quelconques forment un cône.*

Donnons à u deux valeurs fixes et soient a et a_1 les valeurs correspondantes de la fonction A_4. Soient M' et M'_1 les positions fixes correspondantes du point M'; enfin M'' correspond à une valeur de v qu'on fera varier. On a ainsi deux positions de M : M et M_1 déterminées par

$$\frac{MM'}{MM''} = -\frac{a}{B_4}, \qquad \frac{M_1M'_1}{M_1M''} = -\frac{a_1}{B_4}.$$

Or

$$\frac{MM'}{MM''}\,\frac{M_1M''}{M_1M'_1}\,\frac{PM'_1}{PM'} = +1.$$

Donc

$$\frac{PM'}{PM'_1} = \frac{a}{a_1},$$

qui prouve que le point P est fixe.

D'autre part

$$\frac{MM'}{a} = \frac{MM''}{-B_4} = \frac{M''M'}{a + B_4},$$

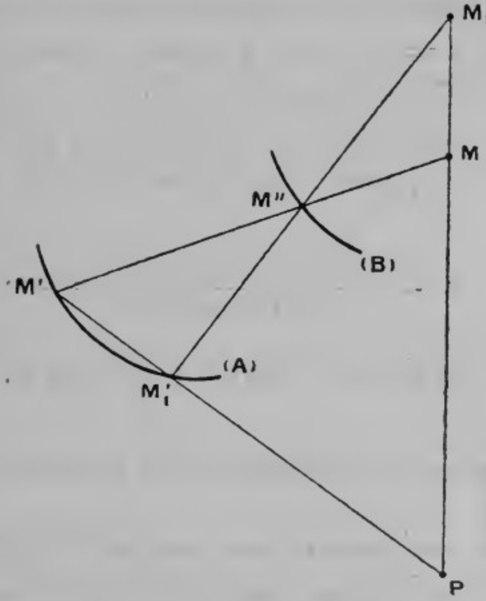
$$\frac{M_1M'_1}{a_1} = \frac{M_1M''}{-B_4} = \frac{M''M'_1}{a_1 + B_4},$$

$$\frac{PM}{PM_1}\,\frac{M'_1M_1}{M_1M''}\,\frac{M'M''}{M'M} = +1.$$

Donc

$$\frac{PM}{PM_1} = \frac{a(a_1 + B_4)}{a_1(a + B_4)}$$

montre que le rapport $\frac{PM}{PM_1}$ varie avec v et peut être une fonction arbitraire de cette variable.



Corollaire. — Il en résulte facilement que :

1° Trois courbes u sont situées deux à deux sur trois cônes et que les sommets des cônes sont en ligne droite ;

2° Quatre courbes u sont deux à deux sur six cônes et les six sommets forment les six sommets d'un quadrilatère complet.

Surface lieu du sommet des cônes.

Sur la corde $M'M'_1$ la position du point P est définie par l'égalité

$$\frac{PM'}{PM'_1} = \frac{A_4(u)}{A_4(u_1)}$$

si M' et M'_1 correspondent respectivement aux valeurs u et u_1. Cette surface (P) est donc définie d'une façon tout à fait analogue à la surface Σ_1, avec cette différence qu'on se sert d'une seule courbe au lieu de deux et d'une seule fonction A_4. Les courbes u et u_1 tracent sur cette surface (P) un système conjugué symétrique et la courbe $u = u_1$ est le lieu des sommets des cônes circonscrits à Σ_1 le long des courbes u de cette surface. En tous les points de cette courbe $u = u_1$, les courbes u et u_1 sont tangentes. Les équations de la surface (P) sont

$$\text{(P)} \qquad x = \frac{A_1(u)A_4(u_1) - A_4(u)A_1(u_1)}{A_4(u_1) - A_4(u)};$$

pour y et z on change l'indice 1 en 2 ou 3.

Cas particulier des surfaces de première espèce.

Je reviens maintenant aux surfaces Σ de première espèce, c'est-à-dire pour lesquelles le plan des courbes u passe par une droite fixe Oz, par exemple :

$$x = \frac{A_1 + B_1}{A_4 + B_4}, \qquad y = \frac{A_2 + B_2}{A_4 + B_4}, \qquad z = \frac{A_3 + B_3}{A_4 + B_4}.$$

Mais pour que $\frac{y}{x}$ dépende de u et pas de v, on montre facilement qu'il faut que B_1 et B_2 soient constants et alors on peut les supposer nuls. Un simple changement de notations conduit alors aux formules

$$x = \frac{A_1 B_4}{A_4 + B_4},$$

$$y = \frac{A_2 B_4}{A_4 + B_4}.$$

$$z = \frac{A_3 B_4 + A_4 B_3}{A_4 + B_4}$$

qui sont les formules (Σ_1) où l'on fait

$$B_1 = 0, \qquad B_2 = 0.$$

Il suffit donc de supposer que la courbe (B) décrite par le point M″ soit une droite pour avoir les nouvelles surfaces. Donc on peut énoncer le théorème suivant :

Théorème. — *Des surfaces* Σ *de première espèce sont telles que deux courbes planes u se correspondent par homologie. Il en résulte que, si l'une de ces courbes coupe l'axe* O*z en un certain nombre de points, les autres courbes u passent par les mêmes points.*

Remarque. — Pour obtenir les surfaces Σ_1 au lieu de poser

$$\frac{MM'}{MM''} = -\frac{A_4}{B_4},$$

on pourrait prendre

$$\frac{MM'}{MM''} = \frac{A_4 + K}{B_4 + K},$$

k étant une constante. Chaque valeur de *k* donne une surface, on a ainsi des surfaces qui se correspondent point par point avec plans tangents parallèles. On trouve ainsi un cas particulier intéressant du théorème suivant, énoncé par M. Darboux au Tome II de la *Théorie des Surfaces :*

Si l'on mène à deux surfaces S *et* S_1 *des plans tangents parallèles, la droite qui joint les points de contact engendre une congruence dont les développables interceptent sur* S *et* S_1 *un réseau conjugué.*

[K¹14f]

SUR UN HEXAÈDRE PARTICULIER;

Par M. R. BRICARD.

1. Il existe dans le plan deux espèces de quadrilatères ayant leurs côtés opposés égaux deux à deux : le *parallélogramme* et le *contre-parallélogramme* (figure formée par les côtés non parallèles et les diagonales d'un trapèze isoscèle).

Dans l'espace, il existe un hexaèdre, le *parallélépipède*, dont toutes les faces sont des parallélogrammes. On peut rechercher, par analogie, s'il existe un hexaèdre dont toutes les faces sont des contre-parallélogrammes. Nous allons voir que la réponse est affirmative. Donnons, dès maintenant, le nom de *contre-parallélépipède* à l'hexaèdre satisfaisant.

2. Soit $abcda'b'c'd'$ le schéma d'un contre-parallélépipède (*fig.* 1). Les lettres ont été tellement disposées que deux quelconques des sommets a, b, c, d soient les sommets opposés d'une même face de l'hexaèdre; a', b', c', d' sont les sommets de l'hexaèdre respectivement opposés aux premiers.

Par hypothèse, le quadrilatère $a'cb'd$ par exemple est un contre-parallélogramme; ses diagonales $a'b'$ et cd sont donc parallèles. De même, $a'c'$ est parallèle à db, et $a'd'$ est parallèle à bc. Autrement dit, $a'b'$, $a'c'$

[$K^1$14f]

SUR UN HEXAÈDRE PARTICULIER;

Par M. R. BRICARD.

1. Il existe dans le plan deux espèces de quadrilatéres ayant leurs côtés opposés égaux deux à deux : le *parallélogramme* et le *contre-parallélogramme* (figure formée par les côtés non parallèles et les diagonales d'un trapèze isoscèle).

Dans l'espace, il existe un hexaèdre, le *parallélépipède*, dont toutes les faces sont des parallélogrammes. On peut rechercher, par analogie, s'il existe un hexaèdre dont toutes les faces sont des contre-parallélogrammes. Nous allons voir que la réponse est affirmative. Donnons, dès maintenant, le nom de *contre-parallélépipède* à l'hexaèdre satisfaisant.

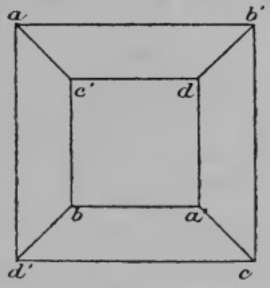
2. Soit $abcda'b'c'd'$ le schéma d'un contre-parallélépipède (*fig.* 1). Les lettres ont été tellement disposées que deux quelconques des sommets a, b, c, d soient les sommets opposés d'une même face de l'hexaèdre; a', b', c', d' sont les sommets de l'hexaèdre respectivement opposés aux premiers.

Par hypothèse, le quadrilatère $a'cb'd$ par exemple est un contre-parallélogramme; ses diagonales $a'b'$ et cd sont donc parallèles. De même, $a'c'$ est parallèle à db, et $a'd'$ est parallèle à bc. Autrement dit, $a'b'$, $a'c'$

et $a'd'$ sont respectivement parallèles aux côtés du triangle bcd; ces trois droites sont donc dans un même plan, d'ailleurs parallèle au plan du triangle. On verra, par un raisonnement semblable, que ce dernier plan contient aussi le point a.

Ainsi, les deux quadrangles $abcd$ et $a'b'c'd'$ appartiennent respectivement à deux plans parallèles P et P'.

Fig. 1.

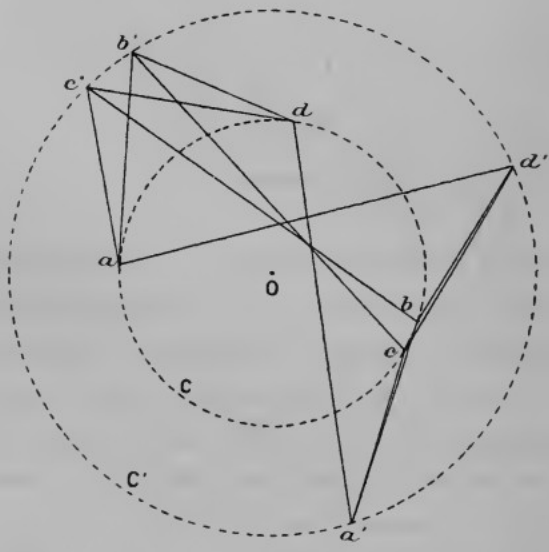


En outre, les côtés du premier quadrangle sont parallèles à ceux du second, deux côtés parallèles étant désignés par des lettres différentes (par exemple ab et $c'd'$). On voit qu'à trois côtés concourants de l'un des quadrangles correspondent dans l'autre trois côtés formant un triangle. On reconnaît là les *quadrangles réciproques* de la statique graphique.

Pour aller plus loin, faisons une projection orthogonale de l'hexaèdre sur le plan P. Le contre-parallélogramme $a'db'c$ restera visiblement tel en projection : il en résulte que les médiatrices des segments $a'b'$ et cd (c'est-à-dire les perpendiculaires élevées aux milieux de ces segments) sont confondues. De même les médiatrices des segments $a'c'$ et db, et celles des segments $a'd'$ et bc. Mais les médiatrices des segments cd, db, bc concourent en un point O, centre du cercle circonscrit au triangle bcd. Il résulte immédiatement de là que les quatre points a', b', c', d' appartiennent à un cercle ayant le même centre O. On verra aussi que le point a appartient au premier cercle contenant les points b, c, d. En résumé les deux quadrangles $abcd$ et $a'b'c'd'$ sont, en projection sur le plan P, inscrits à deux cercles concentriques.

Il est facile d'achever. Soient α, β, ..., γ', δ' les angles que font les rayons Oa, Ob, ..., Oc', Od' avec un axe quelconque Ox. Pour exprimer que le quadrilatère $a'cb'd$ (*fig.* 2) est un contre-parallélogramme, il suffit évidemment d'écrire que les deux angles $\widehat{a'Ob'}$ et $\widehat{cOd}$ ont les mêmes bissectrices, ce qui donne

Fig. 2.



$$\alpha' + \beta' = \gamma + \delta.$$

On aura de même

$$\alpha' + \gamma' = \beta + \delta,$$
$$\alpha' + \delta' = \beta + \gamma,$$
$$\beta' + \gamma' = \alpha + \delta,$$
$$\beta' + \delta' = \alpha + \gamma,$$
$$\gamma' + \delta' = \alpha + \beta.$$

On reconnaît tout de suite que ces six équations sont compatibles, *et cela établit définitivement l'existence du contre-parallélépipède.* En résolvant le système par rapport à α', β', γ', δ', il vient

$$\alpha' = \frac{-\alpha+\beta+\gamma+\delta}{2},$$

$$\beta' = \frac{\alpha-\beta+\gamma+\delta}{2},$$

$$\gamma' = \frac{\alpha+\beta-\gamma+\delta}{2},$$

$$\delta' = \frac{\alpha+\beta+\gamma-\delta}{2}.$$

On peut donc se donner arbitrairement les points a, b, c, d sur le cercle C. Les positions des points a', b', c', d' sur le cercle C′ en résultent. Pratiquement, il vaut mieux se donner trois points sur le cercle C et un point sur le cercle C′, par exemple les points a, b, c et d'. On obtient les autres points en utilisant la réciprocité des deux quadrangles. On aboutit ainsi à la construction suivante :

Tracer deux cercles concentriques C *et* C′ ; *marquer arbitrairement les points* a, b, c *sur le premier et* d' *sur le second. Construire successivement les points* c', a', d *et* b', *appartenant au cercle* C′ *ou au cercle* C *suivant qu'ils sont désignés par des lettres accentuées ou non, en menant* $d'c'$, *parallèle à* ba ; $d'a'$, *parallèle à* bc ; bd, *parallèle à* $a'c'$; $c'b'$, *parallèle à* ad.

Les points a, b, c, d *et ceux qu'on obtient en donnant au quadrangle* $a'b'c'd'$ *une translation quelconque perpendiculaire au plan de la figure sont les sommets d'un contre-parallélépipède.*

On reconnaît tout de suite que ces six équations sont compatibles, *et cela établit définitivement l'existence du contre-parallélépipède*. En résolvant le système par rapport à α', β', γ', δ', il vient

$$\alpha' = \frac{-\alpha+\beta+\gamma+\delta}{2},$$
$$\beta' = \frac{\alpha-\beta+\gamma+\delta}{2},$$
$$\gamma' = \frac{\alpha+\beta-\gamma+\delta}{2},$$
$$\delta' = \frac{\alpha+\beta+\gamma-\delta}{2}.$$

On peut donc se donner arbitrairement les points a, b, c, d sur le cercle C. Les positions des points a', b', c', d' sur le cercle C' en résultent. Pratiquement, il vaut mieux se donner trois points sur le cercle C et un point sur le cercle C', par exemple les points a, b, c et d'. On obtient les autres points en utilisant la réciprocité des deux quadrangles. On aboutit ainsi à la construction suivante :

Les points a, b, c, d *et ceux qu'on obtient en donnant au quadrangle* $a'b'c'd'$ *une translation quelconque perpendiculaire au plan de la figure sont les sommets d'un contre-parallélépipède.*

3. Le contre-parallélépipède jouit de propriétés qui résultent immédiatement de sa construction. Tout d'abord, il est évident qu'il est inscrit à une sphère. On voit tout aussi facilement que les douze arêtes du polyèdre sont réparties quatre par quatre sur trois hyperboloïdes de révolution autour de l'axe commun des cercles C et C', savoir :

H_1, contenant les arêtes ab', ba', cd', dc' ;
H_2, contenant les arêtes ac', ca', bd', db' ;
H_3, contenant les arêtes ad', da', bc', cb'.

Il existe d'autres hyperboloïdes attachés au contre-parallélépipède. Considérons en effet les deux systèmes de quatre droites

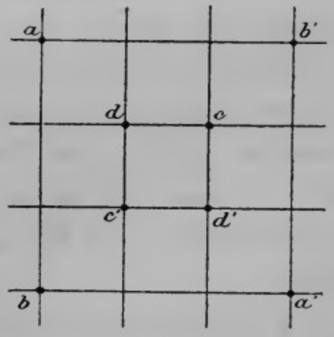
$$ab, \quad a'b', \quad cd', \quad dc'$$

et

$$ab', \quad ba', \quad cd, \quad c'd';$$

on se rend compte que chaque droite de l'un des systèmes rencontre chaque droite de l'autre système (à distance finie ou infinie). Ces huit droites sont donc à

Fig. 3.



un hyperboloïde H'_1 où elles se répartissent en deux groupes de génératrices de l'un et de l'autre système, comme le montre le schéma de la figure 3. La configuration des huit sommets forme donc ce que M. Fontené appelle un *octuple gauche complet*.

L'hyperboloïde H'_1 touche les deux plans P et P′, puisqu'il les coupe respectivement suivant les génératrices ab et cd, $a'b'$ et $c'd'$. Ces deux plans étant parallèles, le centre de l'hyperboloïde se trouve sur le plan parallèle et équidistant P″.

Il existe deux hyperboloïdes analogues :

$$H'_2, \text{ contenant les droites } \left\{ \begin{array}{llll} ac, & a'c', & bd', & db'. \\ ac', & ca', & bd, & b'd', \end{array} \right.$$

et

$$H'_3, \text{ contenant les droites } \left\{ \begin{array}{llll} ad, & a'd', & bc', & cb', \\ ad', & da', & bc, & b'c', \end{array} \right.$$

Ils ont aussi leur centre sur le plan P″.

Enfin une propriété intéressante du contre-parallélépipède est relative à la possibilité de sa déformation avec conservation des longueurs des arêtes. En effet, le polyèdre le plus général de cette nature dépend de six paramètres de grandeur, à savoir les rayons des cercles C et C′, les longueurs des segments ab, ac, ad', et la valeur de la translation finale qui sert à le définir. D'autre part, ses douze arêtes sont égales quatre par quatre, et la connaissance de leurs longueurs se traduit par trois relations seulement entre les six paramètres. On voit donc *qu'il existe une triple infinité de contre-parallélépipèdes ayant des arêtes de longueurs données*.

Il est curieux de constater que le contre-parallélépipède se comporte, au point de la déformabilité, exactement comme le parallélépipède.

Chapter 7. The Physical Point of View in the Theory of Surfaces

We start from the idea that a surface should play a double role in physics. First, it plays the obvious role of separator, specifically for separating the matter from space or of the space from matter, for these are altogether two different situations. This statement cannot be made understandable without the second role of the surface which is closer to the regular mathematical role: that of *locus of an ensemble of positions* in the geometrical acceptance. It pays, however, to notice that it is in this instance that the surface allows the mathematical description and the consequent physical understanding of that property of the material points of 'penetrating without merging', to use the phrasing of Erwin Madelung. In order to get a better grip of this idea, some introductory observations seem to be in order here.

A Few Mathematical Prerequisites

It seems to us obvious that a physical theory of surfaces cannot be developed but by the idea of embedding. As a matter of fact, the embedding is an interpretation and, forcing a little the idea, the essential point of the Darwin's definition of interpretation is the existence of an ensemble of positions giving the possibility of interpretation of the surface as a geometrical locus. Here a position can be taken geometrically as a point and physically as a material particle in the sense of Hertz. In this last instance, the material particle is to us a little more than it was to Hertz himself, in the sense that we added to it the feature of *indicator of a point in space*, by a process of application of a field to a position, being it in space or in matter in a sense which will be explained here shortly. For instance, in keeping with the classical physics, one can imagine the point of application of a force or of a resultant of many forces, according to the third principle of classical dynamics, but this is quite a particular example.

The mathematical method itself, for carying out the task of embedding a surface, and therefore the task of interpretation in general, is based on an almost trivial statement that emerged apparently largely unnoticed, or if noticed, it has not been properly used for physical purposes. In order to make it obvious, we reproduce here two of the Élie Cartan's algebraical theorems which form the ground of his approach of differential geometry by *moving frames* [for a clear description of the idea from the point of view we adopt here, see (Spivak 1999), Volume II, Chapter 7]. These theorems are borrowed directly from one of Cartan's courses, published via the Russian geometrical school of S. P. Finikov [(Cartan, 2001); pp. 16 17, Theorems 7 & 9]. We just appropriate them here under the name of *Cartan Lemmas 1 and 2*, only in order to be suitably used in making our point as explicit as possible:

Lemma 1. Suppose that $s^1, s^2, ..., s^p$ is a set of linearly independent 1-forms. Then we have

$$s^\alpha \wedge \phi_\alpha = 0 \quad \leftrightarrow \quad \phi_\alpha = a_{\alpha\beta} s^\beta \quad , \quad a_{\alpha\beta} = a_{\beta\alpha}$$

where $\phi_1, \phi_2, ...\phi_p$ is another set of linearly independent 1-forms, and summation over repeated indices is understood.

Lemma 2. Suppose the basis differential elements $du^1, du^2, ..., du^n$ are connected by a system of equations

$$\omega^1 = 0, \quad \omega^2 = 0, ..., \ \omega^p = 0$$

where ω^α, $\alpha = 1, 2, ..., p$ are linearly independent 1-forms. Then the 2-form 'f' *vanishes as a consequence of this system* if, and only if, 'f' can be written as

$$f = \omega^\alpha \wedge \phi_\alpha$$

where, again, summation over α is understood, and ϕ_α are p *conveniently chosen* 1-forms.

The first one of these theorems is, by and large, known as *Cartan's Lemma* proper in the specialty literature, while the second one carries no specific name. What seems to be essential in these lemmas, and is always stressed in many old treatises, but apparently forgotten lately perhaps due to exclusive mathematical applications − is the fact that the symmetric matrix **a** from Lemma 1, as well as the 1-forms ϕ_α from Lemma 2, are *things external to the geometrical problem*, things through which the physics can therefore be introduced. In concentrating on the local description at a point of a surface, without being interested of the global aspects of that surface, as it is almost always the case in physics, this observation is essential. In this respect another convention referring to our use of indices is again in order: insofar as the space contemplated as environment in the embedding problem necessary to physical interpretation is here the usual, possibly Euclidean, three-dimensional space of our intuition, we reserve the Latin indices exclusively for this case. The Greek indices are used for any other dimension, as in the case above, but especially for dimension reproduce here two of the Élie Cartan's algebraical theorems which form the ground of his approach of differential geometry by *moving frames* [for a clear description of the idea from the point of view we adopt here, see (Spivak 1999), Volume II, Chapter 7]. These theorems are borrowed directly from one of Cartan's courses, published via the Russian geometrical school of S. P. Finikov [(Cartan, 2001); pp. 16 17, Theorems 7 & 9]. We just appropriate them here under the name of *Cartan Lemmas 1 and 2*, only in order to be suitably used in making our point as explicit as possible:

Lemma 1. Suppose that $s^1, s^2, ..., s^p$ is a set of linearly independent 1-forms. Then we have

$$s^\alpha \wedge \phi_\alpha = 0 \quad \leftrightarrow \quad \phi_\alpha = a_{\alpha\beta} s^\beta \quad , \quad a_{\alpha\beta} = a_{\beta\alpha}$$

where $\phi_1, \phi_2, ...\phi_p$ is another set of linearly independent 1-forms, and summation over repeated indices is understood.

Lemma 2. Suppose the basis differential elements $du^1, du^2, ..., du^n$ are connected by a system of equations

$$\omega^1 = 0, \quad \omega^2 = 0, ..., \ \omega^p = 0$$

where ω^α, $\alpha = 1, 2, ..., p$ are linearly independent 1-forms. Then the 2-form 'f' *vanishes as a consequence of this system* if, and only if, 'f' can be written as

$$f = \omega^\alpha \wedge \phi_\alpha$$

where, again, summation over α is understood, and ϕ_α are p *conveniently chosen* 1-forms.

The first one of these theorems is, by and large, known as *Cartan's Lemma* proper in the specialty literature, while the second one carries no specific name. What seems to be essential in these lemmas, and is always stressed in many old treatises, but apparently forgotten lately perhaps due to exclusive mathematical applications − is the fact that the symmetric matrix **a** from Lemma 1, as well as the 1-forms ϕ_α from Lemma 2, are *things external to the geometrical problem*, things through which the physics can therefore be introduced. In concentrating on the local description at a point of a surface, without being interested of the global aspects of that surface, as it is almost always the case in physics, this observation is essential. In this respect another convention referring to our use of indices is again in order: insofar as the space contemplated as environment in the embedding problem necessary to physical interpretation is here the usual, possibly Euclidean, three-dimensional space of our intuition, we reserve the Latin indices exclusively for this case. The Greek indices are used for any other dimension, as in the case above, but especially for dimension i.e. properties representative to matter as well as properties representative to space. In other words, here, on this surface, the matter meets the space, and physics needs to describe this 'collision of the two worlds', so to speak. In an electromagnetic structure, the space is simply represented by a 2-form, 'b' say, while the matter is represented by a 2-form, 'd' say. These symbols suggest electromagnetism in the sense of David van Dantzig, as representative for the purely electromagnetic structure of matter (van Dantzig, 1934). To wit, these exterior differential 2-forms can indeed be appropriated here as two forms denoted above ω^ν for a general formulation of theory:

$$\omega^1 \equiv b = b_{ij} dx^i \wedge dx^j; \quad \omega^2 \equiv d = d_{ij} dx^i \wedge dx^j.$$

They correspond to *magnetic induction* and respectively *electric induction*, from the classical theory of electricity and associated magnetism. An explanation is in order: if the surface delimiting matter can be globally defined, as in the case of Dirac's electron for instance, these two exterior forms satisfy the integral equations:

$$\oiint_{Surface} b_{ij} dx^i \wedge dx^j = 0;$$

$$\oiint_{Surface} d_{ij} dx^i \wedge dx^j = \iiint_{Volume} \rho_{ijk}\, dV^{ijk}$$

which justify their names, insofar as the magnetic field is source-free while the electric field has the electirc charge as its source. Here ρ is the third order tensor of the *electric density of matter*, while $d\mathbf{V}$ is the oriented volume 3-form in the space occupied by matter. These relations can be used to justify our choices for describing the matter and space in their common limit.

Indeed, in spite of the global aspect of the problem, as the previous integral equations seem to suggest, the physical definition of the two fields involved here *is always local*, at least experimentally. To wit, we have the infinitesimal *voids* in the magnetic matter for defining 'b', or the *dipoles* in the electric matter for defining 'd'. This means that the tensor **b** should be always realizable *in matter* as a vector, say **h**, defining the 1-form of the magnetic field. Likewise, the tensor **d** is representable *in space* by a vector, **e** say, defining the 1-form of electric field. It is here the point where a theorem which we termed as *Agaoka's theorem*, makes its mark of necessity, because we need a *constitutive law* relating the fields **b** and **d** to the fields **e** and **h**. Thus, between the corresponding differential forms we always need a general relationship of the form:

$$b \wedge h + d \wedge e = 0$$

for only in this case, *according to Agaoka's theorem*, there should be a matrix of exterior differential 1-forms, γ say, which realizes a linear correlation between the 2-forms and 1-forms:

$$b = \gamma^{11} \wedge h + \gamma^{12} \wedge e; \quad d = \gamma^{12} \wedge h + \gamma^{22} \wedge e.$$

In terms of the field vectors themselves, these equations can be turned into linear constitutive equations of the kind used in the classical theory of electromagnetism. The exhaustive characterization of electromagnetism from this point of view is due to Reginald Aubrey Fessenden, at the beginning of the last century (Fessenden, 1900). But the situation is quite general, so that now, after this introduction of the mathematical basis and the reasons for such an approach to a physics of surfaces, we need to present in detail the essence of the geometric theory necessary to achieve this physics.

The Differential Theory of Surfaces

Élie Cartan's exterior differential approach to the theory of surfaces, allows us to say that the local differential theory of surfaces is simply a consequence of the fact that the elementary (differential) displacement of a point of surface is an intrinsic vector of that surface (Guggenheimer, 1977). Everything in the differential theory of surfaces, and in the embedding theory in general, follows from this simple fact through the rules of handling of the differential forms. To wit, if $\mathbf{x}$ is the position vector of a point of surface, then $\mathrm{d}\mathbf{x}$ should be an intrinsic vector of the surface, at least as long as no phenomenon occurs forcing us to consider that the position leaves the surface. But even in such a case, important from a physical point of view, the elementary variation of position *in space* can be described by a process of deformation through a continuous family of surfaces containing the position during that variation. At first, the deformation appears as a purely mathematical device, but as soon as we get into details it becomes gradually obvious that it needs further consideration, especially from physical point of view.

Let us now lay down the proper mathematical form of this portrayal of surfaces. Referring the local geometry at a position $\mathbf{x}$ in space to an orthonormal frame of reference: $(\hat{\mathbf{e}}_|, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3) \equiv \langle \hat{\mathbf{e}}|$, we write

$$d\mathbf{x} = s^1\hat{\mathbf{e}}_1 + s^2\hat{\mathbf{e}}_2 + s^3\hat{\mathbf{e}}_3 \quad \leftrightarrow \quad d\mathbf{x} = \langle s|\hat{\mathbf{e}}\rangle. \tag{7.1}$$

These relations call for a further elucidation regarding the notations. A caret over a bold symbol means a unit vector. Further on, a 'Dirac representation' with 'kets' and 'bras' is used for any sequence of mathematically meaningful objects. For instance, $|s\rangle$ here represents the matrix 3×1 having the components of $\mathbf{x}$ as entries. It is thus understood that the vector notation $\mathbf{x}$ involves also the reference frame $|\hat{\mathbf{e}}\rangle$ in its definition, which, according to our notation

5 2!) $

also characterized by an amplitude $\psi(\boldsymbol{r})$, determining the probability for finding a particle at position $\boldsymbol{r}$ in a volume element $\mathrm{d}^3\boldsymbol{r}$:

$$\mathrm{d}w(\boldsymbol{r}) = w(\boldsymbol{r})\mathrm{d}^3\boldsymbol{r} = \left|\psi(\boldsymbol{r})\right|^2\mathrm{d}^3\boldsymbol{r}. \tag{2.5}$$

And as in optics, diffraction and interference occurs, e.g. at a double slit for which (2.4) describes the experimentally observable signal of particles.

However, in contrast to electromagnetic radiation, where ψ was identified with the electric (or magnetic) field, for matter waves $\psi(\boldsymbol{r})$ cannot be attributed to any directly measurable physical quantity: the observable physics is described by the probability $w(\boldsymbol{r})$. So we call $\psi(\boldsymbol{r})$ simply the *probability amplitude* for finding a particle at position $\boldsymbol{r}$.

Otherwise, analogue considerations are valid for photons and particles of matter. If e.g. we try to localize them on their pathways, we loose the interference patterns! One *important general rule* holds: *interference phenomena are observed if different but indistinguishable pathways exist* on which the particles may proceed toward the detector. In contrast, no interference is observed if the two pathways may in principle be distinguished – even when no distinction is made in the actual experiment.

Section summary

- In classical mechanics well defined trajectories in position $\boldsymbol{r}(t)$ and momentum $\boldsymbol{p}(t)$ space describe the motion of particles. In contrast, quantum mechanics describes probability amplitudes $\psi(\boldsymbol{r})$ and probabilities $\mathrm{d}w(\boldsymbol{r}) = |\psi(\boldsymbol{r})|^2\mathrm{d}^3\boldsymbol{r}$ for finding a particle at a certain position $\boldsymbol{r}$ in a volume element $\mathrm{d}^3\boldsymbol{r}$.
- Diffraction and interference of matter waves can be described by concepts in analogy to those used in wave optics. The big difference is that for photons the “probability amplitude” is also a directly measurable quantity (electric or magnetic field) while for matter waves $\psi(\boldsymbol{r})$ cannot be measured directly – only probabilities $|\psi(\boldsymbol{r})|^2$ refer to the real world.

2.2 SCHRÖDINGER Equation

Wave equations for matter waves were derived independently by Erwin SCHRÖDINGER and PAUL DIRAC who in 1933 jointly received the NOBEL prize in physics for their ground breaking work. The nonrelativistic SCHRÖDINGER equation is most commonly used in AMO physics and will briefly be introduced here. As we shall see in Chap. 6, the relativistically correct DIRAC equation, valid for fermions, is significantly more complex and describes inherently also the electron spin. Its key results may, however, also be introduced as perturbations into the SCHRÖDINGER equation which then leads to sufficiently accurate results in the non relativistic energy regime.

2.2.1 Stationary SCHRÖDINGER Equation

In contrast to photons, particles of matter may be exposed to external forces which change their momentum and hence their wavelength. One may start from the wave equation (2.2) and try to guess, how to modify it for matter waves. Considering a particle of mass m with a total energy W moving in a conservative potential $V(\boldsymbol{r})$, we simply use the (nonrelativistic) energy conservation law of classical mechanics $W = W_{\text{kin}} + V$ to determine its momentum from the kinetic energy W_{kin}:

$$p^2 = 2mW_{\text{kin}} = 2m\big(W - V(\boldsymbol{r})\big).$$

With W being a constant of motion we 'derive' from this and (1.118) the absolute value of the wave vector $k = p/\hbar$ and insert it into (2.2):

$$\Delta\psi(\boldsymbol{r}) + \frac{p^2}{\hbar^2}\psi(\boldsymbol{r}) = \Delta\psi(\boldsymbol{r}) + \frac{2m(W - V(\boldsymbol{r}))}{\hbar^2}\psi(\boldsymbol{r}) = 0.$$

Rewritten, this is already the *stationary* SCHRÖDINGER *equation*

$$-\frac{\hbar^2}{2m}\Delta\psi(\boldsymbol{r}) + V(\boldsymbol{r})\psi(\boldsymbol{r}) = W\psi(\boldsymbol{r}), \tag{2.6}$$

or somewhat more compact

$$\widehat{H}\psi(\boldsymbol{r}) = W\psi(\boldsymbol{r}) \tag{2.7}$$

with the *eigenfunction* $\psi(\boldsymbol{r})$ and the *eigenenergy* W. The HAMILTON *operator* $\widehat{H}$ represents the total energy (briefly just *Hamiltonian*):

$$\widehat{H} = -\frac{\hbar^2}{2m}\Delta + V(\boldsymbol{r}). \tag{2.8}$$

In the often encountered one-dimensional case the SCHRÖDINGER equation (2.6) is further simplified:

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\psi(x)}{\mathrm{d}x^2} + V(x)\psi(x) = W\psi(x). \tag{2.9}$$

2.2.2 HAMILTON and Momentum Operators

We may write the HAMILTON operator (2.8) even more suggestive:

$$\widehat{H} = -\frac{\hbar^2}{2m}\nabla^2 + V(\boldsymbol{r}) = \frac{\widehat{\boldsymbol{p}}^2}{2m} + V(\boldsymbol{r}). \tag{2.10}$$

Here we have introduced the *momentum operator* (a *vector operator*)

$$\widehat{\boldsymbol{p}} = -\mathrm{i}\hbar\nabla = -\mathrm{i}\hbar \begin{pmatrix} \partial/\partial x \\ \partial/\partial y \\ \partial/\partial z \end{pmatrix} \tag{2.11}$$

so that

$$\widehat{\boldsymbol{p}}^2 = \widehat{\boldsymbol{p}} \cdot \widehat{\boldsymbol{p}} = -\hbar^2\nabla^2 = -\hbar^2\Delta = -\hbar^2\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right). \tag{2.12}$$

Thus, (2.10) is the operator form of the *classical energy conservation law*

$$W = W_{\mathrm{kin}} + V = \frac{p^2}{2m} + V(\boldsymbol{r}).$$

2.2.3 Time Dependent SCHRÖDINGER Equation

So far we have discussed probability amplitudes only as a function of $\boldsymbol{r}$, the particle's position in space. For many problems in AMO physics such a description of quantum systems by stationary states is fully sufficient. However, often time dependence is equally important. In respect of photons we know, that electromagnetic waves follow a time dependent wave equation, which is a 2nd order partial differential equation (PDE) in space *and* time derived from the MAXWELL equations. In contrast, for matter waves the *time dependent* SCHRÖDINGER *equation* holds:

$$\widehat{H}\Psi(\boldsymbol{r},t) = \mathrm{i}\hbar\frac{\partial\Psi(\boldsymbol{r},t)}{\partial t} \tag{2.13}$$

or more explicitly: $$-\frac{\hbar^2}{2m}\Delta\Psi(\boldsymbol{r},t) + V(\boldsymbol{r})\Psi(\boldsymbol{r},t) = \mathrm{i}\hbar\frac{\partial\Psi(\boldsymbol{r},t)}{\partial t}.$$

It cannot be derived, and we just communicate it here as it was 'found' by Erwin SCHRÖDINGER in the beginning of 1926 – by the way: during a winter ski holiday in the Swiss Alps. *We point out some key aspects:*

- The SCHRÖDINGER equation is a linear PDE of 2nd order in space and 1st order in time! As a consequence, time dependence of stationary states is truly complex.
- The linear superposition principle may be applied to the solutions.
- The statistical interpretation of quantum mechanics understands solutions $\Psi(\boldsymbol{r},t)$ of this PDE as probability amplitudes for finding a particle at a position $\boldsymbol{r}$ in space at time t according to (2.1).
- Although the SCHRÖDINGER equation cannot be 'derived', it is able to describe a wealth of atomic phenomena and to predict observables quantitatively (under nonrelativistic conditions) with excellent accuracy: we emphasize that is this very fact which defines the "validity" of a physical theory.
- Equivalently, formal (algebraic) quantum mechanics can be deduced from a consistent set of axioms, which are, however, also heuristically assumed.

- Consistent alternatives of wave equations for matter waves are the DIRAC equation for fermions, a multi component spinor equation and the KLEIN-GORDON equation, a single component PDE of 2nd order in time, which turns out to be valid for bosons – both are relativistically correct.

If the *Hamiltonian itself does not depend on time*, $\widehat{H}(\boldsymbol{r},t) = \widehat{H}(\boldsymbol{r})$, the time dependence of the wave function may be *factored by a product ansatz*:

$$\Psi(\boldsymbol{r},t) = \psi(\boldsymbol{r})\varphi(t) \tag{2.14}$$

$$\widehat{H}\Psi(\boldsymbol{r},t) = \mathrm{i}\hbar\frac{\partial\Psi(\boldsymbol{r},t)}{\partial t} \quad \Rightarrow \quad \widehat{H}\psi(\boldsymbol{r})\varphi(t) = \mathrm{i}\hbar\frac{\partial\psi(\boldsymbol{r})\varphi(t)}{\partial t}$$

$$\frac{\widehat{H}\psi(\boldsymbol{r})}{\psi(\boldsymbol{r})} = \frac{\mathrm{i}\hbar}{\varphi(t)}\frac{\partial\varphi(t)}{\partial t} \equiv W.$$

The last identity (with the constant W which has to be determined) must hold so that the former equality can be valid for all values of $\boldsymbol{r}$ and t. One thus has to solve $\mathrm{i}\hbar\mathrm{d}\varphi(t)/\mathrm{d}t = W\varphi(t)$ and $\widehat{H}\psi(\boldsymbol{r}) = W\psi(\boldsymbol{r})$. In this case, the time dependent equation leads to the trivial solution

$$\varphi(t) \propto \exp\left(-\mathrm{i}\frac{W}{\hbar}t\right). \tag{2.15}$$

The position dependent part is nothing but *the stationary* SCHRÖDINGER *equation* (2.6) and the parameter W introduced *is the total energy of the system*. The overall wave function is given by

$$\Psi(\boldsymbol{r},t) = \psi(\boldsymbol{r})\exp\left(-\mathrm{i}\frac{W}{\hbar}t\right). \tag{2.16}$$

Note: The time dependence is truly complex and the imaginary unit i in the prefactor is needed for the solution! In the present case, however, with $\widehat{H} \neq \widehat{H}(t)$ the time dependence is trivial in the sense that only

$$w(\boldsymbol{r},t) = \left|\Psi(\boldsymbol{r},t)\right|^2 = \left|\psi(\boldsymbol{r})\right|^2 \tag{2.17}$$

can be measured, which contains only information about the stationary state.

In order to find these stationary atomic states for a given potential $V(\boldsymbol{r})$ – which are the equivalent to BOHR's stationary orbits – one has to solve the stationary SCHRÖDINGER equation (2.6) under suitably chosen boundary conditions. For bound states this typically leads to a whole *series of discrete total energies* $W_\gamma < 0$ with a set of *quantum numbers* γ characterizing the states. The corresponding *series of wave functions* – for individual electrons called *orbitals* – describe the probability of finding the particles at a given position in space.

./01. . .+ . (/ A ! +2 5
2!) (- !

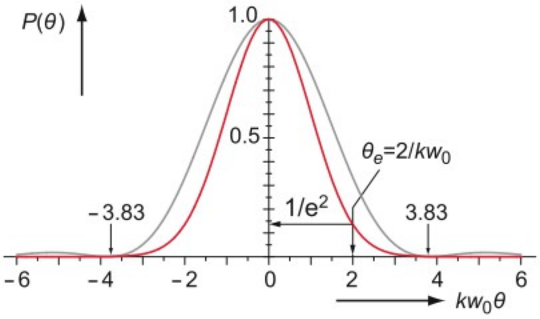

Fig. 1.13 Comparison of the angular dependence of a Gaussian beam (*red*), with a beam waist radius w_0, and the far field of a plane wave (*grey*), diffraction limited by an aperture of radius w_0. The two profiles are normalized to each other at $\theta = 0$

$\hbar k_\perp = \hbar k \theta_e$ one finds $\hbar k_\perp w_0 \geq 2\hbar$. Generally, one defines a so called *beam parameter product* BPP $\equiv w_0\theta_e$ as a measure for the quality of a light beam (specifically for lasers). For a *Gaussian beam* we have

$$\mathrm{BPP} = w_0\theta_e = 2/k = \lambda/\pi, \tag{1.69}$$

while for the *aperture limited plane wave* according to (1.68) the divergence angle

$$w_0\theta_e \geq 3.83/k = 1.22\frac{\lambda}{2} \quad \text{and} \quad s_{\mathrm{Airy}} = \theta_e z = 1.22\frac{z\lambda}{2w_0} \tag{1.70}$$

holds. The characteristic quantity here is the radius s_{Airy} of the central diffraction pattern (the so called AIRY *disc*) on the detector screen.[10] We shall come back to these expressions again in Sect. 2.1.7 in the context of *lateral coherence of natural light* and laser radiation.

1.2.3 Ray Transfer Matrices

Before we can efficiently treat the manipulation of laser beams (focussing, defocussing, deflecting etc.) we have to introduce an important tool of geometrical optics, applicable also to Gaussian beams: the so called *ray transfer matrices* or *ABCD matrices*. They are used for *ray tracing* of paraxial light rays (with $\sin\theta \cong \theta$), i.e. they allow to describe in a simple manner the propagation of light rays through an optical arrangement. These ABCD matrices are efficient tools e.g. for designing laser systems and for computing the properties of laser resonators – typically describing the propagation of well collimated Gaussian beams through a number of optical elements such as mirrors, lenses, and prisms.

---

[10] Note that this formula is the basis of the well known RAYLEIGH criterium for the diffraction limited resolving power of optical instruments. It states that s_{Airy} is the smallest distance between two objects that can be resolved by an instrument with an effective limiting aperture of diameter $D = 2w_0$ and focal length $f = z$.

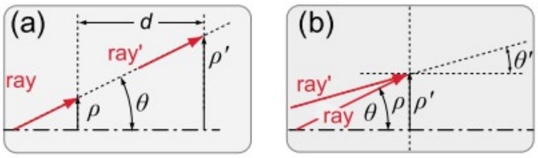

Fig. 1.14 ABCD matrices operating on a light ray. **(a)** Ray translation through a distance d. **(b)** Refraction at an interface between two materials

A paraxial light ray that propagates at a (small) angle θ in a distance ρ from the optical axis, is described by a *ray vector*:

$\begin{pmatrix}\rho\\ \theta\end{pmatrix}$ corresponding to the scheme 
In Fig. 1.14 the change of a *ray* into *ray*′ is illustrated for two important cases: *translation* and *refraction*. Such a change upon transition of the ray through the optical setup corresponds to a linear transformation of the ray vector,[11] described by an ABCD matrix:

$$\begin{pmatrix}\rho'\\ \theta'\end{pmatrix}=\begin{pmatrix}A & B\\ C & D\end{pmatrix}\begin{pmatrix}\rho\\ \theta\end{pmatrix}. \tag{1.71}$$

Specifically, for a Gaussian beam the complex beam parameter (1.41) changes under such transformation from q to q' (here without proof; see e.g. KOGELNIK and LI 1966):

$$q'=\frac{Aq+B}{Cq+D} \quad \text{or} \quad \frac{1}{q'}=\frac{C+D/q}{A+B/q}. \tag{1.72}$$

The most important simple cases are collected in Table 1.2. One verifies

$$\text{that case 1} \quad \begin{pmatrix}\rho'\\ \theta'\end{pmatrix}=\begin{pmatrix}1 & d\\ 0 & 1\end{pmatrix}\begin{pmatrix}\rho\\ \theta\end{pmatrix}=\begin{pmatrix}\rho+\theta d\\ \theta\end{pmatrix}$$

describes a translation,

$$\text{while case 2} \quad \begin{pmatrix}\rho'\\ \theta'\end{pmatrix}=\begin{pmatrix}1 & 0\\ 0 & \frac{n}{n'}\end{pmatrix}\begin{pmatrix}\rho\\ \theta\end{pmatrix}=\begin{pmatrix}\rho\\ \frac{n\theta}{n'}\end{pmatrix}$$

represents the SNELLIUS diffraction law for small angles, $n'\theta'=n\theta$ (paraxial rays). Note that in the latter case $\rho'=\rho$ does not change.

The propagation of a ray through several optical devices is described by the product of the respective ABCD matrices. For example, the ray vector after translation *and* refraction by a thin lens is derived by multiplying matrix 1 with matrix 3 from

---

[11] In a mathematical sense the ray vector is simply the position vector expressed by ρ, the distance from the optical axis (z-axis), and $\theta=\rho/z$, the polar angle. The pictographs used in the following are not always correct in that sense, but quite instructive.

Table 1.2 The most important, simple ABCD matrices

Case	Description	ABCD	Scheme
1	translation through distance d in medium with index of refraction n	$\begin{pmatrix}1 & \frac{d}{n}\\ 0 & 1\end{pmatrix}$	2	refraction by a plane surface with index of refraction left n, right n'	$\begin{pmatrix}1 & 0\\ 0 & \frac{n}{n'}\end{pmatrix}$	3	thin lens of focal length f	$\begin{pmatrix}1 & 0\\ -\frac{1}{f} & 1\end{pmatrix}$	4	reflection from a concave mirror	$\begin{pmatrix}1 & 0\\ -\frac{2}{R} & 1\end{pmatrix}$	5	refraction at a spherical surface	$\begin{pmatrix}1 & 0\\ -\frac{n'-n}{n'R'} & \frac{n'}{n}\end{pmatrix}$	
Table 1.2:

$$\begin{pmatrix}1 & 0\\ -\frac{1}{f} & 1\end{pmatrix}\begin{pmatrix}1 & d\\ 0 & 1\end{pmatrix}\begin{pmatrix}\rho\\ \theta\end{pmatrix}=\begin{pmatrix}1 & d\\ -\frac{1}{f} & 1-\frac{d}{f}\end{pmatrix}\begin{pmatrix}\rho\\ \theta\end{pmatrix}=\begin{pmatrix}\rho+\theta d\\ \theta-\frac{\rho+\theta d}{f}\end{pmatrix}. \qquad (1.73)$$

One verifies e.g. for any ray coming out of the focal point ($d=f$ and $\rho=0$), that after passing the lens the exit angle is always $\theta'=0$, i.e. all such rays leave the lens parallel – as well known from geometrical optics. Conversely, a ray entering the lens parallel to the optical axis ($\theta=0$) always leaves the lens at $\rho'=\rho$ with $\theta'=-\rho/f$, independently of d, i.e. the ray is refracted into the focal point.

We may also describe ray propagation behind the lens to a position d' if we know the ray vector in front of the lens:

$$\begin{pmatrix}1 & d'\\ 0 & 1\end{pmatrix}\begin{pmatrix}1 & 0\\ -\frac{1}{f} & 1\end{pmatrix}\begin{pmatrix}\rho\\ \theta\end{pmatrix}=\begin{pmatrix}1-\frac{d'}{f} & d'\\ -\frac{1}{f} & 1\end{pmatrix}\begin{pmatrix}\rho\\ \theta\end{pmatrix}=\begin{pmatrix}\rho-\frac{\rho d'}{f}+d'\theta\\ -\frac{\rho}{f}+\theta\end{pmatrix}. \qquad (1.74)$$

One verifies e.g. that rays which are parallel to the axis before entering the lens ($\theta=0$) cross the axis behind the lens at $d'=f$.

Finally, the product of matrix 1 with matrix 3 and again matrix 1 allows one to describe imaging by a lens. Further multiplication with the matrices for additional optical pathways and other elements allows one to easily describe even complex optical setups very efficiently. We shall now apply this technique to the manipulation of a Gaussian beam with lenses.

1.2.4 Focussing a Gaussian Beam

Focussing and de-focussing, expanding and concentrating Gaussian beams is very important in experimental practice. In principle, very wide beams with large radii may be generated as well as tightly focused ones with extremely high intensity at the focal point. In any case, however, the *product of beam radius w and divergence angle θ_e remains constant*, and is according to (1.69) for a Gaussian beam $\theta_e w = \lambda/\pi$.

To familiarize ourselves with the tools we let a Gaussian beam propagate freely, say, emerging from a laser system. Let us assume that we start with an ideally parallel beam ($R = \infty$) of radius w_L. With the RAYLEIGH length $z_R = \pi w_L^2/\lambda$ the complex beam parameter according to (1.41) is

$$\frac{1}{q} = -\mathrm{i}\frac{\lambda}{\pi w_L^2} = -\frac{\mathrm{i}}{z_R}. \tag{1.75}$$

It changes with distance travelled according to (1.72). With the propagation matrix 1 in Table 1.2 we find at a distance $z' = d$

$$\frac{1}{q'} = \frac{C + D/q}{A + B/q} = \frac{1/q}{1 + z'/q},$$

which can be rewritten in the form (1.41) as

$$\frac{1}{q'} = \frac{1}{z'(1 + z_R^2/z'^2)} - \frac{\mathrm{i}}{z_R(1 + z'^2/z_R^2)} = \frac{1}{R'} - \mathrm{i}\frac{\lambda}{\pi w'^2}.$$

Thus we find $R' = z'(1 + z_R^2/z'^2)$ and $w' = w_L\sqrt{1 + z'^2/z_R^2}$, expressions which are completely equivalent to (1.42) and (1.43). We see that the matrix method reproduces indeed the behaviour of a Gaussian beam as it propagates along the optical axis – including the correct divergence angle $\theta_e = \lambda/\pi w_L$ corresponding to (1.52).

We now want to *focus this laser beam by a collecting lens* of focal length f. Let the lens be positioned at $z = 0$, and we state now more precisely that the assumed initial parallelism implies $R_L \gg f$. In geometrical optics such a "plane wave" is assumed to be focused in the focal *point* of the lens, whereby the initial plane wave front ($R_L = \infty$) is converted into a spherical wave with a radius of curvature $R' = (z - f)$. In reality, however, due to diffraction the focal *point* becomes a circular disc of radius w_0, as sketched in Fig. 1.15.

The complex beam parameter in front of the lens is given by (1.75) as in the previous example. According to (1.72) we use this time the product matrix (1.74) to obtain the new complex beam parameter at a distance z' behind the lens:

$$\frac{1}{q'} = \frac{C + D/q}{A + B/q} = \frac{-1/f - \mathrm{i}\lambda/(\pi w_L^2)}{(1 - \frac{z'}{f}) - z'\mathrm{i}\lambda/(\pi w_L^2)}. \tag{1.76}$$

+9 4 9

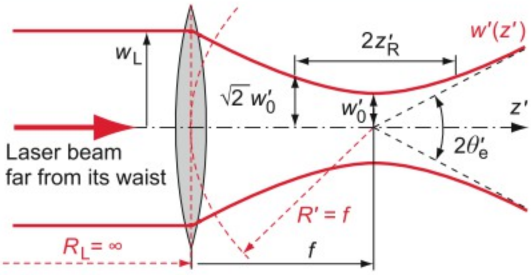

Fig. 1.15 Focussing a parallel Gaussian beam

Without going into further details we concentrate onto the focal point of the lens, $z' = f$, in order to determine the waist $w'_0 = w'(f)$.[12] The result is simply

$$\frac{1}{q'} = \frac{1}{f} - \mathrm{i}\frac{\pi w_L^2}{\lambda f^2} = \frac{1}{R'} - \mathrm{i}\frac{\lambda}{\pi w_0'^2}$$

with the latter equality again according to (1.41). Comparing real and imaginary parts we obtain the *waist radius w'_0 of the focused beam*

$$w'_0 = \frac{f\lambda}{\pi w_L}, \tag{1.77}$$

while the radius of curvature of the wave front becomes $R'(f) = f$. For practical purposes we also note the relation with the $1/\mathrm{e}$ intensity GAUSS radius $a = w/\sqrt{2}$

$$a'_0 = \frac{f\lambda}{2\pi a_L}, \tag{1.78}$$

and recall that the maximum intensity (1.60) in the beam centre which may be obtained by this kind of focussing is $I_0 = P_{\mathrm{tot}}/\pi a_0'^2$.

Inserting (1.77) into (1.45) gives for the focused beam the RAYLEIGH length z'_R and the *confocal parameter* (the distance around the focus for which the intensity on axis is above 50 % of the maximum):

$$b' = 2z'_R = \frac{2\pi w_0'^2}{\lambda} = \frac{2\lambda f^2}{\pi w_L^2}.$$

Table 1.3 presents numerical examples for three different focal lengths f and two different initial beam diameters w_L, all at the 800 nm wavelength of the Titanium-sapphire laser – the workhorse of ultrafast spectroscopy.

---

[12] A closer look into the algebra shows, however, that the smallest cross section is found at $z = fz_0^2/(z_R^2 + f^2)$, i.e. slightly in front of the focal point of the lens. There the radius of curvature even approaches $R \to \infty$. Since typically we start with a relatively large beam radius w_L the RAYLEIGH length is very large, $z_R = \pi w_L^2/\lambda \gg f$, so that the small difference does not play a practical role.

Table 1.3 Beam radius w_0' (at $1/\mathrm{e}^2$ intensity) and confocal parameter $b' = z_R'$ in the focus of a lens with focal length f. An initially parallel Gaussian beam is assumed, at $\lambda = 800\,\text{nm}$ with radius w_L

f/mm	w_L/mm	w_L/f	w_0'/μm	b'
100	0.4	0.004	64	31 mm
100	2	0.02	13	1.3 mm
50	0.4	0.008	31	8 mm
50	2	0.04	6.4	318 μm
10	0.4	0.04	6.4	318 μm
10	2	0.2	1.2	12 μm

Conversely, one may *parallelize a diverging laser beam* by putting a lens of focal lengths f at a distance f behind its waist. As illustrated in Fig. 1.16 the lens converts the curved wave front into an essentially plane wave. Starting with a beam waist w_0 at $z = 0$ and a radius of curvature $R_L = -f$ the complex beam parameter at the waist is

$$\frac{1}{q} = -\frac{1}{f} - \mathrm{i}\frac{\lambda}{\pi w_0^2}.$$

We use again (1.72), this time with the product matrix (1.73). After a brief calculation we obtain the new complex beam parameter directly behind the lens:

$$\frac{1}{q'} = \frac{C + D/q}{A + B/q} = -\mathrm{i}\frac{\pi}{f^2\lambda} w_0^2.$$

Beam radius and radius of curvature immediately behind the lens are thus

$$w_0' = \frac{f\lambda}{\pi w_0} \quad \text{and} \quad R' = \infty, \quad \text{respectively.}$$

As expected, this is just the inverse of the focussing process according to (1.77). We have to be aware that the 'new' laser beam thus generated has now its waist just behind the lens. From there it will propagate in a slightly divergent manner. According to (1.55) the new divergence angle of the 'parallelized' Gaussian beam

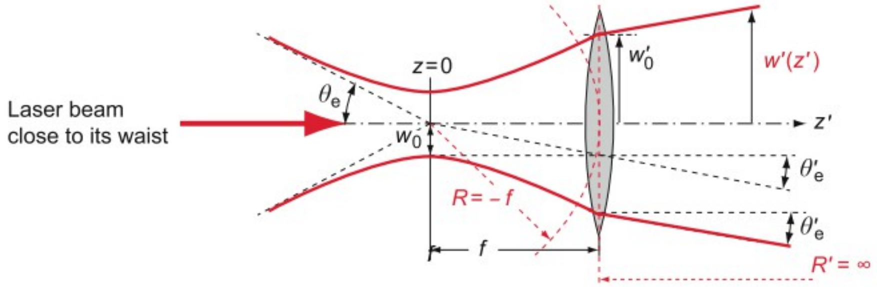

Fig. 1.16 De-focussing of a Gaussian beam

Table 1.4 Beam radii of Gaussian beams as a function from the beam waist for different initial waist radii w_0 according to (1.43). The RAYLEIGH length z_R and the far field divergence angle θ_e are related to w_0 by (1.45) and (1.55), respectively. The numbers are given for the Titanium-sapphire laser wavelength $\lambda = 800\,\text{nm}$

Nr.	Beam parameter			w/mm Beam radius at $1/\text{e}^2$ Intensity at z (distance to waist)				
	w_0/mm	z_R/mm	θ_e/mrad	1 m	2 m	20 m	100 m	1000 m
1	10	400×10^3	2.5×10^{-2}	10	10	10	10.3	27
2	3	35×10^3	3×10^{-2}	3	3	3.4	9	85
3	1	3.9×10^3	0.25	1	1.1	5.2	25	255
4	0.3	353	0.84	0.9	1.7	16	85	850
5	0.1	39	2.5	2.5	5	51	254	2546
6	0.03	3.5	8.5	8.5	16	170	850	8500
7	0.01	0.4	25	25	50	250	2550	25 465

is

$$\theta'_e = \frac{\lambda}{\pi w'_0} = \frac{\lambda \pi w_0}{\pi f \lambda} = \frac{w_0}{f}. \tag{1.79}$$

This divergence angle may even be interpreted geometrically as indicated in Fig. 1.16: it corresponds to the divergence one would expect from classical ray optics imaging an extended light source with a radius w_0 to infinity.

To give a feeling for the divergence of Gaussian beams, in Table 1.4 numerical examples are collected for different initial beam radii w_0 (equivalently RAYLEIGH lengths z_R or divergence angles θ_e). The beam radii w at different distances z from the waist illustrate clearly how the beams diverge – one may often observe this by laser illuminations in the nightly skies of big cities (thanks to RAYLEIGH scattering in dry weather, or even better in humid air due to MIE scattering as discussed in Sect. 8.4.5, Vol. 1).

These numbers are astonishing indeed, at least at first glance. Compare e.g. beam 1, 3, and 5 in Table 1.4. Beam 1 may initially appear as a rather broad 'brush' of light. Note, however, that it widens only by a factor of 3 over the distance of 1km, and it would thus be well suited e.g. in telecommunication or metrology. In contrast, beams 3 or 5 look on the laser table nicely thin and 'laser-like'. They expand, however, very rapidly and get a rather large radius in some distance. Beam 5 will hardly be useable in a neighbouring lab at 20 m distance, while beam 6, finally, is a highly focussed beam generating very high intensity in its focal point, but with a RAYLEIGH length of 0.4 mm, its on axis intensity decays rapidly to less than 50 % outside the confocal length of 0.8 mm around the focus.

For transporting beams over wide distances one first has to expand them. To this end one uses telescope systems as sketched in Fig. 1.17. In the destination where the beam is to be used, one may place a second telescope system – more or less identical to the first one – in order to re-compress the beam. Even if one wants to

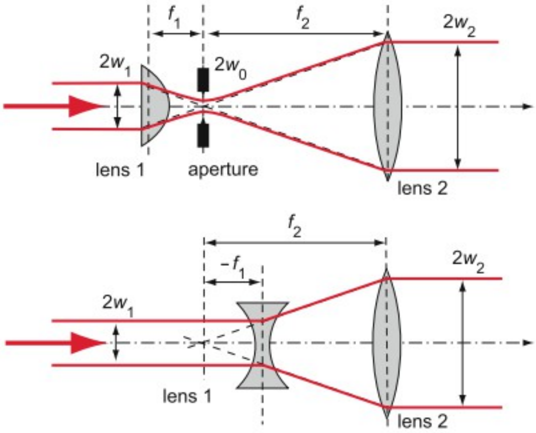

Fig. 1.17 Telescope systems for expanding a Gaussian beam. The *top setup* according to Kepler (two collecting lenses) contains an aperture, positioned in the focus, for beam improvement (spatial filter). The *lower setup* according to Galilei (dispersing lens and collecting lens) can be used even for very high intensities

generate a particularly tight focus, it is recommendable to first expand the beam: according to (1.77) the minimal radius w_0 achievable in the focus of a lens is inversely proportional to the radius w_L of the laser beam in front of the focusing lens.

As illustrated in Fig. 1.17 one may construct telescope systems essentially in two ways: either according to Kepler with two collecting lenses, arranged con-focally or according to Galilei with one dispersing and one collecting lens, the focus of the latter matching the backward focus of the dispersing lens. From the geometry shown in Fig. 1.17 one reads the beam expansion from radius w_1 to w_2 in both cases to be

$$w_2 = w_1 |f_2/f_1|. \tag{1.80}$$

The divergence angle of the expanded beam is again estimated from (1.55):

$$\theta_2 = \frac{\lambda}{\pi w_2}. \tag{1.81}$$

Strictly, this only holds if the radius of the phase surfaces at lens 2 exactly matches f_2 – which may always be achieved by fine adjustment of the lens positions.

Both types of telescope systems have their specific merits. Between two collecting lenses a real focal-point exists, into which one may e.g. place a small, circular aperture (diameter typically 3 to 5 × w_0) as indicated in Fig. 1.17. With such a *spatial filter* one often may improve the lateral profile of not completely perfect Gaussian beams considerably. The (lateral and longitudinal) adjustment of such an aperture requires some experimental skills.

On the other hand, for very high laser intensities – as often encountered when working with femtosecond laser pulses – one must avoid a real focus where ionization and electric breakdown in air may occur, and destroy the laser pulse. In such cases only the Galilei type of telescopes is applicable.

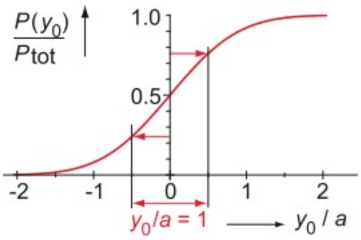

Fig. 1.18 Signal from a Gaussian beam measured with the knife edge method. One determines a from the y_0 position for a signal ratio of 0.24 and 0.76 – as indicated

1.2.5 Measuring Beam Profiles with a Razor Blade

If one already knows that the radial beam profile is Gaussian, or is least described well enough by (1.58), one may determine the radii a or w according to (1.59) by the rather simple, practical "knife-edge" method. One mounts a razor blade onto a precision optical table, which can be moved perpendicularly into the beam, say in y-direction. One registers the power $P(y_0)$ which reaches a detector positioned behind it as a function of y. If the beam is covered from $y = y_0$ to $y = \infty$ this amounts to (with $\rho = \sqrt{x^2 + y^2}$)

$$P(y_0) = \frac{P_{\mathrm{tot}}}{\pi a^2} \int_{-\infty}^{y_0} \mathrm{d}y \left(\int_{-\infty}^{+\infty} \mathrm{d}x \exp\left(-\frac{x^2 + y^2}{a^2} \right) \right). \tag{1.82}$$

This expression may be integrated in closed form and gives

$$\frac{P(y_0)}{P_{\mathrm{tot}}} = \frac{1}{a\sqrt{\pi}} \int_{-\infty}^{y_0} \exp\left(-\frac{y^2}{a^2} \right) \mathrm{d}y = \frac{1}{2} \left(\mathrm{erf}\left(\frac{y_0}{a} \right) + 1 \right) \tag{1.83}$$

with the error function $\mathrm{erf}(y_0/a)$. $P(y_0/a)/P_{\mathrm{tot}}$ is shown in Fig. 1.18, being 0.2398 and 0.7602 for $y_0/a = \mp 0.5$, respectively. At these two positions one reads the GAUSS radius $a = w/\sqrt{2}$ as marked in Fig. 1.18.

1.2.6 The M^2 Factor

In practice, of course, laser beams are never completely perfect. More or less pronounced deviations from the ideal Gaussian beam profile are the rule. This is very important when describing the quality of a laser system. Most concisely this is expressed by the beam parameter product (BPP) according to (1.69): the larger the BPP, the poorer the beam quality. The international norm ISO 11146 defines as a quantitative characteristic of a laser beam with a divergence angle θ_e and a beam radius w_0 the so called M^2 factor by

$$\theta_e = M^2 \frac{\lambda}{\pi w_0}. \tag{1.84}$$

2.2.1 Stationary SCHRÖDINGER Equation

In contrast to photons, particles of matter may be exposed to external forces which change their momentum and hence their wavelength. One may start from the wave equation (2.2) and try to guess, how to modify it for matter waves. Considering a particle of mass m with a total energy W moving in a conservative potential $V(\boldsymbol{r})$, we simply use the (nonrelativistic) energy conservation law of classical mechanics $W = W_{\text{kin}} + V$ to determine its momentum from the kinetic energy W_{kin}:

$$p^2 = 2m W_{\text{kin}} = 2m\big(W - V(\boldsymbol{r})\big).$$

With W being a constant of motion we 'derive' from this and (1.118) the absolute value of the wave vector $k = p/\hbar$ and insert it into (2.2):

$$\Delta\psi(\boldsymbol{r}) + \frac{p^2}{\hbar^2}\psi(\boldsymbol{r}) = \Delta\psi(\boldsymbol{r}) + \frac{2m(W - V(\boldsymbol{r}))}{\hbar^2}\psi(\boldsymbol{r}) = 0.$$

Rewritten, this is already the *stationary* SCHRÖDINGER *equation*

$$-\frac{\hbar^2}{2m}\Delta\psi(\boldsymbol{r}) + V(\boldsymbol{r})\psi(\boldsymbol{r}) = W\psi(\boldsymbol{r}), \tag{2.6}$$

or somewhat more compact

$$\widehat{H}\psi(\boldsymbol{r}) = W\psi(\boldsymbol{r}) \tag{2.7}$$

with the *eigenfunction* $\psi(\boldsymbol{r})$ and the *eigenenergy* W. The HAMILTON *operator* $\widehat{H}$ represents the total energy (briefly just *Hamiltonian*):

$$\widehat{H} = -\frac{\hbar^2}{2m}\Delta + V(\boldsymbol{r}). \tag{2.8}$$

In the often encountered one-dimensional case the SCHRÖDINGER equation (2.6) is further simplified:

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\psi(x)}{\mathrm{d}x^2} + V(x)\psi(x) = W\psi(x). \tag{2.9}$$

2.2.2 HAMILTON and Momentum Operators

We may write the HAMILTON operator (2.8) even more suggestive:

$$\widehat{H} = -\frac{\hbar^2}{2m}\nabla^2 + V(\boldsymbol{r}) = \frac{\widehat{\boldsymbol{p}}^2}{2m} + V(\boldsymbol{r}). \tag{2.10}$$

Here we have introduced the *momentum operator* (a *vector operator*)

) " (C (

In the above crude analysis, we obtained very little information concerning the location of the unique limit cycle given in Theorem 1.6. When a differential equation contains a parameter, one can sometimes discuss the precise limiting behavior as the parameter tends to some value. This is illustrated with van der Pol's equation (1.7). Suppose k is very large; more specifically, suppose $k = \varepsilon^{-1}$ and let us determine the behavior of the periodic solution as $\varepsilon \to 0^+$. Oscillations of this type are called *relaxation oscillations*. System (1.7) is equivalent to

$$\varepsilon\dot{u} = v - G(u), \qquad \dot{v} = -\varepsilon u, \tag{1.8}$$

where $G(u) = u^3/3 - u$. From Theorem 1.6, equation (1.8) has a unique asymptotically stable limit cycle $\Gamma(\varepsilon)$ for every $\varepsilon > 0$. From (1.8), if ε is small and the orbit is away from the curve $v = G(u)$ in Fig. 1.6, then the u coordinate has a large velocity and the v coordinate is moving slowly. Therefore, the orbit has a tendency to jump in horizontal directions except when it is very close to the curve $v = G(u)$. These intuitive remarks are made precise in

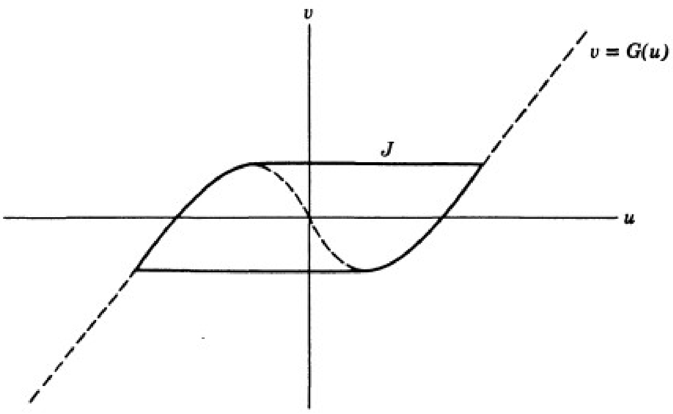

Figure II.1.6

Theorem 1.7. As $\varepsilon \to 0$, the limit cycle of (1.8) approaches the Jordan curve J shown in Fig. 1.6 consisting of arcs of the curve $v = G(u)$ and horizontal line segments.

To prove this, we construct a closed annular region U containing J such that dist(U, J) is any preassigned constant and yet for ε sufficiently small, all paths cross the boundary of U inward. U will thus contain (from the Poincaré-Bendixson theorem) the limit cycle $\Gamma(\varepsilon)$. The construction of

U is shown in Fig. 1.7 where h is a positive constant. The straight lines 81 and 45 are tangent to $v = G(u) + h$, $v = G(u) - h$ respectively and the lines 56, 12, 9–10, 13–14, are horizontal while 23, 67, 11–12, 15–16 are vertical. The remainder of the construction should be clear. The inner and outer boundaries are chosen to be symmetrical about the origin. Also marked on the figure are arrows designating the direction segments of the boundaries crossed. These are obtained directly from the differential equation and are independent of $\varepsilon > 0$. It is necessary to show that the other segments of the boundary are also crossed inward by orbits if ε is small. By symmetry, it is only necessary to discuss 34, 45 and 10–11.

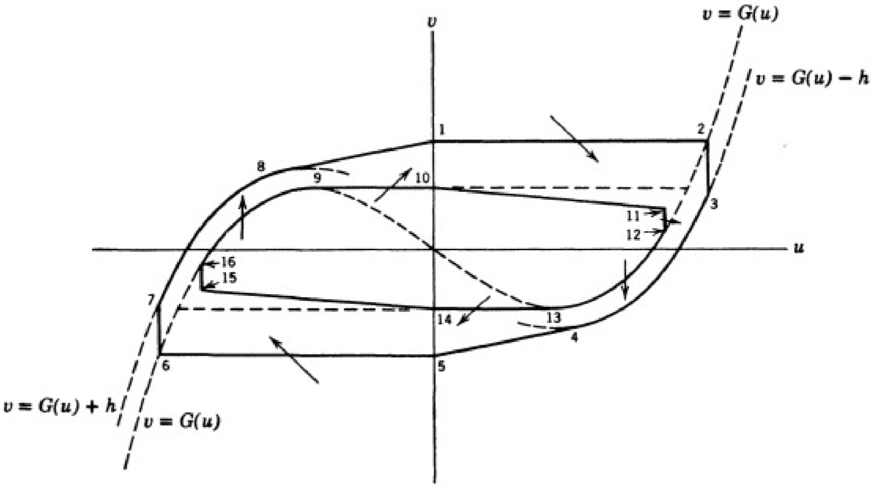

Figure II.1.7

At any point $(u, G(u) - h)$ on 34, along the orbits of (1.8), we have

$$\frac{dv}{du} = \frac{-\varepsilon^2 u}{v - G(u)} = \frac{\varepsilon^2 u}{h} < \frac{\varepsilon^2 u(3)}{h}$$

where $u(3)$ is the value of u at point 3. Hence for ε small enough, this is less than $g(4) < g(u)$ which is the slope of the curve $G(u) - h$. Thus, $\dot{v} < 0$ on this arc implies the orbits enter the region along this arc.

Along the arc 45, we have $|v - G(u)| > h$ and, hence, the absolute value of the slope of the path $|dv/du| = |-\varepsilon^2 u/[v - G(u)]| < \varepsilon^2 u(4)/h$ approaches zero as $\varepsilon \to 0$. For ε small enough this can be made $< g(4)$ which is the slope of the line 45. Thus, $\dot{v} < 0$ on this arc implies the orbits enter into U if ε is small enough.

Let K be the length of the arc 11–12. For K small enough, $|v - G(u)| > K$ along the arc 10–11. Hence, $|dv/du|$ along orbits of (1.8) is less than $\varepsilon^2 u/K < \varepsilon^2 u(11)/K$, which approaches zero as $\varepsilon \to 0$. Thus, for ε small, the orbits enter U since $\dot{u} > 0$ on this arc.

This shows that given a region U of the above type, one can always choose ε small enough to ensure that the orbits cross the boundary of U inward. This proves the desired result since it is clear that U can be made to approximate J as well as desired by appropriately choosing the parameters used in the construction.

Exercise 1.1. Prove the following *Theorem*. Any open disk in R^2 which contains a bounded semiorbit of (1.1) must contain an equilibrium point. Hint: Use the Poincaré-Bendixson Theorem and Theorem I.8.2.

Exercise 1.2. Give a generalization of Exercise 1.1 which remains valid in R^3? Give an example.

Exercise 1.3. Prove the following *Theorem*. If div f has a fixed sign (excluding zero) in a closed two cell Ω, then Ω has no periodic orbits. Hint: Prove by contradiction using Green's theorem over the region bounded by a periodic orbit in Ω.

Exercise 1.4. Consider the two dimensional system $\dot{x} = f(t, x)$, $f(t+1, x) = f(t, x)$, where f has continuous first derivatives with respect to x. Suppose Ω is a subset of R^2 which is homeomorphic to the closed unit disk. Also, for any solution $x(t, x_0)$, $x(0, x_0) = x_0$, suppose there is a $T(x_0)$ such that $x(t, x_0)$ is in Ω for all $t \geqq T(x_0)$. Prove by Brouwer's fixed point theorem that there is an integer m such that the equation has a periodic solution of period m. Does there exist a periodic solution of period 1?

Exercise 1.5. Suppose f as in exercise (1.4) and there is a $\lambda > 0$ such that $x'f(t, x) \leqq -\lambda|x|^2$ for all t, x. If $g(t) = g(t+1)$ is a continuous function, prove the equation $\dot{x} = f(t, x) + g(t)$ has a periodic solution of period 1.

Exercise 1.6. Suppose γ_0 is a periodic orbit of a two dimensional system and let G_e and G_i be the sets defined in Theorem 1.4. Is it possible for an equation to have $\alpha(\gamma(p)) = \gamma_0$ for all noncritical points p in G_i and $\omega(\gamma(q)) = \gamma_0$ for all q in G_e? Explain.

Exercise 1.7. For Lienard's equation, must there always be a periodic orbit which is stable from the outside? Must there be one stable from the inside? Explain.

8.7.4 Persistence images

There is another approach that proceeds by treating a barcode, recoded as a persistence diagram, as a collection of point masses and then smoothing the corresponding measure to produce and image, which is finally discretized by selecting pixels and assigning each pixel the average value of the function on a box surrounding that pixel. It is described in [2]. The detailed description is given in several steps. The input is a persistence diagram (it is more natural to use the persistence diagram view in this case), a collection of points $B = \{(x_1, y_1), \ldots, (x_n, y_n)\} \subset \mathbb{R}^2$. We assume we are given a function $\phi : \mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{R}$ so that (a) $\phi_u = \phi(u, -)$ is a probability distribution on $\mathbb{R}^2$ for each $u \in \mathbb{R}^2$ and (b) the mean of ϕ_u is u. A standard choice is that of a spherically symmetric Gaussian with mean u and a fixed variance σ. We also assume we are given a continuous and piecewise differentiable nonnegative weighting function $f : \mathbb{R}^2 \to \mathbb{R}$ that is zero along the x-axis.

that

$$\lambda_k(B)(t) \geq \lambda_{k+1}(B)(t)$$

and that

$$\lambda_k(B)(l) = 0 \text{ for } k > n.$$

In [12] it is also proved that each function $\lambda_k(B)$ is 1-Lipschitz, i.e. that

$$|\lambda_k(B)(t) - \lambda_k B)(t')| \leq |t - t'|.$$

To summarize, the persistence landscape lies in the vector space $\mathfrak{F}$ of real valued functions on $\mathbb{N} \times \mathbb{R}$, and it follows directly from Remark 8.7.2 that the definition gives us a function $PL : \mathfrak{B} \to \mathfrak{F}$.

One extremely useful fact about the persistence landscape is that it is compatible with the various distances assigned to barcode spaces. We let $\mathfrak{F}_p \subset \mathfrak{F}$ denote the space of functions with finite L_p-norm $|| \; ||_p$. It is clear that the function PL takes values in $\mathfrak{F}_p$ for all p. Recall the definition of the p-Wasserstein distance W_p between barcodes from Section 8.5.1. Bubenik now proves the following in [12].

Theorem 8.7.3. *The function* $d_p(B, B') = ||PL(B) - PL(B')||_p$ *is a metric on* $\mathfrak{B}$. *The two metrics* W_{p+1} *and* d_p *generate the same topology on* $\mathfrak{B}$. *It follows that the map* PL *is continuous when* $\mathfrak{B}$ *is equipped with the metric* W_{p+1} *and* $\mathfrak{F}_p$ *is equipped with the metric associated with the* L_p *norm.*

Remark 8.7.4. Bubenik also provides explicit inequalities involving the two metrics in [12]

Bubenik also proves the following continuity theorem.

Theorem 8.7.5. *The map* PL *is 1-Lipschitz from* $\mathfrak{B}$ *equipped with the bottleneck distance to the space of persistent landscapes equipped with the sup norm distance. This is equivalent to the algebraic statement*

$$|\lambda_k(B)(t) - \lambda_k(B')(t)| \leq W_\infty(B, B').$$

Remark 8.7.6. The map PL separates points.

8.7.4 Persistence images

There is another approach that proceeds by treating a barcode, recoded as a persistence diagram, as a collection of point masses and then smoothing the corresponding measure to produce and image, which is finally discretized by selecting pixels and assigning each pixel the average value of the function on a box surrounding that pixel. It is described in [2]. The detailed description is given in several steps. The input is a persistence diagram (it is more natural to use the persistence diagram view in this case), a collection of points $B = \{(x_1, y_1), \ldots, (x_n, y_n)\} \subset \mathbb{R}^2$. We assume we are given a function $\phi : \mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{R}$ so that (a) $\phi_u = \phi(u, -)$ is a probability distribution on $\mathbb{R}^2$ for each $u \in \mathbb{R}^2$ and (b) the mean of ϕ_u is u. A standard choice is that of a spherically symmetric Gaussian with mean u and a fixed variance σ. We also assume we are given a continuous and piecewise differentiable nonnegative weighting function $f : \mathbb{R}^2 \to \mathbb{R}$ that is zero along the x-axis.

- Apply the coordinate change $(x,y) \to (x, y-x) = (\xi, \eta)$ to $\mathbb{R}^2$, to obtain the new set of points $\mathcal{B} = \{(\xi_1, \eta_1) \ldots, (\xi_n, \eta_n)\}$ of the same cardinality in $\mathbb{R}^2$. The points that correspond to short intervals are now all located near the ξ-axis. The ξ-axis itself corresponds to intervals of length zero.

- Construct a new function $\rho_{\mathcal{B}}(z) : \mathbb{R}^2 \to \mathbb{R}$, called the *persistence surface of* $\mathcal{B}$, defined by

$$\rho(z) = \sum_{i=1}^{n} f(\xi_i, \eta_i) \phi((\xi_i, \eta_i), z).$$

  Notice that ρ vanishes on the x-axis.

- To construct a finite dimensional representation, we first assume that the persistence diagrams we will be dealing with will always lie in a bounded region in $\mathbb{R}^2$, and divide a box containing that region into a square grid. Construct the vector with coordinates in one to one correspondence with the squares of the grid, and assign the entry corresponding to a square to be the integral over that square of $\rho_{\mathcal{B}}$.

The following is proved in [2].

Theorem 8.7.7. *The map* $PI : \mathfrak{B} \to \mathbb{R}^N$ *that assigns to a persistence diagram a vector using the above procedure is continuous when the metric on* $\mathfrak{B}$ *is the* 1*-Wasserstein distance.*

Remark 8.7.8. In [2], estimates proving this result are given both in the case of a general choice of ϕ and the special case where ϕ is given by Gaussian distributions with fixed variance. Of course, the estimates in the latter case are stronger.

8.8 Generalized persistence

8.8.1 Introduction

Persistent homology operates on functors F from the category $\mathbb{R}_+$ to simplicial complexes, by composing them with the homology functor to obtain a persistence vector space. It is useful to consider other parameter categories for the diagrams, which can also help clarify the structure of data sets. There are at least two such constructions that have been discussed. The first is *zig-zag* persistence, introduced in [19], and the second is *multidimensional persistence*, discussed for example in [22]. The first is designed to study the relationship between homology of constructions that are not nested within each other, such as distinct samples from a given space, and the second provides invariants of situations where it is natural to study filtrations of spaces involving more than one parameter, such as filtering by both the scale parameter R and a measure of density. We describe both extensions of the standard persistent homology methods.

8.8.2 Zig-zag persistence

Consider the triangulation of $\mathbb{R}$ whose vertices are the integers. The set of vertices of the barycentric subdivision of this simplicial complex is equipped with a partial ordering, by recognizing that its elements are in one-to-one correspondence with the simplices in the original triangulation, and that that set is equipped with a partial ordering by treating it as a subset of the power set of $\mathbb{R}$. In concrete terms, we may view it as in one to one correspondence with the set all integers and half integers, with every integer n being less than or equal to the elements $n \pm \frac{1}{2}$. We'll refer to this partially ordered set as $\mathfrak{Z}$. A partially ordered set (and its corresponding category) is said to be connected if any two objects can be connected by a zig-zag sequence of morphisms. Connected partially ordered subsets of $\mathfrak{Z}$ are always determined by a pair (x, y), where x and y are both integers or half integers, via the rule that assigns to the pair (x, y) the collection of objects z for which $x \leq z \leq y$ (in the total ordering on $\mathbb{R}$).

Definition 8.8.1. *For any category $\underline{C}$, a* zig-zag persistence object *in $\underline{C}$ is a functor from a connected subcategory of $\mathfrak{Z}$ to $\underline{C}$. Suppose further that $\underline{C}$ is equipped with an object c_0 that is both initial and terminal. Then for any connected subcategory $\mathfrak{Z}_0 \subseteq \mathfrak{Z}$ and object $c \in \underline{C}$, we define the* interval object *for $\mathfrak{Z}_0$ and c to be the functor $F = F_{\mathfrak{Z}_0, c} : \mathfrak{Z} \to \underline{C}$ defined on objects by $F(x) = c$ for all $x \in \mathfrak{Z}_0$ and $F(x) = c_0$ for any $x \notin \mathfrak{Z}_0$, and on morphisms by $F(x \leq y) = id_c$ whenever $x, y \in \mathfrak{Z}_0$. The behavior on morphisms into or out of $\mathfrak{Z}_0$ is uniquely determined by the fact that c_0 is both initial and terminal. When $\underline{C}$ is the category of vector spaces over a field K, then it is understood that c will be chosen to be a one-dimensional vector space over K.*

Given a zig-zag persistence object in the category of simplicial complexes, we may apply a homology functor $H_i(-; A)$ for an abelian group A to obtain a zig-zag persistence object in the category of abelian groups. The category of abelian groups has the zero object as an object that is both initial and terminal, and so the notion of interval objects makes sense. Of course if $A = K$, where K is a field, then we obtain a zig-zag persistence vector space. It turns out that they can be classified up to isomorphism.

Theorem 8.8.2. (P. Gabriel, [37]) *Let $\mathfrak{Z}' \subset \mathfrak{Z}$ be any finite connected subcategory, and let F denote any zig-zag persistence object in the category of finite dimensional vector spaces over a field K defined on $\mathfrak{Z}'$. Then there is a finite direct sum decomposition*

$$F \cong \bigoplus_i F_i$$

where each F_i is an interval object for $\mathfrak{Z}_0$ and K, where $\mathfrak{Z}_0 \subseteq \mathfrak{Z}'$ is a connected subcategory of $\mathfrak{Z}'$. Moreover, the sum is unique up to isomorphism and reordering of the sum.

Corollary 8.8.3. *The classification of zig-zag persistence vector spaces based on a connected subcategory $\mathfrak{Z}$ is given by barcodes where the intervals have endpoints integers or half integers. We'll refer to these barcodes as the zig-zag persistence barcodes of the zig-zag persistence vector space.*

This theory with applications is discussed in [19] and [20]. Here are some particular situations in which this construction can be used.

1. **Samples:** Given a finite metric space, one can ask to what extent the persistent homology is captured on smaller samples from the data set. For example, suppose that we have taken a very large uniform sample X from the circle, and equip them with a metric by restricting the intrinsic metric (say) on the circle to these points. We will then with high probability find that the one-dimensional persistence barcode for the Vietoris-Rips construction on X will contain one long bar and many much shorter ones. Supposing that we do not actually know that the sample is coming from a circle, but simply observe that we obtain a one-dimensional barcode with one long bar and many shorter ones. A hypothesis suggested by this observation is that the data is obtained by sampling from a space with the homotopy type of the circle, but we may wonder if instead it has somehow appeared "by accident". One way to provide confirmation of our hypothesis would be to observe that we obtain the same result for various subsamples of our space, and that they are compatible in an appropriate sense. Zig-zag persistence provides a way for carrying this out. We suppose that we have chosen samples $X_1, \ldots, X_n \subseteq X$, and create a persistence object in the category of finite metric spaces and distance non-increasing maps

$$\begin{tikzcd}
& X_1 \cap X_2 \arrow[dl] \arrow[dr] & & \cdots \arrow[dl] \arrow[dr] & & X_n \cap X_{n-1} \arrow[dl] \arrow[dr] & \\
X_1 & & X_2 & & X_{n-1} & & X_n.
\end{tikzcd}$$

   If we apply $\mathcal{V}(-, r)$ for a fixed choice of r, guided by the beginning and endpoints of the observed long bar in the barcode for X, we obtain a persistence object in the category of simplicial complexes. If we further apply $H_1(-, K)$ for a field K, we obtain a zig-zag persistence K-vector space. By the classification Theorem 8.8.2 above, we obtain a decomposition of the resulting zig-zag persistence K-vector space. The interpretation of the informal idea that each sample has a one-dimensional homology class and that they are consistent is the presence of an interval K-vector space for a relatively long interval within the set $\{1, \frac{3}{2}, 2, \ldots n - \frac{1}{2}, n\}$, or equivalently a relatively long bar in the zig-zag persistence barcode.

2. **Functions on spaces:** Suppose that we have a topological space X equipped with a continuous map $f : X \to \mathbb{R}_+$. Then we have the ordinary persistence K-vector spaces $\{H_i(f^{-1}([0, r], K)\}_r$, which encode information about the evolution of the homology of the sublevel sets of f as r increases. However, one might be interested in gaining information about approximations to *level sets* instead. They can provide more useful invariants in a number of cases, and are approachable through zig-zag persistent homology. We construct a zig-zag diagram of topological spaces as follows.

$$\begin{tikzcd}
& f^{-1}(1) \arrow[dl] \arrow[dr] & & \cdots \arrow[dl] \arrow[dr] & & f^{-1}(N-1) \arrow[dl] \arrow[dr] & \\
f^{-1}I_0 & & f^{-1}I_1 & & f^{-1}I_{N-2} & & f^{-1}I_{N-1}
\end{tikzcd}$$

   where $I_k = [k, k+1]$ for all k. Again we can apply $H_i(-, K)$ to this diagram, an obtain a zig-zag persistence barcode. It contains information about how the spaces $f^{-1}[k, k+1]$ change as k changes, and how they assemble together. This situation is studied in [20].

3. **Witness complexes:** One of the problems with the witness complex is that we have very little theory about the extent to which it reflects accurately the persistent homology of the underlying metric space. A related problem is that there is no direct relationship between the construction for two different landmark sets. Even if $\mathcal{L}_1 \subseteq \mathcal{L}_2$, there are no maps directly relating $W(X, \mathcal{L}_1, R)$ and $W(X, \mathcal{L}_2, R)$ for two different landmark sets. One approach is to attempt to assess in some manner how consistent the results of the constructions based on $\mathcal{L}_1$ and $\mathcal{L}_2$ are. It turns out that given two landmark sets $\mathcal{L}_1$ and $\mathcal{L}_2$, it is possible to construct an intermediate bivariant construction $W(X, \{\mathcal{L}_1, \mathcal{L}_2\}, R)$ for which there is an evident diagram

$$W(X, \mathcal{L}_1, R) \longleftarrow W(X, \{\mathcal{L}_1, \mathcal{L}_2\}, R) \longrightarrow W(X, \mathcal{L}_2, R).$$

This is itself a short zig-zag diagram of length three, but if we have landmark sets $\{\mathcal{L}_i\}_{i=0}^{N}$ we can clearly construct a longer diagram that includes the bivariant constructions $W(X, \{\mathcal{L}_i, \mathcal{L}_{i+1}\}, R)$ for $i = 0, \ldots, N-1$. The construction is quite simple. Its vertex set is $\mathcal{L}_1 \times \mathcal{L}_2$, and a subset

$$\{l_1^1 \times l_2^1, l_1^2 \times l_2^2, \ldots, l_1^k \times l_2^k\} \subseteq \mathcal{L}_1 \times \mathcal{L}_2$$

spans a simplex in $W(X, \{\mathcal{L}_i, \mathcal{L}_{i+1}\}, R)$ if and only if there is a point $x \in X$ so that x is a witness for $\{l_1^1, l_1^2, \ldots, l_1^k\}$ and $\{l_2^1, l_2^2, \ldots, l_2^k\}$ in the complexes $W(X, \mathcal{L}_1, R)$ and $W(X, \mathcal{L}_1, R)$, respectively. The projections to $W(X, \mathcal{L}_1, R)$ and $W(X, \mathcal{L}_1, R)$ are defined in the evident way.

8.8.3 Multidimensional persistence

There are many situations where it can be useful to introduce families of spaces varying with more than one real parameter. For example, in any kind of topological analysis of data sets, it usually is the case that if one considers the persistent homology of the entire data set, the presence of outliers means that we do not typically obtain the"right homology". For example, if we have data sampled from the unit circle, but a small number of points sprinkled throughout the unit disc, then persistent homology will end up reflecting the homology of the disc rather than that of the circle. This is often circumvented by selecting only the points of sufficient density, as measured by a density estimator, since outliers will typically have very low density. The question then becomes, though, how to choose the threshold for density. Also, it turns out that in general, there will be variation through different topologies as one changes the threshold. The solution to this problem is to attempt to study all thresholds at once, just as we do when considering the scale parameter in the Vietoris-Rips construction. This leads us to the following definition.

Definition 8.8.4. *Let $\underline{C}$ be a category. Then by an n-dimensional persistence object in $\underline{C}$ we mean a functor $\mathbb{R}_+^n \to \underline{C}$, where $\mathbb{R}_+^n$ denotes the n-fold product of copies of the category $\mathbb{R}_+$.*

Example 8.8.5. Let X be any metric space, and suppose that X is equipped with a function $f : X \to \mathbb{R}$. It might be a density estimator, but it might also be a measure of centrality. Then if $X[s]$ denotes the subset $\{x \in X | f(x) \leq s\}$, we obtain family of spaces $\mathcal{V}(X[s], r)$, and by applying homology with coefficients in a field K, we obtain a 2-dimensional persistence K-vector space parametrized by the pair (r, s). While density is used as described above to remove outliers or noise, the case of a centrality measure allows one to capture the presence of the analogues of ends in a finite metric space.

Example 8.8.6. Multidimensional persistent homology can also be used to capture geometric information that is not strictly topological (see [23]). For example, given a Riemannian manifold, one can compute Gaussian curvature at each point and filter by that quantity. Considering the entire manifold, one can obtain a one-dimensional persistence vector space by applying homology over a field K. For computational purposes, though, we would need to deal with a sample and use a second parameter, namely the scale parameter in a Vietoris-Rips complex. This kind of analysis can for example be used to distinguish between various ellipsoids.

The equivalence of categories in Proposition 8.3.1 has the following straightforward analogue.

Proposition 8.8.7. *The category of n-dimensional persistence vector spaces over K is equivalent to the category of $\mathbb{R}^n_+$-graded modules over the $\mathbb{R}^n_+$-graded ring $K[\mathbb{R}^n_+]$. The analogous result with $\mathbb{R}^n_+$ replaced by $\mathbb{N}^n$ also holds.*

Although useful, this result does not give us a classification of multidimensional persistence K-vector spaces analogous to the barcode classification that works in the one-dimensional case. The reason can be understood as analogous to the commutative algebraic situation, where finitely generated $K[x]$-modules can be classified because $K[x]$ is a principal ideal domain, but $K[x_1, \ldots, x_n]$-modules cannot be classified for $n \geq 2$. In a sense it is provable that there is no classification strictly analogous to the $n = 1$ case, because the classification in the case $n \geq 2$ depends on the structure of the field K, as is demonstrated in [22]. This is not the case when $n = 1$, because the classification is always by barcodes, and that is independent of the structure of K.

Although there is no complete classification of multidimensional persistence vector spaces, there exist interesting invariants. For any k-dimensional persistence K-vector space $\{V_x\}_{x \in \mathbb{R}^k}$, and pair of points $x, y \in \mathbb{R}^k$, with $x \leq y$ in the natural partial ordering on $\mathbb{R}^k$, we can define $r(x, y)$ to be the rank of the linear transformation $V_x \to V_y$. We extend the definition to all pairs $x, y \in \mathbb{R}^k$ by setting $r(x, y) = 0$ when x is not less than or equal to y. The function r is therefore defined on $\mathbb{R}^k \times \mathbb{R}^k$, and we refer to it as the *rank invariant*. In the case $k = 1$, the rank invariant is complete, in that it differentiates between distinct barcodes. There is an analogue for multidimensional persistence K-vector spaces of the results described in Section 8.7.2. To state it, we first define an analogue of barcodes. By a *cube* in $\mathbb{R}^k$, we mean a set of the form $I_1 \times I_2 \times \cdots \times I_k$, where each I_s is an interval $[a_s, b_s]$, and write $C(a_1, \ldots, a_k, b_1, \ldots, b_k)$ for this cube. We write $\mathcal{C}_k$ for the set of all k-dimensional cubes. There is a straightforward analogue to the space $\mathfrak{B}$ defined in Section 8.7.1. We first define $B_n = Sp^n(\mathcal{C}_k)$, and define $\mathfrak{B}(k)_+ = \coprod Sp^n(\mathcal{C}_k)$. Next, we say a cube $C(a_1, \ldots, a_k, b_1, \ldots, b_k)$

is *negligible* if $a_i = b_i$ for some i, and define an equivalence relation $\sim$ on $\mathfrak{B}(k)_+$ to be the equivalence relation generated by the relation

$$\{C_1, C_2, \ldots C_n\} \sim \{C_1, \ldots, C_{n-1}\} \text{ for all negligible } C_n.$$

We define $\mathfrak{B}(k)$ to be $\mathfrak{B}(k)_+/\sim$. Every equivalence class under $\sim$ has a unique minimal representative consisting entirely of non-negligible cubes. Let $\mathcal{M}(k)$ denote the set of isomorphism classes of k-dimensional persistence K-vector spaces. For each cube $C = C(a_1, \ldots, a_k, b_1, \ldots, b_k)$ we let $\mu(C)$ denote the isomorphism class of the the k-dimensional persistence K-vector space $\{V_{\vec{x}}\}_{\vec{x} \in \mathbb{R}^k_+}$ for which $V_{\vec{x}} = K$ whenever $\vec{x} \in C$, $V_{\vec{x}} = \{0\}$ whenever $\vec{x} \notin C$, and for which all induced morphisms $V_{\vec{x}} \to V_{\vec{y}}$ for $\vec{x} \leq \vec{y}$ and $\vec{x}, \vec{y} \in C$ are equal to the identity. There is an obvious map $\theta : \mathfrak{B}(k) \to \mathcal{M}(k)$ which assigns to each minimal representative $\{C_1, \ldots, C_n\}$ the direct sum $\oplus_i \mu(C_i)$.

Theorem 8.8.8. [64] *The constructions above satisfy the following properties.*

1. *The set $\mathfrak{B}(k)$ is a subset of the set of real points of an affine scheme Spec(A).*
2. *The ring A is complicated, but there is a $\mathbb{G}_m$-action on Spec(A) that allows us to define a more manageable subring $A^{fin} \subseteq A$.*
3. *A^{fin} is isomorphic to the polynomial ring $\mathbb{R}[x_{\vec{a},\vec{b}}]$ where $\vec{a}$ and $\vec{b}$ are k-vectors of integers for which $a_i \geq 1$ and $b_i \geq 0$ for all i.*
4. *The ring A^{fin} separates points in $\mathfrak{B}(k)$, and maps injectively to the ring of all real valued functions on $\mathfrak{B}(k)$.*
5. *There is a natural lift of the ring homomorphism $A^{fin} \to F(\mathfrak{B}(k), \mathbb{R})$ along θ to a ring homomorphism $j : A^{fin} \to F(\mathcal{M}(k), \mathbb{R})$. $F(X, \mathbb{R})$ denotes the ring of real-valued functions on a set X.*
6. *For any $\alpha \in A^{fin}$, the function $j(\alpha) : \mathcal{M}(k) \to \mathbb{R}$ factors through the rank invariant. For any two elements $X, Y \in \mathcal{M}(k)$, if for all $\alpha \in A^{fin}$, $j(\alpha)(X) = j(\alpha)(Y)$, then the rank invariants of X and Y are equal.*

This result gives one approach to the study of multidimensional persistence. There is a great deal of other work on this topic. The paper [24] deals with computing persistent homology using commutative algebra techniques, via the equivalence of categories from Proposition 8.8.7. They demonstrate that the multigrading yields significant simplification. In [62] and [24], an algebraic framework is constructed for dealing with the fact that there is alway noise in the applications to data analysis. In [14], multidimensional persistence is studied by examining the family of all one dimensional persistence modules obtained by considering lines with varying angles in the persistence domain. M. Lesnick in [49] has defined metric properties of the set of isomorphism classes of multidimensional persistence vector spaces, and proven uniqueness results for them. Finally, in [50], software is developed for visualization and interrogation of two-dimensional persistence vector spaces.

One generalization that has not been studied yet is to multidimensional persistence where some of the persistence directions might be "zig-zag" directions rather than ordinary persistence directions. Formally, this would mean functors from the categories of the form $\mathbb{R}_+^m \times \mathfrak{Z}^n$. This would be very useful in a number of situations. For example, in the zig-zag constructions discussed in Section 8.8 for samples and for witness complexes, we were forced to choose a threshold for the scale parameter. If we had a way of representing functors from $\mathbb{R}_+ \times \mathfrak{Z}$ to vector spaces, we would not be forced to make this selection.

8.9 Coverage and evasion problems

There is an interesting set of technologies used for sensing of various kinds called *sensor nets*. A sensor net consists of a collection of sensors distributed throughout a domain. The sensors are very primitive in the sense that they are only capable of sensing the presence of an intruder or of another sensor within a fixed detection radius R. We also assume each sensor is given an identifying label or number, and that other sensors can sense that identifier when they are within the radius R of each other. One problem of interest is whether or not the balls of radius R cover the domain, and it does not have an immediate solution due to the fact that the positions of the sensors are not available. V. de Silva, and R. Ghrist have developed a very interesting method for addressing this problem based on persistent homology (see [31] and [32]). The rough idea is as follows. Suppose that one has a domain D in the plane, with a connected and compact curve boundary ∂D, that one has a collection of points $\{v_i\}_{i\in I}$ in the region, one for each sensor, and that one knows in some way that ∂D is covered by the open balls $B_R(v_i)$. Let $\mathcal{U}$ denote the family of open subsets $\{B_R(v_i)\cap D\}_{i\in I}$ of D, and let $\mathcal{U}^\partial$ denote the covering $\{B_R(v_i)\cap \partial D\}_{i\in I}$ of ∂D. Suppose further that one knows that spaces

$$B_R(v_{i_1})\cap\cdots\cap B_R(v_{i_s})\cap D \quad\text{and}\quad B_R(v_{i_1})\cap\cdots\cap B_R(v_{i_s})\cap \partial D$$

are all either contractible or empty, for all choices of subsets $\{i_1,\ldots,i_s\}\subseteq I$. The conditions ensure that D is homotopy equivalent to the nerve of $\mathcal{U}$, and that ∂D is homotopy equivalent to the nerve of the covering $\mathcal{U}^\partial$, as a consequence of the nerve theorem. It further ensures that the pair $(N.\mathcal{U}, N.\mathcal{U}^\partial)$ is equivalent to the pair $(D,\partial D)$. For any field, the relative group $H_2(D,\partial D;K)\cong K$, since D is a connected orientable manifold with boundary ∂D, and it follows that the relative group $H_2(N.\mathcal{U}, N.\mathcal{U}^\partial;K)\cong K$. On the other hand, suppose that the sets $B_R(v_i)$ do not cover all of D, and let $D_0\subseteq D$ denote the union

$$\bigcup_i B_r(v_i)\cap D.$$

The space D_0 is a non-compact manifold with boundary, and consequently the relative group $H_2(D_0,\partial D;K)\cong 0$. As above, it will follows that

$$H_2(N.\mathcal{U}, N.\mathcal{U}^\partial;K)\cong 0.$$

Theorem 8.10.6. [8] *For fixed n and k, and $\mathcal{P}$, $\Delta_{\mathcal{P}}(n,k,-)$ is uniformly robust with robustness coefficient r and estimate bound $nr/(1+r)$ for any r.*

It is also possible to obtain a somewhat simpler result, which does not require calculation of the full distribution $\mu(n,k,X)$. Instead of fixing a reference distribution $\mathcal{P}$, we choose a reference barcode $B \in \overline{\mathfrak{B}}$, and define $\Delta_B^{med}(n,k,X)$ to the median of the distribution of $d_B(B,-)$ applied to samples of k-dimensional barcodes attached to samples of size n taken from the metric measure space X.

Theorem 8.10.7. *For fixed n, k, and B, the function $\Delta_B^{med}(n,k,-)$ from finite metric spaces (with uniform probability measure) is robust with robustness coefficient greater than* $\ln 2/n$.

8.10.3 Random fields

Suppose that we have a function f on a manifold. We have seen in Section 8.5 that we can associate to f the persistence vector spaces $\{H_i(f^{-1}((-\infty,r],K)\}_r$ for i a nonnegative integer and K a field, and further that there are stability results that show that small changes in the function f lead to small changes, as measured by the bottleneck distance, in the corresponding sublevel set barcode. One can also ask, though, what the expected behavior of various of the features attached to barcode space is for a class of functions chosen at random. An initial question is what one means by a function chosen at random. The notion of a *random field* is defined in [4] as follows.

Definition 8.10.8. *By a* real-valued random field *on a topological space T we mean a measurable mapping*

$$F : \Omega \to \mathbb{R}^T$$

*where $\mathbb{R}^T$ denotes the set of all real-valued functions on T and $(\Omega, \mathcal{F}, \mathbb{P})$ is a complete probability space. The set $\mathbb{R}^T$ is equipped with the product σ-algebra over the set T. F creates a probability measure on $\mathbb{R}^T$, from which one can sample. Similarly, one can define an s-*dimensional vector-valued random field *as a measurable mapping*

$$F : \Omega \to (\mathbb{R}^T)^s.$$

Remark 8.10.9. Note that the definition does not use the topology of T. However, in much of the work done in this area, one studies additional hypotheses on the random fields in which the topology of T plays a role.

The idea here is that rather than being a function, a random field is an assignment to each $t \in T$ a distribution on $\mathbb{R}$, rather than a fixed value. Each of the restrictions $\mathbb{R}^T \to \mathbb{R}^{\{t\}} \cong \mathbb{R}$ produces a random variable, and therefore the corresponding distribution, which we denote F_t. In fact, for any finite set of points $t_1, \ldots, t_n \in T$, we obtain a distribution on $\mathbb{R}^n$ which we denote $F_{t_1,\ldots,t_n}$. There is a particular class of random fields called the *Gaussian random fields* that is particularly amenable to analysis.

Definition 8.10.10. *A real-valued random field F is a* Gaussian random field *if for all n, the n-dimensional distributions $F_{t_1,\ldots,t_n}$ are multivariate Gaussian distributions on $\mathbb{R}^n$.*

An s-dimensional random field is Gaussian, if all the distributions $F_{t_1,\ldots,t_n}$ are multivariate Gaussian distributions on $\mathbb{R}^{n\times s}$. Note that in Gaussian fields, the behavior of the random function is completely determined by the expectation function $m(t) = E(F_{t_1,\ldots,t_n})$, and the covariance function C.

The first example of this construction comes out of work of Wiener (see [67] and [6]), using analysis of Brownian motion. Wiener studied the case $T = \mathbb{R}_+$, and produced a Gaussian random field W, where the expected value of W_t is always $= 0$ and the variance is given by $C(s,t) = \min(s,t)$. He also showed that when one samples from the associated measure on $\mathbb{R}^{\mathbb{R}_+}$, one obtains continuous functions with probability 1, and so one calls W a *continuous Gaussian field.* Given any analytic property of functions on manifolds, such as k-th order differentiability, smoothness, or the property of being a Morse function, one can create and study Gaussian random fields whose samples have the given property with probability 1. Further, there are frequently a priori conditions on the covariance function of the random field that can be readily verified and guarantee the satisfaction of such properties.

The paper [9] proves a result concerning the persistent homology of the sublevel sets of functions sampled from Gaussian random fields. We consider the real-valued function σ on barcodes given by

$$\sigma\{[a_1,b_1],\ldots,[a_n,b_n]\} = \sum_i (b_i - a_i).$$

For any fixed $x \in \mathbb{R}$ and barcode $\beta = \{[a_1,b_1],\ldots,[a_n,b_n]\}$, we define the *$x$-truncation of β*, $\beta[x]$, to be the barcode

$$\{[a_1,\min(b_1,x)],\ldots,[a_n,\min(b_n,x)]\}$$

where it is understood that for any i such that $x \leq a_i$, the interval $[a_i,b_i]$ is simply deleted. Finally, we define

$$\chi^{pers}(M,f,x) = \sum_{i=0}^{\infty}(-1)^i\sigma(\{H_i(f^{-1}((-\infty,r],K)\}_r[x]).$$

In [9], the following result is proved concerning the distribution of $\chi^{pers}(M,f,x)$ for Gaussian random fields on Riemannian manifolds which produce Morse functions with probability one.

Theorem 8.10.11. *Let M be a closed d-dimensional Riemannian manifold, and let F be a smooth real valued Gaussian random field so that F is Morse with probability 1, and so that the mean is identically zero and the variance is identically equal to 1. Then for any $x \in \mathbb{R}$, we have*

$$\mathbb{E}\{\chi^{pers}(M,f,x)\} = \chi(M)(\varphi(x) + x\Phi(x)) + \varphi(x)\sum_{j=1}^{d}(2\pi)^{-j/2}\mathcal{L}_j(M)H_{j-2}(-x)$$

where

1. *H_n denotes the n-th Hermite polynomial.*
2. *$\varphi(x) = (2\pi)^{-1/2}e^{-x^2/2}$ is the density function for the standard Gaussian distribution.*

3. $\Phi(x) = \int_{-\infty}^{x} \varphi(u)du$.

4. $\mathcal{L}_j(M)$ *denotes the* j*-th Lipschitz-Killing curvature of* M *(defined for example in [4], Section 7.6) with respect to a metric constructed from the covariance metric attached to* F.

Remark 8.10.12. The point of this result is that it gives a theoretical estimate for the persistent Euler characteristic of sublevel sets in terms of classical invariants of the manifols. Also, the result in [9] is actually proved in a much more general context, that of regular stratified spaces and stratified Morse theory, which in particular permits the study of manifolds with boundary. It also includes the study of random fields that are of the form $G \circ (F_1, \ldots, F_k)$, where G is a deterministic function from $\mathbb{R}^k$ to $\mathbb{R}$, and $(F_1, \ldots, F_k)$ is a vector-valued Gaussian random field.

and the first half of the 1700s. The first examples involved arc lengths of ellipses and led to the name "elliptic integrals." In the mid-1700s, Leonhard Euler revolutionized the study of elliptic integrals by establishing the identity

$$\int_a^{x_1} g(t)^{-1/2}\,dt + \int_a^{x_2} g(t)^{-1/2}\,dt = \int_a^{x_3} g(t)^{-1/2}\,dt \tag{8}$$

for any polynomial $g(t)$ of degree 3 of 4, where x_3 is a rational function of x_1, x_2, a, $g(x_1)^{1/2}$, $g(x_2)^{1/2}$, $g(a)^{1/2}$.

Certain cubics are now called "elliptic curves" because of their connection with elliptic integrals. This connection was discovered by Gauss, Niels Abel, and Carl Jacobi in the 1820s. Their results were clarified and extended by Riemann in the 1850s, Weierstrass in 1863, and Henri Poincaré in 1901. We summarize a small part of this work below.

Let

$$g(t) = 4t^3 + ct + d$$

be a polynomial of degree 3 without repeated roots. The Weierstrass P-function

$$x = P(u) \tag{9}$$

parametrizes the nonsingular, irreducible complex cubic

$$y^2 = g(x) \tag{10}$$

in the following sense: Equation (9) and the equation

$$y = P'(u) \tag{11}$$

match up the complex numbers u on and inside a parallelogram in the complex plane with the points (x, y) of the complex cubic (10), except that any two complex numbers u in corresponding positions on opposite sides of the parallelogram map to the same point (x, y). The function $P(u)$ can be written in the form

$$P(u) = \frac{1}{u^2} + a_2u^2 + a_4u^4 + \cdots$$

for complex numbers a_2, a_4, ...

Equations (9)–(11) imply that

$$\frac{dx}{du} = P'(u) = y = g(x)^{1/2},$$

and taking reciprocals gives

$$\frac{du}{dx} = g(x)^{-1/2}.$$

know this result for polynomials in two variables over the complex numbers, since Theorem 15.7 applies to the homogenizations.

Theorem 16.11 is a version of Gauss's Lemma, a standard result in abstract algebra. We continue to work over the real numbers except where we state otherwise.

Theorem 16.11
Let $f(u, w, x)$ *and* $g(u, w, x)$ *be polynomials in indeterminates* u, w, *and* x, *and let* $b(u, w)$ *be an irreducible polynomial in* u *and* w. *If neither* $f(u, w, x)$ *nor* $g(u, w, x)$ *has* $b(u, w)$ *as a factor, then neither does* $f(u, w, x)g(u, w, x)$.

know this result for polynomials in two variables over the complex numbers, since Theorem 15.7 applies to the homogenizations.

Theorem 16.11 is a version of Gauss's Lemma, a standard result in abstract algebra. We continue to work over the real numbers except where we state otherwise.

Theorem 16.11
Let $f(u,w,x)$ and $g(u,w,x)$ be polynomials in indeterminates u, w, and x, and let $b(u,w)$ be an irreducible polynomial in u and w. If neither $f(u,w,x)$ nor $g(u,w,x)$ has $b(u,w)$ as a factor, then neither does $f(u,w,x)g(u,w,x)$.

Proof
Collecting terms by powers of x gives

$$f(u,w,x)=\sum c_i(u,w)x^i \qquad \text{and} \qquad g(u,w,x)=\sum d_i(u,w)x^i$$

for polynomials c_i and d_i in u and w. Because neither f nor g has $b(u,w)$ as a factor, we can let k and l be the smallest integers such that $c_k(u,w)$ and $d_l(u,w)$ do not have $b(u,w)$ as a factor over the real numbers. Over the complex numbers, neither $c_k(u,w)$ nor $d_l(u,w)$ has an irreducible factor in common with $b(u,w)$ (by Theorem 11.9), and so neither does $c_k(u,w)d_l(u,w)$ (by Theorem 15.7 applied to the homogenizations). Thus, $b(u,w)$ is not a factor of $c_k(u,w)d_l(u,w)$.

We write

$$f(u,w,x)g(u,w,x)=\sum e_i(u,w)x^i \tag{88}$$

for polynomials e_i in u and w. The coefficient $e_{k+l}(u,w)$ of x^{k+l} is

$$\begin{aligned}&c_kd_l+c_{k-1}d_{l+1}+c_{k-2}d_{l+2}+\cdots\\&\qquad+c_{k+1}d_{l-1}+c_{k+2}d_{l-2}+\cdots.\end{aligned}$$

Because b is a factor of $c_{k-1},\ldots,c_0$ and $d_{l-1},\ldots,d_0$, it is not a factor of e_{k+l}: if it were, then it would be a factor of

$$\begin{aligned}&e_{k+l}-c_{k-1}d_{l+1}-c_{k-2}d_{l+2}-\cdots\\&\qquad-c_{k+1}d_{l-1}-c_{k+2}d_{l-2}-\cdots=c_kd_l,\end{aligned}$$

contradicting the previous paragraph. It follows from (88) that $b(u,w)$ is not a factor of fg. □

Applying the previous theorem repeatedly gives another special case not of the result that polynomials factor uniquely.

Theorem 16.12
Let $p(u,w,x)$ and $f(u,w,x)$ be polynomials in indeterminates u, w, and x, and let $b(u,w)$ be a nonzero polynomial that does not involve x. If f is irreducible and a factor of bp, then it is a factor of b or p.

peatedly can produce any number of points of C with rational coordinates from just one. This addresses a central problem of number theory, finding the rational solutions of equations. An ad hoc algebraic version of the tangent–secant construction was introduced by Diophantus, who lived in Alexandria during the third century A.D. Fermat systematized the construction algebraically, and Newton interpreted it geometrically in terms of tangents and secants.

Complex numbers were introduced in the 1500s to solve cubic equations in one variable. They were reintroduced in the 1700s to facilitate integration by partial fractions. Mathematicians gradually developed proficiency in working with complex numbers, and their confidence increased when Carl Friedrich Gauss gave four proofs of the Fundamental Theorem of Algebra in the first decade of the 1800s. Jean d'Alembert had given an incomplete proof of the Fundamental Theorem in 1746. The main gap in his proof was filled in 1806 when Jean Argand proved a result generally called "d'Alembert's Lemma" (Claim 5 of Section 10). In fact, no truly complete proof of the Fundamental Theorem could be given until the 1870s, when Georg Cantor and Richard Dedekind developed the real numbers formally and Karl Weierstrass derived the basic properties of continuous functions. The proof in Section 10 of the Fundamental Theorem is based on the paper of Charles Fefferman cited in the References, which modernizes and simplifies the work of d'Alembert and Argand.

The idea of a complex curve—an algebraic curve whose coefficients and variables are complex numbers—emerged over centuries. Analytic geometers from Newton onward considered "imaginary points" on curves without clearly specfying the nature of these points. In the 1820s, Jean Poncelet and Michel Chasles argued for using imaginary points systematically in synthetic projective geometry. In 1830, Plücker clarified the nature of imaginary points when the homogeneous coordinates he introduced made it possible to consider points with complex coordinates. Nevertheless, complex curves were not generally considered natural objects of study until Georg Riemann proposed in 1851 a way to consider them topologically: the "Riemann surface" of a polynomial equation $f(w, z) = 0$ consists of sheets that lie over the complex z-plane and correspond to the values of w determined by the equation. In the 1860s, Alfred Clebsch and Paul Gordan recast Riemann's ideas from complex analytic to geometric form, and the modern view of complex curves was established.

"Elliptic integrals" are, speaking roughly, integrals that involve the square root of a polynomial of degree 3 or 4. Unlike integrals that involve the square root of a polynomial of degree 2, elliptic integrals cannot generally be evaluated in closed form. Examples of elliptic integrals arose from scientific and geometric considerations in the last half of the 1600s

III

CHAPTER

Cubics

Introduction and History

Introduction

This chapter is devoted to classifying irreducible cubics. These are curves of degree 3 given by polynomials that do not have factors of degree 1 or 2. We prove that every irreducible cubic can be transformed into the form

$$y^2 = x^3 + fx^2 + gx + h \tag{1}$$

for real numbers f, g, h.

The proof has two main steps. First, we prove in Section 8 that an irreducible cubic C can be transformed into (1) if it has a flex (i.e., a generalized inflection point) or a singular point. Second, we prove in Section 12 that there is a flex on every irreducible cubic that is nonsingular (i.e., has no singular points), and so the previous sentence applies to all irreducible cubics.

In Section 9, we interrupt our work on the classification of cubics to discuss one of their most important properties. We use collinearity of points to define addition on a nonsingular, irreducible cubic C that has a flex O. This definition makes C an abelian group, which means that the sum of two points of C is again a point of C, addition is commutative and associative, O is an identity element, and every point of C has an additive inverse. A central problem in number theory is to determine the set C^* of points of C that have rational coordinates, when C is given by (1) for rational numbers f, g, h. The key to this problem is to observe that C^* is itself a group whose structure can be analyzed.

Sections 10 and 11 lay the groundwork for us to complete the classification of cubics in Section 12. We introduce the complex numbers in Section 10 and prove the Fundamental Theorem of Algebra, which states that every polynomial in one variable factors completely over the complex numbers. We introduce points with complex coordinates in Section 11. The Fundamental Theorem of Algebra ensures that curves have "as many intersections as possible" over the complex numbers. This yields Bezout's Theorem, which states that the number of times that two curves without a common factor intersect in the complex projective plane is the product of their degrees.

We complete the classification of irreducible cubics in Section 12 by proving that every nonsingular, irreducible cubic C has a flex. The Hessian H of C is a cubic formed from the second partial derivatives of C. The points of intersection of C and H are the flexes of C. We use Bezout's Theorem from Section 11 to prove that C and H intersect exactly nine times, counting multiplicities, over the complex numbers. Because nine is odd, and because the intersections of C and H over the complex numbers are interchanged in pairs by conjugating their coordinates, it follows that C and H intersect at least once over the real numbers. Thus, every nonsingular, irreducible cubic C has a flex over the real numbers, as desired.

We end the chapter by asking how many points determine a cubic. We seek an analogue of Theorem 5.10, which says that a conic is uniquely determined by five points, no three collinear. Because the equation of the general cubic

$$\begin{aligned} &ax^3 + bx^2y + cxy^2 + dy^3 + ex^2 + fxy + gy^2 \\ &\quad + hx + iy + j = 0 \end{aligned}$$

has ten coefficients but can be multiplied by a nonzero constant, cubics have nine "degrees of freedom." This suggests that nine points generally lie on a unique cubic, and we see in Section 13 when they do.

History

Newton's classification of cubics in the late 1600s was the first great success of analytic geometry apart from its role in calculus. Newton claimed that the equation of every cubic in the Euclidean plane could be simplified to one of the forms

$$xy^2 + ey = ax^3 + bx^2 + cx + d, \tag{2}$$

$$xy = ax^3 + bx^2 + cx + d, \tag{3}$$

$$y^2 = ax^3 + bx^2 + cx + d, \tag{4}$$

$$y = ax^3 + bx^2 + cx + d, \tag{5}$$

by an appropriate choice of the coordinate axes, which were not required to be perpendicular in Newton's time. James Stirling published a proof of Newton's claim in 1717, possibly in collaboration with Newton. The key to Stirling's proof is to consider the family of chords of the cubic parallel to an asymptote, find the locus of the midpoints of the chords, and choose coordinate axes to simplify the equation of the locus.

Newton multiplied (2) by x and completed the square of the left-hand side to obtain the equation

$$(xy + \tfrac{1}{2}e)^2 = ax^4 + bx^3 + cx^2 + dx + \tfrac{1}{4}e^2. \tag{6}$$

By considering the roots of the right-hand sides of (2)–(6), he divided cubics into 72 species. Stirling identified four more species, and Jean-Paul de Gua de Malves found another two in 1740, giving a total of 78 species of cubics.

Newton also made the remarkable assertion that all cubics could be obtained from those in (4) by projecting between planes. This chapter centers around proving Newton's assertion for irreducible cubics, with the change that projections are replaced by their algebraic equivalent, transformations.

The first proofs of Newton's assertion appeared in 1731, due independently to Alexis Clairaut and Francois Nicole. Clairaut considered the graph of the equation

$$zy^2 = ax^3 + bx^2z + cxz^2 + dz^3 \tag{7}$$

in three-dimensional-Euclidean space. Equation (7) is homogeneous and yields (4) when we set $z = 1$. It follows that (7) describes a cubical cone having the origin as vertex; that is, the graph consists of the lines joining the origin to the cubic given by (4) in the plane $z = 1$. Clairaut showed that every cubic in (2)–(5) is the intersection of a plane and a cubical cone given by (7), which proves Newton's assertion.

Among the important attributes of cubics are flexes, which are generalizations of inflection points. Clairaut asserted in 1731 that an irreducible cubic has from one through three inflection points over the real numbers (Exercises 12.8 and 12.18). For irreducible cubics having three inflection points, de Gua proved in 1740 that the inflection points are collinear (Exercises 8.6 and 9.2(c)). Plücker argued in 1834 that a nonsingular cubic has nine flexes over the complex numbers that lie by threes on twelve lines (Exercise 12.24). His argument was completed in 1844 by Ludwig Hesse, who characterized flexes with a determinant of second partial derivatives that is now called a Hessian (Theorem 12.4).

Suppose that the cubic C in (1) has rational coefficients. If we take the tangent line through a point of C with rational coordinates, or if we take the secant line through two points of C with rational coordinates, the line intersects C at another point that has rational coordinates, as we discuss in Section 9. Applying this tangent–secant construction repeatedly can produce any number of points of C with rational coordinates from just one. This addresses a central problem of number theory, finding the rational solutions of equations. An ad hoc algebraic version of the tangent–secant construction was introduced by Diophantus, who lived in Alexandria during the third century A.D. Fermat systematized the construction algebraically, and Newton interpreted it geometrically in terms of tangents and secants.

Complex numbers were introduced in the 1500s to solve cubic equations in one variable. They were reintroduced in the 1700s to facilitate integration by partial fractions. Mathematicians gradually developed proficiency in working with complex numbers, and their confidence increased when Carl Friedrich Gauss gave four proofs of the Fundamental Theorem of Algebra in the first decade of the 1800s. Jean d'Alembert had given an incomplete proof of the Fundamental Theorem in 1746. The main gap in his proof was filled in 1806 when Jean Argand proved a result generally called "d'Alembert's Lemma" (Claim 5 of Section 10). In fact, no truly complete proof of the Fundamental Theorem could be given until the 1870s, when Georg Cantor and Richard Dedekind developed the real numbers formally and Karl Weierstrass derived the basic properties of continuous functions. The proof in Section 10 of the Fundamental Theorem is based on the paper of Charles Fefferman cited in the References, which modernizes and simplifies the work of d'Alembert and Argand.

The idea of a complex curve—an algebraic curve whose coefficients and variables are complex numbers—emerged over centuries. Analytic geometers from Newton onward considered "imaginary points" on curves without clearly specfying the nature of these points. In the 1820s, Jean Poncelet and Michel Chasles argued for using imaginary points systematically in synthetic projective geometry. In 1830, Plücker clarified the nature of imaginary points when the homogeneous coordinates he introduced made it possible to consider points with complex coordinates. Nevertheless, complex curves were not generally considered natural objects of study until Georg Riemann proposed in 1851 a way to consider them topologically: the "Riemann surface" of a polynomial equation $f(w, z) = 0$ consists of sheets that lie over the complex z-plane and correspond to the values of w determined by the equation. In the 1860s, Alfred Clebsch and Paul Gordan recast Riemann's ideas from complex analytic to geometric form, and the modern view of complex curves was established.

"Elliptic integrals" are, speaking roughly, integrals that involve the square root of a polynomial of degree 3 or 4. Unlike integrals that involve the square root of a polynomial of degree 2, elliptic integrals cannot generally be evaluated in closed form. Examples of elliptic integrals arose from scientific and geometric considerations in the last half of the 1600s and the first half of the 1700s. The first examples involved arc lengths of ellipses and led to the name "elliptic integrals." In the mid-1700s, Leonhard Euler revolutionized the study of elliptic integrals by establishing the identity

$$\int_a^{x_1} g(t)^{-1/2}\,dt + \int_a^{x_2} g(t)^{-1/2}\,dt = \int_a^{x_3} g(t)^{-1/2}\,dt \tag{8}$$

for any polynomial $g(t)$ of degree 3 of 4, where x_3 is a rational function of x_1, x_2, a, $g(x_1)^{1/2}$, $g(x_2)^{1/2}$, $g(a)^{1/2}$.

Certain cubics are now called "elliptic curves" because of their connection with elliptic integrals. This connection was discovered by Gauss, Niels Abel, and Carl Jacobi in the 1820s. Their results were clarified and extended by Riemann in the 1850s, Weierstrass in 1863, and Henri Poincaré in 1901. We summarize a small part of this work below.

Let

$$g(t) = 4t^3 + ct + d$$

be a polynomial of degree 3 without repeated roots. The Weierstrass P-function

$$x = P(u) \tag{9}$$

parametrizes the nonsingular, irreducible complex cubic

$$y^2 = g(x) \tag{10}$$

in the following sense: Equation (9) and the equation

$$y = P'(u) \tag{11}$$

match up the complex numbers u on and inside a parallelogram in the complex plane with the points (x, y) of the complex cubic (10), except that any two complex numbers u in corresponding positions on opposite sides of the parallelogram map to the same point (x, y). The function $P(u)$ can be written in the form

$$P(u) = \frac{1}{u^2} + a_2u^2 + a_4u^4 + \cdots$$

for complex numbers a_2, a_4, ...

Equations (9)–(11) imply that

$$\frac{dx}{du} = P'(u) = y = g(x)^{1/2},$$

and taking reciprocals gives

$$\frac{du}{dx} = g(x)^{-1/2}.$$

This implies that

$$u = \int g(x)^{-1/2}\,dx, \tag{12}$$

which means that u is a multivalued indefinite integral of the two-valued function $g(x)^{-1/2}$ of the complex variable x. In short, we obtain the Weierstrass P-function in (9) by inverting the elliptic integral in (12) and considering x as a function of u.

The idea of parametrizing the complex cubic in (10) by inverting the elliptic integral in (12) arose by drawing analogies with the following familiar facts: the unit circle

$$y^2 = 1 - x^2 \tag{13}$$

is parametrized by setting

$$x = \sin(u) \tag{14}$$

and

$$y = \sin'(u) = \cos(u), \tag{15}$$

where the relation given by (14) is the inverse of the relation

$$u = \arcsin(x) = \int_0^x (1 - t^2)^{-1/2}\,dt. \tag{16}$$

Drawing parallels between the cubic $g(t)$ and the quadratic $1 - t^2$ and between the Weierstrass P-function $x = P(u)$ and the sine function $x = \sin(u)$ creates analogies between (9) and (14), (10) and (13), (11) and (15), and (12) and (16).

In Section 9, we use secants and tangents to define addition of points on a nonsingular cubic given by (10). This method of adding points on the cubic corresponds via the Weierstrass P-function to addition of complex numbers. Specifically, for any complex numbers u_1 and u_2, the point of the complex cubic (10) that corresponds via (9) and (11) to the complex number $u_1 + u_2$ is the sum of the points on the complex cubic that correspond to u_1 and u_2. This is the geometric form of Euler's relation (8). It corresponds to the angle-addition formula for sines via the analogies in the previous paragraph.

The discussion accompanying (9)–(11) shows that the points of a nonsingular complex cubic correspond to the points of a parallelogram whose two pairs of opposite sides are glued together. Gluing together one pair of opposite sides of a parallelogram gives a cylinder. Gluing together the opposite ends of the cylinder gives a torus—the surface of a doughnut. Thus, a nonsingular complex cubic is topologically equivalent to a torus; that is, it can be continuously bent into the surface of a doughnut.

A nonsingular curve $f(x, y) = 0$ over the real numbers can be divided into pieces that are each parametrized by x or y. For example, the unit circle $x^2 + y^2 = 1$ can be divided into the upper and lower half-circles

$$y = (1 - x^2)^{1/2} \qquad \text{and} \qquad y = -(1 - x^2)^{1/2},$$

which are each parametrized by x. The analogous result holds over the complex numbers. In this sense, we can think of complex curves as "one-dimensional over the complex numbers." On the other hand, the complex numbers are themselves two-dimensional over the reals. That explains why a nonsingular complex cubic is topologically equivalent to a two-dimensional surface, the torus. In this text, we always think of complex curves as "one-dimensional over the complex numbers." We work with complex curves algebraically just like real curves.

Colin Maclaurin raised the following issue in 1720. On the one hand, requiring a curve to contain a particular point imposes a linear condition on the coefficients of the curve. A general curve of degree n has $\binom{n+2}{2}$ coefficients. Because we can multiply the coefficients by a nonzero number without changing the curve, a curve of degree n has

$$\binom{n+2}{2} - 1 = \frac{(n+2)(n+1)}{2} - 1 = \frac{n(n+3)}{2}$$

"degrees of freedom." Accordingly, we expect that a curve of degree n is uniquely determined by $n(n+3)/2$ of its points. On the other hand, Bezout's Theorem shows that two complex curves of degree n without multiple intersections intersect at n^2 points. The last two sentences appear to conflict because

$$n^2 \geq n(n+3)/2$$

for $n \geq 3$.

This apparent difficulty was explored by Leonhard Euler in 1748 and by Gabriel Cramer in 1750, and it is now known as "Cramer's paradox." Euler and Cramer suggested that there may be redundancies among the conditions that points impose on curves. We examine this idea for cubics in Section 13. Taking $n = 3$ in the first part of the previous paragraph shows that a cubic is uniquely determined by $n(n+3)/2 = 9$ conditions, provided that the conditions are not redundant. In fact, the $n^2 = 9$ points where two cubics intersect impose redundant conditions—otherwise, the points would not lie on two cubics. If two cubics intersect in nine points, any cubic through eight of the points necessarily contains the ninth, as Exercise 13.4 shows. If nine points are to determine a unique cubic, we show in Section 13 that we can choose eight of the points quite generally, but we must ensure that the ninth point does not lie on every cubic through the first eight.

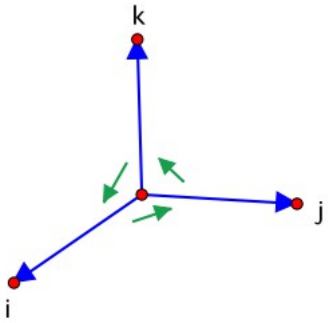

Figure 2.15: The circle of life: $\mathbf{i} \times \mathbf{j} = \mathbf{k}, \quad \mathbf{j} \times \mathbf{k} = \mathbf{i}, \quad \mathbf{k} \times \mathbf{i} = \mathbf{j}$

2.6 The geometry of space curves: Frenet vectors

We take up the following question: *How can one tell when two curves in $\mathbb{R}^3$ are congruent, that is, either curve can be translated, rotated and/or reflected so that it fits exactly on top of the other?* As mentioned earlier, the main idea is to construct a basis of orthogonal unit vectors that moves along the curve and then to study how the basis vectors change during the motion.

So let C be a curve in $\mathbb{R}^3$, parametrized by a differentiable path $\alpha\colon I \to \mathbb{R}^3$, where I is an interval in $\mathbb{R}$. In Section 2.4, we defined two of the vectors in our moving basis:

- the unit tangent vector $\mathbf{T}(t) = \frac{1}{\|\alpha'(t)\|}\alpha'(t) = \frac{1}{v(t)}\mathbf{v}(t)$ and
- the principal normal vector $\mathbf{N}(t) = \frac{1}{\|\mathbf{T}'(t)\|}\mathbf{T}'(t)$.

These definitions make sense only if $\alpha'(t) \neq \mathbf{0}$ and $\mathbf{T}'(t) \neq \mathbf{0}$, so we assume that this is the case from now on. Both $\mathbf{T}(t)$ and $\mathbf{N}(t)$ are constructed to be unit vectors, and we showed before that $\mathbf{T}(t) \cdot \mathbf{N}(t) = 0$. At this point, the third basis vector is easily defined.

Definition. The cross product $\mathbf{B}(t) = \mathbf{T}(t) \times \mathbf{N}(t)$ is called the **binormal vector**.

fingers of your right hand from $\mathbf{i}$ to $\mathbf{j}$, your thumb points in the direction of $\mathbf{k}$. This is not so much a fact as it is an agreement: whenever we draw $\mathbb{R}^3$, we agree to orient the positive x, y, and z-axes so that the right-hand rule for $(\mathbf{i}, \mathbf{j}, \mathbf{k})$ is satisfied, as in Figure 2.15. As we continue with further material, figures in $\mathbb{R}^3$ become increasingly prominent, so it is probably good to state this convention explicitly.

More generally, given a basis $(\mathbf{v}, \mathbf{w}, \mathbf{z})$ of $\mathbb{R}^3$, the plane $\mathcal{P}$ spanned by $\mathbf{v}$ and $\mathbf{w}$ separates $\mathbb{R}^3$ into two half-spaces, or "sides." Once we adopt the right-hand rule for $(\mathbf{i}, \mathbf{j}, \mathbf{k})$, it turns out that $(\mathbf{v}, \mathbf{w}, \mathbf{z})$ is right-handed in the sense of the definition if and only if, when you rotate the fingers of your right hand from $\mathbf{v}$ to $\mathbf{w}$, your thumb lies on the same side of $\mathcal{P}$ as $\mathbf{z}$. In particular, by Proposition 2.19, your thumb lies on the same side as $\mathbf{v} \times \mathbf{w}$. In this way, your right thumb gives the direction of $\mathbf{v} \times \mathbf{w}$.

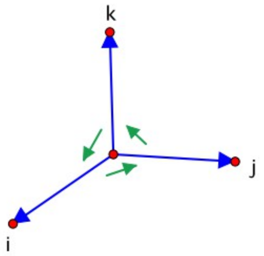

Figure 2.15: The circle of life: $\mathbf{i} \times \mathbf{j} = \mathbf{k}$, $\mathbf{j} \times \mathbf{k} = \mathbf{i}$, $\mathbf{k} \times \mathbf{i} = \mathbf{j}$

Proving the connection between the sign of a determinant and the right-hand rule would be too great a digression. One approach uses the continuity of the determinant and the geometry of rotations to show that, if the rule works for $(\mathbf{i}, \mathbf{j}, \mathbf{k})$, then it works in general. In any case, the right-hand rule is sometimes a convenient way to find cross products geometrically. For instance, in addition to $\mathbf{i} \times \mathbf{j} = \mathbf{k}$, it allows us to see that $\mathbf{j} \times \mathbf{k} = \mathbf{i}$, not $-\mathbf{i}$, and that $\mathbf{k} \times \mathbf{i} = \mathbf{j}$, as pictured in Figure 2.15.

2.6 The geometry of space curves: Frenet vectors

We take up the following question: *How can one tell when two curves in $\mathbb{R}^3$ are congruent, that is, either curve can be translated, rotated and/or reflected so that it fits exactly on top of the other?* As mentioned earlier, the main idea is to construct a basis of orthogonal unit vectors that moves along the curve and then to study how the basis vectors change during the motion.

So let C be a curve in $\mathbb{R}^3$, parametrized by a differentiable path $\alpha \colon I \to \mathbb{R}^3$, where I is an interval in $\mathbb{R}$. In Section 2.4, we defined two of the vectors in our moving basis:

- the unit tangent vector $\mathbf{T}(t) = \frac{1}{\|\alpha'(t)\|}\alpha'(t) = \frac{1}{v(t)}\mathbf{v}(t)$ and
- the principal normal vector $\mathbf{N}(t) = \frac{1}{\|\mathbf{T}'(t)\|}\mathbf{T}'(t)$.

These definitions make sense only if $\alpha'(t) \neq \mathbf{0}$ and $\mathbf{T}'(t) \neq \mathbf{0}$, so we assume that this is the case from now on. Both $\mathbf{T}(t)$ and $\mathbf{N}(t)$ are constructed to be unit vectors, and we showed before that $\mathbf{T}(t) \cdot \mathbf{N}(t) = 0$. At this point, the third basis vector is easily defined.

Definition. The cross product $\mathbf{B}(t) = \mathbf{T}(t) \times \mathbf{N}(t)$ is called the **binormal vector**.

As a cross product, $\mathbf{B}(t)$ is orthogonal to $\mathbf{T}(t)$ and $\mathbf{N}(t)$. Moreover, its length is $\|\mathbf{B}(t)\| = \|\mathbf{T}(t)\|\,\|\mathbf{N}(t)\|\,\sin\theta = 1\cdot 1\cdot \sin\frac{\pi}{2} = 1$. Thus $(\mathbf{T}(t), \mathbf{N}(t), \mathbf{B}(t))$ is a set of orthogonal unit vectors. The vectors are called the **Frenet vectors** of α and are illustrated in Figure 2.16.

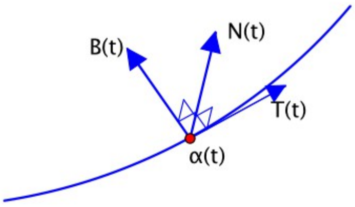

Figure 2.16: The Frenet vectors $\mathbf{T}(t)$, $\mathbf{N}(t)$, $\mathbf{B}(t)$

Example 2.20 (The Frenet vectors of a helix)**.** We shall use the helix

$$\alpha(t) = (a\cos t, a\sin t, bt)$$

as a running example to illustrate new concepts as they arise. Here, a and b are constant and $a > 0$. Recall that the helix is called right-handed if $b > 0$ and left-handed if $b < 0$. If $b = 0$, the curve collapses to a circle of radius a in the xy-plane.

To find the Frenet vectors $\mathbf{T}(t)$, $\mathbf{N}(t)$, and $\mathbf{B}(t)$ of the helix, we simply and carefully follow the definitions.
Unit tangent: $\alpha'(t) = (-a\sin t, a\cos t, b)$, so $\|\alpha'(t)\| = \sqrt{a^2\sin^2 t + a^2\cos^2 t + b^2} = \sqrt{a^2+b^2}$. Thus:

$$\mathbf{T}(t) = \frac{1}{\|\alpha'(t)\|}\alpha'(t) = \frac{1}{\sqrt{a^2+b^2}}(-a\sin t, a\cos t, b).$$

Principal normal: From the last calculation, $\mathbf{T}'(t) = \frac{1}{\sqrt{a^2+b^2}}(-a\cos t, -a\sin t, 0)$, so $\|\mathbf{T}'(t)\| = \frac{1}{\sqrt{a^2+b^2}}\sqrt{a^2\cos^2 t + a^2\sin^2 t + 0^2} = \frac{a}{\sqrt{a^2+b^2}}$. Hence:

$$\begin{aligned}\mathbf{N}(t) = \frac{1}{\|\mathbf{T}'(t)\|}\mathbf{T}'(t) &= \frac{1}{\frac{a}{\sqrt{a^2+b^2}}}\cdot\frac{1}{\sqrt{a^2+b^2}}(-a\cos t, -a\sin t, 0)\\ &= \frac{1}{a}(-a\cos t, -a\sin t, 0)\\ &= (-\cos t, -\sin t, 0).\end{aligned}$$

Binormal: Lastly:

$$\begin{aligned}\mathbf{B}(t) = \mathbf{T}(t)\times\mathbf{N}(t) &= \det\begin{bmatrix}\mathbf{i} & \mathbf{j} & \mathbf{k}\\ -\frac{a\sin t}{\sqrt{a^2+b^2}} & \frac{a\cos t}{\sqrt{a^2+b^2}} & \frac{b}{\sqrt{a^2+b^2}}\\ -\cos t & -\sin t & 0\end{bmatrix}\\ &= \mathbf{i}\Big(\frac{b\sin t}{\sqrt{a^2+b^2}}\Big) - \mathbf{j}\Big(\frac{b\cos t}{\sqrt{a^2+b^2}}\Big) + \mathbf{k}\Big(\frac{a\sin^2 t}{\sqrt{a^2+b^2}} + \frac{a\cos^2 t}{\sqrt{a^2+b^2}}\Big)\\ &= \frac{1}{\sqrt{a^2+b^2}}\big(b\sin t, -b\cos t, a\big).\end{aligned}$$

8. Orthogonality

In Section 5.3 we introduced the dot product in $\mathbb{R}^n$ and extended the basic geometric notions of length and distance. A set $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ of nonzero vectors in $\mathbb{R}^n$ was called an **orthogonal set** if $\mathbf{f}_i \cdot \mathbf{f}_j = 0$ for all $i \neq j$, and it was proved that every orthogonal set is independent. In particular, it was observed that the expansion of a vector as a linear combination of orthogonal basis vectors is easy to obtain because formulas exist for the coefficients. Hence the orthogonal bases are the "nice" bases, and much of this chapter is devoted to extending results about bases to orthogonal bases. This leads to some very powerful methods and theorems. Our first task is to show that every subspace of $\mathbb{R}^n$ *has* an orthogonal basis.

8. Orthogonality

In Section 5.3 we introduced the dot product in $\mathbb{R}^n$ and extended the basic geometric notions of length and distance. A set $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ of nonzero vectors in $\mathbb{R}^n$ was called an **orthogonal set** if $\mathbf{f}_i \cdot \mathbf{f}_j = 0$ for all $i \neq j$, and it was proved that every orthogonal set is independent. In particular, it was observed that the expansion of a vector as a linear combination of orthogonal basis vectors is easy to obtain because formulas exist for the coefficients. Hence the orthogonal bases are the "nice" bases, and much of this chapter is devoted to extending results about bases to orthogonal bases. This leads to some very powerful methods and theorems. Our first task is to show that every subspace of $\mathbb{R}^n$ *has* an orthogonal basis.

8.1 Orthogonal Complements and Projections

If $\{\mathbf{v}_1, \dots, \mathbf{v}_m\}$ is linearly independent in a general vector space, and if $\mathbf{v}_{m+1}$ is not in $\text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_m\}$, then $\{\mathbf{v}_1, \dots, \mathbf{v}_m, \mathbf{v}_{m+1}\}$ is independent (Lemma 6.4.1). Here is the analog for *orthogonal* sets in $\mathbb{R}^n$.

Lemma 8.1.1: Orthogonal Lemma

Let $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ be an orthogonal set in $\mathbb{R}^n$. Given $\mathbf{x}$ in $\mathbb{R}^n$, write

$$\mathbf{f}_{m+1} = \mathbf{x} - \frac{\mathbf{x}\cdot\mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 - \frac{\mathbf{x}\cdot\mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2 - \cdots - \frac{\mathbf{x}\cdot\mathbf{f}_m}{\|\mathbf{f}_m\|^2}\mathbf{f}_m$$

Then:

1. $\mathbf{f}_{m+1} \cdot \mathbf{f}_k = 0$ *for* $k = 1, 2, \dots, m$.
2. *If* $\mathbf{x}$ *is not in* $\text{span}\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$, *then* $\mathbf{f}_{m+1} \neq \mathbf{0}$ *and* $\{\mathbf{f}_1, \dots, \mathbf{f}_m, \mathbf{f}_{m+1}\}$ *is an orthogonal set.*

Proof. For convenience, write $t_i = (\mathbf{x}\cdot\mathbf{f}_i)/\|\mathbf{f}_i\|^2$ for each i. Given $1 \leq k \leq m$:

$$\begin{aligned}
\mathbf{f}_{m+1}\cdot\mathbf{f}_k &= (\mathbf{x} - t_1\mathbf{f}_1 - \cdots - t_k\mathbf{f}_k - \cdots - t_m\mathbf{f}_m)\cdot\mathbf{f}_k \\
&= \mathbf{x}\cdot\mathbf{f}_k - t_1(\mathbf{f}_1\cdot\mathbf{f}_k) - \cdots - t_k(\mathbf{f}_k\cdot\mathbf{f}_k) - \cdots - t_m(\mathbf{f}_m\cdot\mathbf{f}_k) \\
&= \mathbf{x}\cdot\mathbf{f}_k - t_k\|\mathbf{f}_k\|^2 \\
&= 0
\end{aligned}$$

This proves (1), and (2) follows because $\mathbf{f}_{m+1} \neq \mathbf{0}$ if $\mathbf{x}$ is not in $\text{span}\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$. □

The orthogonal lemma has three important consequences for $\mathbb{R}^n$. The first is an extension for orthogonal sets of the fundamental fact that any independent set is part of a basis (Theorem 6.4.1).

Theorem 8.1.1

Let U be a subspace of $\mathbb{R}^n$.

1. *Every orthogonal subset $\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$ in U is a subset of an orthogonal basis of U.*
2. *U has an orthogonal basis.*

Proof.

1. If span $\{\mathbf{f}_1, \dots, \mathbf{f}_m\} = U$, it is *already* a basis. Otherwise, there exists $\mathbf{x}$ in U outside span $\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$. If $\mathbf{f}_{m+1}$ is as given in the orthogonal lemma, then $\mathbf{f}_{m+1}$ is in U and $\{\mathbf{f}_1, \dots, \mathbf{f}_m, \mathbf{f}_{m+1}\}$ is orthogonal. If span $\{\mathbf{f}_1, \dots, \mathbf{f}_m, \mathbf{f}_{m+1}\} = U$, we are done. Otherwise, the process continues to create larger and larger orthogonal subsets of U. They are all independent by Theorem 5.3.5, so we have a basis when we reach a subset containing dim U vectors.
2. If $U = \{\mathbf{0}\}$, the empty basis is orthogonal. Otherwise, if $\mathbf{f} \neq \mathbf{0}$ is in U, then $\{\mathbf{f}\}$ is orthogonal, so (2) follows from (1). □

We can improve upon (2) of Theorem 8.1.1. In fact, the second consequence of the orthogonal lemma is a procedure by which *any* basis $\{\mathbf{x}_1, \dots, \mathbf{x}_m\}$ of a subspace U of $\mathbb{R}^n$ can be systematically modified to yield an orthogonal basis $\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$ of U. The $\mathbf{f}_i$ are constructed one at a time from the $\mathbf{x}_i$.

To start the process, take $\mathbf{f}_1 = \mathbf{x}_1$. Then $\mathbf{x}_2$ is not in span $\{\mathbf{f}_1\}$ because $\{\mathbf{x}_1, \mathbf{x}_2\}$ is independent, so take

$$\mathbf{f}_2 = \mathbf{x}_2 - \frac{\mathbf{x}_2 \cdot \mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1$$

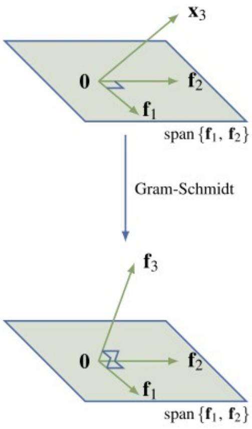
Thus $\{\mathbf{f}_1, \mathbf{f}_2\}$ is orthogonal by Lemma 8.1.1. Moreover, span $\{\mathbf{f}_1, \mathbf{f}_2\}$ = span $\{\mathbf{x}_1, \mathbf{x}_2\}$ (verify), so $\mathbf{x}_3$ is not in span $\{\mathbf{f}_1, \mathbf{f}_2\}$. Hence $\{\mathbf{f}_1, \mathbf{f}_2, \mathbf{f}_3\}$ is orthogonal where

$$\mathbf{f}_3 = \mathbf{x}_3 - \frac{\mathbf{x}_3 \cdot \mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 - \frac{\mathbf{x}_3 \cdot \mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2$$

Again, span $\{\mathbf{f}_1, \mathbf{f}_2, \mathbf{f}_3\}$ = span $\{\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3\}$, so $\mathbf{x}_4$ is not in span $\{\mathbf{f}_1, \mathbf{f}_2, \mathbf{f}_3\}$ and the process continues. At the mth iteration we construct an orthogonal set $\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$ such that

$$\text{span}\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\} = \text{span}\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m\} = U$$

Hence $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ is the desired orthogonal basis of U. The procedure can be summarized as follows.



Theorem 8.1.2: Gram-Schmidt Orthogonalization Algorithm[1]

If $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m\}$ *is any basis of a subspace* U *of* $\mathbb{R}^n$*, construct* $\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m$ *in* U *successively as follows:*

$$\begin{aligned}
\mathbf{f}_1 &= \mathbf{x}_1 \\
\mathbf{f}_2 &= \mathbf{x}_2 - \frac{\mathbf{x}_2 \cdot \mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 \\
\mathbf{f}_3 &= \mathbf{x}_3 - \frac{\mathbf{x}_3 \cdot \mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 - \frac{\mathbf{x}_3 \cdot \mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2 \\
&\vdots \\
\mathbf{f}_k &= \mathbf{x}_k - \frac{\mathbf{x}_k \cdot \mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 - \frac{\mathbf{x}_k \cdot \mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2 - \cdots - \frac{\mathbf{x}_k \cdot \mathbf{f}_{k-1}}{\|\mathbf{f}_{k-1}\|^2}\mathbf{f}_{k-1}
\end{aligned}$$

for each $k = 2, 3, \dots, m$*. Then*

1. $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ *is an orthogonal basis of* U*.*
2. $\operatorname{span}\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_k\} = \operatorname{span}\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k\}$ *for each* $k = 1, 2, \dots, m$*.*

The process (for $k = 3$) is depicted in the diagrams. Of course, the algorithm converts any basis of $\mathbb{R}^n$ itself into an orthogonal basis.

Example 8.1.1

Find an orthogonal basis of the row space of $A = \left[\begin{array}{rrrr} 1 & 1 & -1 & -1 \\ 3 & 2 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{array}\right]$.

Solution. Let $\mathbf{x}_1$, $\mathbf{x}_2$, $\mathbf{x}_3$ denote the rows of A and observe that $\{\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3\}$ is linearly independent. Take $\mathbf{f}_1 = \mathbf{x}_1$. The algorithm gives

$$\begin{aligned}
\mathbf{f}_2 &= \mathbf{x}_2 - \frac{\mathbf{x}_2 \cdot \mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 = (3, 2, 0, 1) - \frac{4}{4}(1, 1, -1, -1) = (2, 1, 1, 2) \\
\mathbf{f}_3 &= \mathbf{x}_3 - \frac{\mathbf{x}_3 \cdot \mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 - \frac{\mathbf{x}_3 \cdot \mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2 = \mathbf{x}_3 - \frac{0}{4}\mathbf{f}_1 - \frac{3}{10}\mathbf{f}_2 = \frac{1}{10}(4, -3, 7, -6)
\end{aligned}$$

Hence $\{(1, 1, -1, -1), (2, 1, 1, 2), \frac{1}{10}(4, -3, 7, -6)\}$ is the orthogonal basis provided by the algorithm. In hand calculations it may be convenient to eliminate fractions (see the Remark below), so $\{(1, 1, -1, -1), (2, 1, 1, 2), (4, -3, 7, -6)\}$ is also an orthogonal basis for row A.

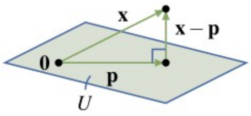
---

[1] Erhardt Schmidt (1876–1959) was a German mathematician who studied under the great David Hilbert and later developed the theory of Hilbert spaces. He first described the present algorithm in 1907. Jörgen Pederson Gram (1850–1916) was a Danish actuary.

Remark

Observe that the vector $\frac{\mathbf{x}\cdot\mathbf{f}_i}{\|\mathbf{f}_i\|^2}\mathbf{f}_i$ is unchanged if a nonzero scalar multiple of $\mathbf{f}_i$ is used in place of $\mathbf{f}_i$. Hence, if a newly constructed $\mathbf{f}_i$ is multiplied by a nonzero scalar at some stage of the Gram-Schmidt algorithm, the subsequent **f**s will be unchanged. This is useful in actual calculations.

Projections



Suppose a point $\mathbf{x}$ and a plane U through the origin in $\mathbb{R}^3$ are given, and we want to find the point $\mathbf{p}$ in the plane that is closest to $\mathbf{x}$. Our geometric intuition assures us that such a point $\mathbf{p}$ exists. In fact (see the diagram), $\mathbf{p}$ must be chosen in such a way that $\mathbf{x}-\mathbf{p}$ is *perpendicular* to the plane.

Now we make two observations: first, the plane U is a *subspace of* $\mathbb{R}^3$ (because U contains the origin); and second, that the condition that $\mathbf{x}-\mathbf{p}$ is perpendicular to the plane U means that $\mathbf{x}-\mathbf{p}$ is *orthogonal* to every vector in U. In these terms the whole discussion makes sense in $\mathbb{R}^n$. Furthermore, the orthogonal lemma provides exactly what is needed to find $\mathbf{p}$ in this more general setting.

Definition 8.1 Orthogonal Complement of a Subspace of $\mathbb{R}^n$

If U is a subspace of $\mathbb{R}^n$, define the ***orthogonal complement*** *$U^\perp$ of U (pronounced "U-perp") by*

$$U^\perp = \{\mathbf{x} \text{ in } \mathbb{R}^n \mid \mathbf{x}\cdot\mathbf{y} = 0 \text{ for all } \mathbf{y} \text{ in } U\}$$

The following lemma collects some useful properties of the orthogonal complement; the proof of (1) and (2) is left as Exercise 8.1.6.

Lemma 8.1.2

Let U be a subspace of $\mathbb{R}^n$.

1. *$U^\perp$ is a subspace of $\mathbb{R}^n$.*
2. *$\{\mathbf{0}\}^\perp = \mathbb{R}^n$ and $(\mathbb{R}^n)^\perp = \{\mathbf{0}\}$.*
3. *If $U = \text{span}\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k\}$, then $U^\perp = \{\mathbf{x} \text{ in } \mathbb{R}^n \mid \mathbf{x}\cdot\mathbf{x}_i = 0 \text{ for } i = 1, 2, \dots, k\}$.*

Proof.

3. Let $U = \text{span}\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k\}$; we must show that $U^\perp = \{\mathbf{x} \mid \mathbf{x}\cdot\mathbf{x}_i = 0 \text{ for each } i\}$. If $\mathbf{x}$ is in $U^\perp$ then $\mathbf{x}\cdot\mathbf{x}_i = 0$ for all i because each $\mathbf{x}_i$ is in U. Conversely, suppose that $\mathbf{x}\cdot\mathbf{x}_i = 0$ for all i; we must show that $\mathbf{x}$ is in $U^\perp$, that is, $\mathbf{x}\cdot\mathbf{y} = 0$ for each $\mathbf{y}$ in U. Write $\mathbf{y} = r_1\mathbf{x}_1 + r_2\mathbf{x}_2 + \cdots + r_k\mathbf{x}_k$, where each r_i is in $\mathbb{R}$. Then, using Theorem 5.3.1,

$$\mathbf{x}\cdot\mathbf{y} = r_1(\mathbf{x}\cdot\mathbf{x}_1) + r_2(\mathbf{x}\cdot\mathbf{x}_2) + \cdots + r_k(\mathbf{x}\cdot\mathbf{x}_k) = r_1 0 + r_2 0 + \cdots + r_k 0 = 0$$

as required. □

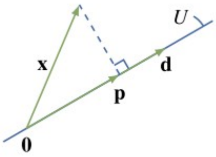
Example 8.1.2

Find $U^\perp$ if $U = \text{span}\,\{(1,\ -1,\ 2,\ 0),\ (1,\ 0,\ -2,\ 3)\}$ in $\mathbb{R}^4$.

Solution. By Lemma 8.1.2, $\mathbf{x} = (x,\ y,\ z,\ w)$ is in $U^\perp$ if and only if it is orthogonal to both $(1,\ -1,\ 2,\ 0)$ and $(1,\ 0,\ -2,\ 3)$; that is,

$$\begin{array}{rl} x - y + 2z \phantom{{}+3w} &= 0 \\ x \phantom{{}-y} - 2z + 3w &= 0 \end{array}$$

Gaussian elimination gives $U^\perp = \text{span}\,\{(2,\ 4,\ 1,\ 0),\ (3,\ 3,\ 0,\ -1)\}$.



Now consider vectors $\mathbf{x}$ and $\mathbf{d} \neq \mathbf{0}$ in $\mathbb{R}^3$. The projection $\mathbf{p} = \text{proj}_{\mathbf{d}}\,\mathbf{x}$ of $\mathbf{x}$ on $\mathbf{d}$ was defined in Section 4.2 as in the diagram.

The following formula for $\mathbf{p}$ was derived in Theorem 4.2.4

$$\mathbf{p} = \text{proj}_{\mathbf{d}}\,\mathbf{x} = \left(\frac{\mathbf{x}\cdot\mathbf{d}}{\|\mathbf{d}\|^2}\right)\mathbf{d}$$

where it is shown that $\mathbf{x} - \mathbf{p}$ is orthogonal to $\mathbf{d}$. Now observe that the line $U = \mathbb{R}\mathbf{d} = \{t\mathbf{d} \mid t \in \mathbb{R}\}$ is a subspace of $\mathbb{R}^3$, that $\{\mathbf{d}\}$ is an orthogonal basis of U, and that $\mathbf{p} \in U$ and $\mathbf{x} - \mathbf{p} \in U^\perp$ (by Theorem 4.2.4).

In this form, this makes sense for any vector $\mathbf{x}$ in $\mathbb{R}^n$ and any subspace U of $\mathbb{R}^n$, so we generalize it as follows. If $\{\mathbf{f}_1,\ \mathbf{f}_2,\ \dots,\ \mathbf{f}_m\}$ is an orthogonal basis of U, we define the projection $\mathbf{p}$ of $\mathbf{x}$ on U by the formula

$$\mathbf{p} = \left(\frac{\mathbf{x}\cdot\mathbf{f}_1}{\|\mathbf{f}_1\|^2}\right)\mathbf{f}_1 + \left(\frac{\mathbf{x}\cdot\mathbf{f}_2}{\|\mathbf{f}_2\|^2}\right)\mathbf{f}_2 + \cdots + \left(\frac{\mathbf{x}\cdot\mathbf{f}_m}{\|\mathbf{f}_m\|^2}\right)\mathbf{f}_m \tag{8.1}$$

Then $\mathbf{p} \in U$ and (by the orthogonal lemma) $\mathbf{x} - \mathbf{p} \in U^\perp$, so it looks like we have a generalization of Theorem 4.2.4.

However there is a potential problem: the formula (8.1) for $\mathbf{p}$ must be shown to be independent of the choice of the orthogonal basis $\{\mathbf{f}_1,\ \mathbf{f}_2,\ \dots,\ \mathbf{f}_m\}$. To verify this, suppose that $\{\mathbf{f}'_1,\ \mathbf{f}'_2,\ \dots,\ \mathbf{f}'_m\}$ is another orthogonal basis of U, and write

$$\mathbf{p}' = \left(\frac{\mathbf{x}\cdot\mathbf{f}'_1}{\|\mathbf{f}'_1\|^2}\right)\mathbf{f}'_1 + \left(\frac{\mathbf{x}\cdot\mathbf{f}'_2}{\|\mathbf{f}'_2\|^2}\right)\mathbf{f}'_2 + \cdots + \left(\frac{\mathbf{x}\cdot\mathbf{f}'_m}{\|\mathbf{f}'_m\|^2}\right)\mathbf{f}'_m$$

As before, $\mathbf{p}' \in U$ and $\mathbf{x} - \mathbf{p}' \in U^\perp$, and we must show that $\mathbf{p}' = \mathbf{p}$. To see this, write the vector $\mathbf{p} - \mathbf{p}'$ as follows:

$$\mathbf{p} - \mathbf{p}' = (\mathbf{x} - \mathbf{p}') - (\mathbf{x} - \mathbf{p})$$

This vector is in U (because $\mathbf{p}$ and $\mathbf{p}'$ are in U) and it is in $U^\perp$ (because $\mathbf{x} - \mathbf{p}'$ and $\mathbf{x} - \mathbf{p}$ are in $U^\perp$), and so it must be zero (it is orthogonal to itself!). This means $\mathbf{p}' = \mathbf{p}$ as desired.

Hence, the vector $\mathbf{p}$ in equation (8.1) depends only on $\mathbf{x}$ and the subspace U, and *not* on the choice of orthogonal basis $\{\mathbf{f}_1,\ \dots,\ \mathbf{f}_m\}$ of U used to compute it. Thus, we are entitled to make the following definition:

Definition 8.2 Projection onto a Subspace of $\mathbb{R}^n$

Let U be a subspace of $\mathbb{R}^n$ with orthogonal basis $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$. If $\mathbf{x}$ is in $\mathbb{R}^n$, the vector

$$\operatorname{proj}_U \mathbf{x} = \frac{\mathbf{x}\cdot\mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 + \frac{\mathbf{x}\cdot\mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2 + \cdots + \frac{\mathbf{x}\cdot\mathbf{f}_m}{\|\mathbf{f}_m\|^2}\mathbf{f}_m$$

*is called the **orthogonal projection** of $\mathbf{x}$ on U. For the zero subspace $U = \{\mathbf{0}\}$, we define*

$$\operatorname{proj}_{\{\mathbf{0}\}} \mathbf{x} = \mathbf{0}$$

The preceding discussion proves (1) of the following theorem.

Theorem 8.1.3: Projection Theorem

If U is a subspace of $\mathbb{R}^n$ and $\mathbf{x}$ is in $\mathbb{R}^n$, write $\mathbf{p} = \operatorname{proj}_U \mathbf{x}$. Then:

1. *$\mathbf{p}$ is in U and $\mathbf{x} - \mathbf{p}$ is in $U^\perp$.*
2. *$\mathbf{p}$ is the vector in U closest to $\mathbf{x}$ in the sense that*

$$\|\mathbf{x} - \mathbf{p}\| < \|\mathbf{x} - \mathbf{y}\| \quad \text{for all } \mathbf{y} \in U,\ \mathbf{y} \neq \mathbf{p}$$

Proof.

1. This is proved in the preceding discussion (it is clear if $U = \{\mathbf{0}\}$).
2. Write $\mathbf{x} - \mathbf{y} = (\mathbf{x} - \mathbf{p}) + (\mathbf{p} - \mathbf{y})$. Then $\mathbf{p} - \mathbf{y}$ is in U and so is orthogonal to $\mathbf{x} - \mathbf{p}$ by (1). Hence, the Pythagorean theorem gives

$$\|\mathbf{x} - \mathbf{y}\|^2 = \|\mathbf{x} - \mathbf{p}\|^2 + \|\mathbf{p} - \mathbf{y}\|^2 > \|\mathbf{x} - \mathbf{p}\|^2$$

because $\mathbf{p} - \mathbf{y} \neq \mathbf{0}$. This gives (2). □

Example 8.1.3

Let $U = \operatorname{span}\{\mathbf{x}_1, \mathbf{x}_2\}$ in $\mathbb{R}^4$ where $\mathbf{x}_1 = (1, 1, 0, 1)$ and $\mathbf{x}_2 = (0, 1, 1, 2)$. If $\mathbf{x} = (3, -1, 0, 2)$, find the vector in U closest to $\mathbf{x}$ and express $\mathbf{x}$ as the sum of a vector in U and a vector orthogonal to U.

Solution. $\{\mathbf{x}_1, \mathbf{x}_2\}$ is independent but not orthogonal. The Gram-Schmidt process gives an orthogonal basis $\{\mathbf{f}_1, \mathbf{f}_2\}$ of U where $\mathbf{f}_1 = \mathbf{x}_1 = (1, 1, 0, 1)$ and

$$\mathbf{f}_2 = \mathbf{x}_2 - \frac{\mathbf{x}_2\cdot\mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 = \mathbf{x}_2 - \frac{3}{3}\mathbf{f}_1 = (-1, 0, 1, 1)$$

Hence, we can compute the projection using $\{\mathbf{f}_1, \mathbf{f}_2\}$:

$$\mathbf{p} = \operatorname{proj}_U \mathbf{x} = \frac{\mathbf{x}\cdot\mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 + \frac{\mathbf{x}\cdot\mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2 = \frac{4}{3}\mathbf{f}_1 + \frac{-1}{3}\mathbf{f}_2 = \frac{1}{3}\left[\begin{array}{cccc} 5 & 4 & -1 & 3 \end{array}\right]$$

Thus, $\mathbf{p}$ is the vector in U closest to $\mathbf{x}$, and $\mathbf{x}-\mathbf{p}=\frac{1}{3}(4,\ -7,\ 1,\ 3)$ is orthogonal to every vector in U. (This can be verified by checking that it is orthogonal to the generators $\mathbf{x}_1$ and $\mathbf{x}_2$ of U.) The required decomposition of $\mathbf{x}$ is thus

$$\mathbf{x}=\mathbf{p}+(\mathbf{x}-\mathbf{p})=\tfrac{1}{3}(5,\ 4,\ -1,\ 3)+\tfrac{1}{3}(4,\ -7,\ 1,\ 3)$$

Example 8.1.4

Find the point in the plane with equation $2x+y-z=0$ that is closest to the point $(2,\ -1,\ -3)$.

Solution. We write $\mathbb{R}^3$ as rows. The plane is the subspace U whose points $(x,\ y,\ z)$ satisfy $z=2x+y$. Hence

$$U=\{(s,\ t,\ 2s+t)\mid s,\ t \text{ in } \mathbb{R}\}=\operatorname{span}\{(0,\ 1,\ 1),\ (1,\ 0,\ 2)\}$$

The Gram-Schmidt process produces an orthogonal basis $\{\mathbf{f}_1,\ \mathbf{f}_2\}$ of U where $\mathbf{f}_1=(0,\ 1,\ 1)$ and $\mathbf{f}_2=(1,\ -1,\ 1)$. Hence, the vector in U closest to $\mathbf{x}=(2,\ -1,\ -3)$ is

$$\operatorname{proj}_U \mathbf{x}=\tfrac{\mathbf{x}\cdot\mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1+\tfrac{\mathbf{x}\cdot\mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2=-2\mathbf{f}_1+0\mathbf{f}_2=(0,\ -2,\ -2)$$

Thus, the point in U closest to $(2,\ -1,\ -3)$ is $(0,\ -2,\ -2)$.

The next theorem shows that projection on a subspace of $\mathbb{R}^n$ is actually a linear operator $\mathbb{R}^n\to\mathbb{R}^n$.

Theorem 8.1.4

Let U be a fixed subspace of $\mathbb{R}^n$. If we define $T:\mathbb{R}^n\to\mathbb{R}^n$ by

$$T(\mathbf{x})=\operatorname{proj}_U \mathbf{x} \quad \text{for all } \mathbf{x} \text{ in } \mathbb{R}^n$$

1. *T is a linear operator.*
2. *$\operatorname{im} T=U$ and $\ker T=U^\perp$.*
3. *$\dim U+\dim U^\perp=n$.*

Proof. If $U=\{\mathbf{0}\}$, then $U^\perp=\mathbb{R}^n$, and so $T(\mathbf{x})=\operatorname{proj}_{\{\mathbf{0}\}}\mathbf{x}=\mathbf{0}$ for all $\mathbf{x}$. Thus $T=0$ is the zero (linear) operator, so (1), (2), and (3) hold. Hence assume that $U\neq\{\mathbf{0}\}$.

1. If $\{\mathbf{f}_1,\ \mathbf{f}_2,\ \dots,\ \mathbf{f}_m\}$ is an orthonormal basis of U, then

$$T(\mathbf{x})=(\mathbf{x}\cdot\mathbf{f}_1)\mathbf{f}_1+(\mathbf{x}\cdot\mathbf{f}_2)\mathbf{f}_2+\cdots+(\mathbf{x}\cdot\mathbf{f}_m)\mathbf{f}_m \quad \text{for all } \mathbf{x} \text{ in } \mathbb{R}^n \tag{8.2}$$

by the definition of the projection. Thus T is linear because

$$(\mathbf{x}+\mathbf{y})\cdot\mathbf{f}_i=\mathbf{x}\cdot\mathbf{f}_i+\mathbf{y}\cdot\mathbf{f}_i \quad \text{and} \quad (r\mathbf{x})\cdot\mathbf{f}_i=r(\mathbf{x}\cdot\mathbf{f}_i) \quad \text{for each } i$$

2. We have $\text{im } T \subseteq U$ by (8.2) because each $\mathbf{f}_i$ is in U. But if $\mathbf{x}$ is in U, then $\mathbf{x} = T(\mathbf{x})$ by (8.2) and the expansion theorem applied to the space U. This shows that $U \subseteq \text{im } T$, so $\text{im } T = U$.

   Now suppose that $\mathbf{x}$ is in $U^\perp$. Then $\mathbf{x} \cdot \mathbf{f}_i = 0$ for each i (again because each $\mathbf{f}_i$ is in U) so $\mathbf{x}$ is in $\ker T$ by (8.2). Hence $U^\perp \subseteq \ker T$. On the other hand, Theorem 8.1.3 shows that $\mathbf{x} - T(\mathbf{x})$ is in $U^\perp$ for all $\mathbf{x}$ in $\mathbb{R}^n$, and it follows that $\ker T \subseteq U^\perp$. Hence $\ker T = U^\perp$, proving (2).

3. This follows from (1), (2), and the dimension theorem (Theorem 7.2.4). □

Exercises for 8.1

Exercise 8.1.1 In each case, use the Gram-Schmidt algorithm to convert the given basis B of V into an orthogonal basis.

a. $V = \mathbb{R}^2$, $B = \{(1, -1), (2, 1)\}$

b. $V = \mathbb{R}^2$, $B = \{(2, 1), (1, 2)\}$

c. $V = \mathbb{R}^3$, $B = \{(1, -1, 1), (1, 0, 1), (1, 1, 2)\}$

d. $V = \mathbb{R}^3$, $B = \{(0, 1, 1), (1, 1, 1), (1, -2, 2)\}$

Exercise 8.1.2 In each case, write $\mathbf{x}$ as the sum of a vector in U and a vector in $U^\perp$.

a. $\mathbf{x} = (1, 5, 7)$, $U = \text{span}\{(1, -2, 3), (-1, 1, 1)\}$

b. $\mathbf{x} = (2, 1, 6)$, $U = \text{span}\{(3, -1, 2), (2, 0, -3)\}$

c. $\mathbf{x} = (3, 1, 5, 9)$,
$U = \text{span}\{(1, 0, 1, 1), (0, 1, -1, 1), (-2, 0, 1, 1)\}$

d. $\mathbf{x} = (2, 0, 1, 6)$,
$U = \text{span}\{(1, 1, 1, 1), (1, 1, -1, -1), (1, -1, 1, -1)\}$

e. $\mathbf{x} = (a, b, c, d)$,
$U = \text{span}\{(1, 0, 0, 0), (0, 1, 0, 0), (0, 0, 1, 0)\}$

f. $\mathbf{x} = (a, b, c, d)$,
$U = \text{span}\{(1, -1, 2, 0), (-1, 1, 1, 1)\}$

Exercise 8.1.3 Let $\mathbf{x} = (1, -2, 1, 6)$ in $\mathbb{R}^4$, and let $U = \text{span}\{(2, 1, 3, -4), (1, 2, 0, 1)\}$.

a. Compute $\text{proj}_U \mathbf{x}$.

b. Show that $\{(1, 0, 2, -3), (4, 7, 1, 2)\}$ is another orthogonal basis of U.

c. Use the basis in part (b) to compute $\text{proj}_U \mathbf{x}$.

Exercise 8.1.4 In each case, use the Gram-Schmidt algorithm to find an orthogonal basis of the subspace U, and find the vector in U closest to $\mathbf{x}$.

a. $U = \text{span}\{(1, 1, 1), (0, 1, 1)\}$, $\mathbf{x} = (-1, 2, 1)$

b. $U = \text{span}\{(1, -1, 0), (-1, 0, 1)\}$, $\mathbf{x} = (2, 1, 0)$

c. $U = \text{span}\{(1, 0, 1, 0), (1, 1, 1, 0), (1, 1, 0, 0)\}$,
$\mathbf{x} = (2, 0, -1, 3)$

d. $U = \text{span}\{(1, -1, 0, 1), (1, 1, 0, 0), (1, 1, 0, 1)\}$,
$\mathbf{x} = (2, 0, 3, 1)$

Exercise 8.1.5 Let $U = \text{span}\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k\}$, $\mathbf{v}_i$ in $\mathbb{R}^n$, and let A be the $k \times n$ matrix with the $\mathbf{v}_i$ as rows.

a. Show that $U^\perp = \{\mathbf{x} \mid \mathbf{x} \text{ in } \mathbb{R}^n, A\mathbf{x}^T = \mathbf{0}\}$.

b. Use part (a) to find $U^\perp$ if
$U = \text{span}\{(1, -1, 2, 1), (1, 0, -1, 1)\}$.

Exercise 8.1.6

a. Prove part 1 of Lemma 8.1.2.

b. Prove part 2 of Lemma 8.1.2.

Exercise 8.1.7 Let U be a subspace of $\mathbb{R}^n$. If $\mathbf{x}$ in $\mathbb{R}^n$ can be written in any way at all as $\mathbf{x} = \mathbf{p} + \mathbf{q}$ with $\mathbf{p}$ in U and $\mathbf{q}$ in $U^\perp$, show that necessarily $\mathbf{p} = \operatorname{proj}_U \mathbf{x}$.

Exercise 8.1.8 Let U be a subspace of $\mathbb{R}^n$ and let $\mathbf{x}$ be a vector in $\mathbb{R}^n$. Using Exercise 8.1.7, or otherwise, show that $\mathbf{x}$ is in U if and only if $\mathbf{x} = \operatorname{proj}_U \mathbf{x}$.

Exercise 8.1.9 Let U be a subspace of $\mathbb{R}^n$.

a. Show that $U^\perp = \mathbb{R}^n$ if and only if $U = \{\mathbf{0}\}$.

b. Show that $U^\perp = \{\mathbf{0}\}$ if and only if $U = \mathbb{R}^n$.

Exercise 8.1.10 If U is a subspace of $\mathbb{R}^n$, show that $\operatorname{proj}_U \mathbf{x} = \mathbf{x}$ for all $\mathbf{x}$ in U.

Exercise 8.1.11 If U is a subspace of $\mathbb{R}^n$, show that $\mathbf{x} = \operatorname{proj}_U \mathbf{x} + \operatorname{proj}_{U^\perp} \mathbf{x}$ for all $\mathbf{x}$ in $\mathbb{R}^n$.

Exercise 8.1.12 If $\{\mathbf{f}_1, \dots, \mathbf{f}_n\}$ is an orthogonal basis of $\mathbb{R}^n$ and $U = \operatorname{span}\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$, show that $U^\perp = \operatorname{span}\{\mathbf{f}_{m+1}, \dots, \mathbf{f}_n\}$.

Exercise 8.1.13 If U is a subspace of $\mathbb{R}^n$, show that $U^{\perp\perp} = U$. [*Hint*: Show that $U \subseteq U^{\perp\perp}$, then use Theorem 8.1.4 (3) twice.]

Exercise 8.1.14 If U is a subspace of $\mathbb{R}^n$, show how to find an $n \times n$ matrix A such that $U = \{\mathbf{x} \mid A\mathbf{x} = \mathbf{0}\}$. [*Hint*: Exercise 8.1.13.]

Exercise 8.1.15 Write $\mathbb{R}^n$ as rows. If A is an $n \times n$ matrix, write its null space as $\operatorname{null} A = \{\mathbf{x} \text{ in } \mathbb{R}^n \mid A\mathbf{x}^T = \mathbf{0}\}$. Show that:

a. $\operatorname{null} A = (\operatorname{row} A)^\perp$;

b. $\operatorname{null} A^T = (\operatorname{col} A)^\perp$.

Exercise 8.1.16 If U and W are subspaces, show that $(U+W)^\perp = U^\perp \cap W^\perp$. [See Exercise 5.1.22.]

Exercise 8.1.17 Think of $\mathbb{R}^n$ as consisting of rows.

a. Let E be an $n \times n$ matrix, and let $U = \{\mathbf{x}E \mid \mathbf{x} \text{ in } \mathbb{R}^n\}$. Show that the following are equivalent.

   i. $E^2 = E = E^T$ (E is a **projection matrix**).

   ii. $(\mathbf{x} - \mathbf{x}E) \cdot (\mathbf{y}E) = 0$ for all $\mathbf{x}$ and $\mathbf{y}$ in $\mathbb{R}^n$.

   iii. $\operatorname{proj}_U \mathbf{x} = \mathbf{x}E$ for all $\mathbf{x}$ in $\mathbb{R}^n$.

   [*Hint*: For (ii) implies (iii): Write $\mathbf{x} = \mathbf{x}E + (\mathbf{x} - \mathbf{x}E)$ and use the uniqueness argument preceding the definition of $\operatorname{proj}_U \mathbf{x}$. For (iii) implies (ii): $\mathbf{x} - \mathbf{x}E$ is in $U^\perp$ for all $\mathbf{x}$ in $\mathbb{R}^n$.]

b. If E is a projection matrix, show that $I - E$ is also a projection matrix.

c. If $EF = 0 = FE$ and E and F are projection matrices, show that $E + F$ is also a projection matrix.

d. If A is $m \times n$ and AA^T is invertible, show that $E = A^T(AA^T)^{-1}A$ is a projection matrix.

Exercise 8.1.18 Let A be an $n \times n$ matrix of rank r. Show that there is an invertible $n \times n$ matrix U such that UA is a row-echelon matrix with the property that the first r rows are orthogonal. [*Hint*: Let R be the row-echelon form of A, and use the Gram-Schmidt process on the nonzero rows of R from the bottom up. Use Lemma 2.4.1.]

Exercise 8.1.19 Let A be an $(n-1) \times n$ matrix with rows $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_{n-1}$ and let A_i denote the $(n-1) \times (n-1)$ matrix obtained from A by deleting column i. Define the vector $\mathbf{y}$ in $\mathbb{R}^n$ by

$$\mathbf{y} = \left[\begin{array}{ccccc} \det A_1 & -\det A_2 & \det A_3 & \cdots & (-1)^{n+1} \det A_n \end{array}\right]$$

Show that:

a. $\mathbf{x}_i \cdot \mathbf{y} = 0$ for all $i = 1, 2, \dots, n-1$. [*Hint*: Write $B_i = \left[\begin{array}{c} x_i \\ A \end{array}\right]$ and show that $\det B_i = 0$.]

b. $\mathbf{y} \neq \mathbf{0}$ if and only if $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_{n-1}\}$ is linearly independent. [*Hint*: If some $\det A_i \neq 0$, the rows of A_i are linearly independent. Conversely, if the $\mathbf{x}_i$ are independent, consider $A = UR$ where R is in reduced row-echelon form.]

c. If $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_{n-1}\}$ is linearly independent, use Theorem 8.1.3(3) to show that all solutions to the system of $n-1$ homogeneous equations

$$A\mathbf{x}^T = \mathbf{0}$$

are given by $t\mathbf{y}$, t a parameter.

8.2 Orthogonal Diagonalization

Recall (Theorem 5.5.3) that an $n \times n$ matrix A is diagonalizable if and only if it has n linearly independent eigenvectors. Moreover, the matrix P with these eigenvectors as columns is a diagonalizing matrix for A, that is

$$P^{-1}AP \text{ is diagonal.}$$

As we have seen, the really nice bases of $\mathbb{R}^n$ are the orthogonal ones, so a natural question is: which $n \times n$ matrices have an *orthogonal* basis of eigenvectors? These turn out to be precisely the symmetric matrices, and this is the main result of this section.

Before proceeding, recall that an orthogonal set of vectors is called *orthonormal* if $\|\mathbf{v}\| = 1$ for each vector $\mathbf{v}$ in the set, and that any orthogonal set $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k\}$ can be "*normalized*", that is converted into an orthonormal set $\{\frac{1}{\|\mathbf{v}_1\|}\mathbf{v}_1, \frac{1}{\|\mathbf{v}_2\|}\mathbf{v}_2, \dots, \frac{1}{\|\mathbf{v}_k\|}\mathbf{v}_k\}$. In particular, if a matrix A has n orthogonal eigenvectors, they can (by normalizing) be taken to be orthonormal. The corresponding diagonalizing matrix P has orthonormal columns, and such matrices are very easy to invert.

Theorem 8.2.1

The following conditions are equivalent for an $n \times n$ matrix P.

1. *P is invertible and $P^{-1} = P^T$.*
2. *The rows of P are orthonormal.*
3. *The columns of P are orthonormal.*

Proof. First recall that condition (1) is equivalent to $PP^T = I$ by Corollary 2.4.1 of Theorem 2.4.5. Let $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ denote the rows of P. Then $\mathbf{x}_j^T$ is the jth column of P^T, so the (i, j)-entry of PP^T is $\mathbf{x}_i \cdot \mathbf{x}_j$. Thus $PP^T = I$ means that $\mathbf{x}_i \cdot \mathbf{x}_j = 0$ if $i \neq j$ and $\mathbf{x}_i \cdot \mathbf{x}_j = 1$ if $i = j$. Hence condition (1) is equivalent to (2). The proof of the equivalence of (1) and (3) is similar. □

Definition 8.3 Orthogonal Matrices

An $n \times n$ matrix P is called an **orthogonal matrix**[2] *if it satisfies one (and hence all) of the conditions in Theorem 8.2.1.*

Example 8.2.1

The rotation matrix $\left[\begin{array}{rr} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{array} \right]$ is orthogonal for any angle θ.

These orthogonal matrices have the virtue that they are easy to invert—simply take the transpose. But they have many other important properties as well. If $T : \mathbb{R}^n \to \mathbb{R}^n$ is a linear operator, we will prove

---

[2] In view of (2) and (3) of Theorem 8.2.1, *orthonormal matrix* might be a better name. But *orthogonal matrix* is standard.

(Theorem 10.4.3) that T is distance preserving if and only if its matrix is orthogonal. In particular, the matrices of rotations and reflections about the origin in $\mathbb{R}^2$ and $\mathbb{R}^3$ are all orthogonal (see Example 8.2.1).

It is not enough that the rows of a matrix A are merely orthogonal for A to be an orthogonal matrix. Here is an example.

Example 8.2.2

The matrix $\left[\begin{array}{rrr} 2 & 1 & 1 \\ -1 & 1 & 1 \\ 0 & -1 & 1 \end{array}\right]$ has orthogonal rows but the columns are not orthogonal. However, if the rows are normalized, the resulting matrix $\left[\begin{array}{ccc} \frac{2}{\sqrt{6}} & \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{6}} \\ \frac{-1}{\sqrt{3}} & \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} \\ 0 & \frac{-1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \end{array}\right]$ is orthogonal (so the columns are now orthonormal as the reader can verify).

Example 8.2.3

If P and Q are orthogonal matrices, then PQ is also orthogonal, as is $P^{-1} = P^T$.

Solution. P and Q are invertible, so PQ is also invertible and

$$(PQ)^{-1} = Q^{-1}P^{-1} = Q^TP^T = (PQ)^T$$

Hence PQ is orthogonal. Similarly,

$$(P^{-1})^{-1} = P = (P^T)^T = (P^{-1})^T$$

shows that P^{-1} is orthogonal.

Definition 8.4 Orthogonally Diagonalizable Matrices

An $n \times n$ matrix A is said to be ***orthogonally diagonalizable*** *when an orthogonal matrix P can be found such that $P^{-1}AP = P^TAP$ is diagonal.*

This condition turns out to characterize the symmetric matrices.

Theorem 8.2.2: Principal Axes Theorem

The following conditions are equivalent for an $n \times n$ matrix A.

1. *A has an orthonormal set of n eigenvectors.*
2. *A is orthogonally diagonalizable.*
3. *A is symmetric.*

Proof. (1) $\Leftrightarrow$ (2). Given (1), let $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ be orthonormal eigenvectors of A. Then $P = \left[\begin{array}{cccc} \mathbf{x}_1 & \mathbf{x}_2 & \dots & \mathbf{x}_n \end{array}\right]$ is orthogonal, and $P^{-1}AP$ is diagonal by Theorem 3.3.4. This proves (2). Conversely, given (2) let $P^{-1}AP$ be diagonal where P is orthogonal. If $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ are the columns of P then $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$ is an orthonormal basis of $\mathbb{R}^n$ that consists of eigenvectors of A by Theorem 3.3.4. This proves (1).

(2) $\Rightarrow$ (3). If $P^TAP = D$ is diagonal, where $P^{-1} = P^T$, then $A = PDP^T$. But $D^T = D$, so this gives $A^T = P^{TT}D^TP^T = PDP^T = A$.

(3) $\Rightarrow$ (2). If A is an $n \times n$ symmetric matrix, we proceed by induction on n. If $n = 1$, A is already diagonal. If $n > 1$, assume that (3) $\Rightarrow$ (2) for $(n-1)\times(n-1)$ symmetric matrices. By Theorem 5.5.7 let λ_1 be a (real) eigenvalue of A, and let $A\mathbf{x}_1 = \lambda_1\mathbf{x}_1$, where $\|\mathbf{x}_1\| = 1$. Use the Gram-Schmidt algorithm to find an orthonormal basis $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$ for $\mathbb{R}^n$. Let $P_1 = \left[\begin{array}{cccc} \mathbf{x}_1 & \mathbf{x}_2 & \dots & \mathbf{x}_n \end{array}\right]$, so P_1 is an orthogonal matrix and $P_1^TAP_1 = \left[\begin{array}{cc} \lambda_1 & B \\ 0 & A_1 \end{array}\right]$ in block form by Lemma 5.5.2. But $P_1^TAP_1$ is symmetric (A is), so it follows that $B = 0$ and A_1 is symmetric. Then, by induction, there exists an $(n-1)\times(n-1)$ orthogonal matrix Q such that $Q^TA_1Q = D_1$ is diagonal. Observe that $P_2 = \left[\begin{array}{cc} 1 & 0 \\ 0 & Q \end{array}\right]$ is orthogonal, and compute:

$$\begin{aligned}(P_1P_2)^TA(P_1P_2) &= P_2^T(P_1^TAP_1)P_2 \\ &= \left[\begin{array}{cc} 1 & 0 \\ 0 & Q^T \end{array}\right]\left[\begin{array}{cc} \lambda_1 & 0 \\ 0 & A_1 \end{array}\right]\left[\begin{array}{cc} 1 & 0 \\ 0 & Q \end{array}\right] \\ &= \left[\begin{array}{cc} \lambda_1 & 0 \\ 0 & D_1 \end{array}\right]\end{aligned}$$

is diagonal. Because P_1P_2 is orthogonal, this proves (2). ☐

A set of orthonormal eigenvectors of a symmetric matrix A is called a set of **principal axes** for A. The name comes from geometry, and this is discussed in Section 8.9. Because the eigenvalues of a (real) symmetric matrix are real, Theorem 8.2.2 is also called the **real spectral theorem**, and the set of distinct eigenvalues is called the **spectrum** of the matrix. In full generality, the spectral theorem is a similar result for matrices with complex entries (Theorem 8.7.8).

Example 8.2.4

Find an orthogonal matrix P such that $P^{-1}AP$ is diagonal, where $A = \left[\begin{array}{rrr} 1 & 0 & -1 \\ 0 & 1 & 2 \\ -1 & 2 & 5 \end{array}\right]$.

Solution. The characteristic polynomial of A is (adding twice row 1 to row 2):

$$c_A(x) = \det \left[\begin{array}{ccc} x-1 & 0 & 1 \\ 0 & x-1 & -2 \\ 1 & -2 & x-5 \end{array}\right] = x(x-1)(x-6)$$

Thus the eigenvalues are $\lambda = 0$, 1, and 6, and corresponding eigenvectors are

$$\mathbf{x}_1 = \left[\begin{array}{r} 1 \\ -2 \\ 1 \end{array}\right] \quad \mathbf{x}_2 = \left[\begin{array}{r} 2 \\ 1 \\ 0 \end{array}\right] \quad \mathbf{x}_3 = \left[\begin{array}{r} -1 \\ 2 \\ 5 \end{array}\right]$$

respectively. Moreover, by what appears to be remarkably good luck, these eigenvectors are *orthogonal*. We have $\|\mathbf{x}_1\|^2 = 6$, $\|\mathbf{x}_2\|^2 = 5$, and $\|\mathbf{x}_3\|^2 = 30$, so

$$P = \left[\begin{array}{ccc} \frac{1}{\sqrt{6}}\mathbf{x}_1 & \frac{1}{\sqrt{5}}\mathbf{x}_2 & \frac{1}{\sqrt{30}}\mathbf{x}_3 \end{array} \right] = \frac{1}{\sqrt{30}} \left[\begin{array}{ccc} \sqrt{5} & 2\sqrt{6} & -1 \\ -2\sqrt{5} & \sqrt{6} & 2 \\ \sqrt{5} & 0 & 5 \end{array} \right]$$

is an orthogonal matrix. Thus $P^{-1} = P^T$ and

$$P^TAP = \left[\begin{array}{ccc} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 6 \end{array} \right]$$

by the diagonalization algorithm.

Actually, the fact that the eigenvectors in Example 8.2.4 are orthogonal is no coincidence. Theorem 5.5.4 guarantees they are linearly independent (they correspond to distinct eigenvalues); the fact that the matrix is *symmetric* implies that they are orthogonal. To prove this we need the following useful fact about symmetric matrices.

Theorem 8.2.3

If A is an $n \times n$ symmetric matrix, then

$$(A\mathbf{x}) \cdot \mathbf{y} = \mathbf{x} \cdot (A\mathbf{y})$$

for all columns $\mathbf{x}$ and $\mathbf{y}$ in $\mathbb{R}^n$.[3]

Proof. Recall that $\mathbf{x} \cdot \mathbf{y} = \mathbf{x}^T\mathbf{y}$ for all columns $\mathbf{x}$ and $\mathbf{y}$. Because $A^T = A$, we get

$$(A\mathbf{x}) \cdot \mathbf{y} = (A\mathbf{x})^T\mathbf{y} = \mathbf{x}^TA^T\mathbf{y} = \mathbf{x}^TA\mathbf{y} = \mathbf{x} \cdot (A\mathbf{y})$$

☐

Theorem 8.2.4

If A is a symmetric matrix, then eigenvectors of A corresponding to distinct eigenvalues are orthogonal.

Proof. Let $A\mathbf{x} = \lambda\mathbf{x}$ and $A\mathbf{y} = \mu\mathbf{y}$, where $\lambda \neq \mu$. Using Theorem 8.2.3, we compute

$$\lambda(\mathbf{x} \cdot \mathbf{y}) = (\lambda\mathbf{x}) \cdot \mathbf{y} = (A\mathbf{x}) \cdot \mathbf{y} = \mathbf{x} \cdot (A\mathbf{y}) = \mathbf{x} \cdot (\mu\mathbf{y}) = \mu(\mathbf{x} \cdot \mathbf{y})$$

Hence $(\lambda - \mu)(\mathbf{x} \cdot \mathbf{y}) = 0$, and so $\mathbf{x} \cdot \mathbf{y} = 0$ because $\lambda \neq \mu$. ☐

---

[3] The converse also holds (Exercise 8.2.15).

Now the procedure for diagonalizing a symmetric $n \times n$ matrix is clear. Find the distinct eigenvalues (all real by Theorem 5.5.7) and find orthonormal bases for each eigenspace (the Gram-Schmidt algorithm may be needed). Then the set of all these basis vectors is orthonormal (by Theorem 8.2.4) and contains n vectors. Here is an example.

Example 8.2.5

Orthogonally diagonalize the symmetric matrix $A = \left[\begin{array}{rrr} 8 & -2 & 2 \\ -2 & 5 & 4 \\ 2 & 4 & 5 \end{array}\right]$.

Solution. The characteristic polynomial is

$$c_A(x) = \det \left[\begin{array}{ccc} x-8 & 2 & -2 \\ 2 & x-5 & -4 \\ -2 & -4 & x-5 \end{array}\right] = x(x-9)^2$$

Hence the distinct eigenvalues are 0 and 9 of multiplicities 1 and 2, respectively, so $\dim(E_0) = 1$ and $\dim(E_9) = 2$ by Theorem 5.5.6 (A is diagonalizable, being symmetric). Gaussian elimination gives

$$E_0(A) = \text{span}\,\{\mathbf{x}_1\}, \quad \mathbf{x}_1 = \left[\begin{array}{r} 1 \\ 2 \\ -2 \end{array}\right], \quad \text{and} \quad E_9(A) = \text{span}\left\{ \left[\begin{array}{r} -2 \\ 1 \\ 0 \end{array}\right], \left[\begin{array}{r} 2 \\ 0 \\ 1 \end{array}\right] \right\}$$

The eigenvectors in E_9 are both orthogonal to $\mathbf{x}_1$ as Theorem 8.2.4 guarantees, but not to each other. However, the Gram-Schmidt process yields an orthogonal basis

$$\{\mathbf{x}_2,\ \mathbf{x}_3\} \text{ of } E_9(A) \quad \text{where} \quad \mathbf{x}_2 = \left[\begin{array}{r} -2 \\ 1 \\ 0 \end{array}\right] \text{ and } \mathbf{x}_3 = \left[\begin{array}{r} 2 \\ 4 \\ 5 \end{array}\right]$$

Normalizing gives orthonormal vectors $\{\frac{1}{3}\mathbf{x}_1,\ \frac{1}{\sqrt{5}}\mathbf{x}_2,\ \frac{1}{3\sqrt{5}}\mathbf{x}_3\}$, so

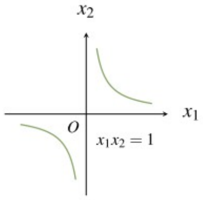
$$P = \left[\begin{array}{ccc} \frac{1}{3}\mathbf{x}_1 & \frac{1}{\sqrt{5}}\mathbf{x}_2 & \frac{1}{3\sqrt{5}}\mathbf{x}_3 \end{array}\right] = \frac{1}{3\sqrt{5}} \left[\begin{array}{rrr} \sqrt{5} & -6 & 2 \\ 2\sqrt{5} & 3 & 4 \\ -2\sqrt{5} & 0 & 5 \end{array}\right]$$

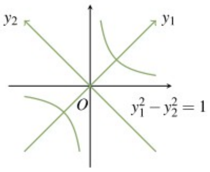
is an orthogonal matrix such that $P^{-1}AP$ is diagonal.

It is worth noting that other, more convenient, diagonalizing matrices P exist. For example, $\mathbf{y}_2 = \left[\begin{array}{r} 2 \\ 1 \\ 2 \end{array}\right]$ and $\mathbf{y}_3 = \left[\begin{array}{r} -2 \\ 2 \\ 1 \end{array}\right]$ lie in $E_9(A)$ and they are orthogonal. Moreover, they both have norm 3 (as does $\mathbf{x}_1$), so

$$Q = \left[\begin{array}{ccc} \frac{1}{3}\mathbf{x}_1 & \frac{1}{3}\mathbf{y}_2 & \frac{1}{3}\mathbf{y}_3 \end{array}\right] = \frac{1}{3} \left[\begin{array}{rrr} 1 & 2 & -2 \\ 2 & 1 & 2 \\ -2 & 2 & 1 \end{array}\right]$$

is a nicer orthogonal matrix with the property that $Q^{-1}AQ$ is diagonal.





If A is symmetric and a set of orthogonal eigenvectors of A is given, the eigenvectors are called principal axes of A. The name comes from geometry. An expression $q = ax_1^2 + bx_1x_2 + cx_2^2$ is called a **quadratic form** in the variables x_1 and x_2, and the graph of the equation $q = 1$ is called a **conic** in these variables. For example, if $q = x_1x_2$, the graph of $q = 1$ is given in the first diagram.

But if we introduce new variables y_1 and y_2 by setting $x_1 = y_1 + y_2$ and $x_2 = y_1 - y_2$, then q becomes $q = y_1^2 - y_2^2$, a diagonal form with no cross term y_1y_2 (see the second diagram). Because of this, the y_1 and y_2 axes are called the principal axes for the conic (hence the name). Orthogonal diagonalization provides a systematic method for finding principal axes. Here is an illustration.

Example 8.2.6

Find principal axes for the quadratic form $q = x_1^2 - 4x_1x_2 + x_2^2$.

Solution. In order to utilize diagonalization, we first express q in matrix form. Observe that

$$q = \left[\begin{array}{cc} x_1 & x_2 \end{array}\right] \left[\begin{array}{rr} 1 & -4 \\ 0 & 1 \end{array}\right] \left[\begin{array}{c} x_1 \\ x_2 \end{array}\right]$$

The matrix here is not symmetric, but we can remedy that by writing

$$q = x_1^2 - 2x_1x_2 - 2x_2x_1 + x_2^2$$

Then we have

$$q = \left[\begin{array}{cc} x_1 & x_2 \end{array}\right] \left[\begin{array}{rr} 1 & -2 \\ -2 & 1 \end{array}\right] \left[\begin{array}{c} x_1 \\ x_2 \end{array}\right] = \mathbf{x}^T A\mathbf{x}$$

where $\mathbf{x} = \left[\begin{array}{c} x_1 \\ x_2 \end{array}\right]$ and $A = \left[\begin{array}{rr} 1 & -2 \\ -2 & 1 \end{array}\right]$ is symmetric. The eigenvalues of A are $\lambda_1 = 3$ and $\lambda_2 = -1$, with corresponding (orthogonal) eigenvectors $\mathbf{x}_1 = \left[\begin{array}{r} 1 \\ -1 \end{array}\right]$ and $\mathbf{x}_2 = \left[\begin{array}{c} 1 \\ 1 \end{array}\right]$. Since $\|\mathbf{x}_1\| = \|\mathbf{x}_2\| = \sqrt{2}$, so

$$P = \tfrac{1}{\sqrt{2}} \left[\begin{array}{rr} 1 & 1 \\ -1 & 1 \end{array}\right] \text{ is orthogonal and } P^TAP = D = \left[\begin{array}{rr} 3 & 0 \\ 0 & -1 \end{array}\right]$$

Now define new variables $\left[\begin{array}{c} y_1 \\ y_2 \end{array}\right] = \mathbf{y}$ by $\mathbf{y} = P^T\mathbf{x}$, equivalently $\mathbf{x} = P\mathbf{y}$ (since $P^{-1} = P^T$). Hence

$$y_1 = \tfrac{1}{\sqrt{2}}(x_1 - x_2) \quad \text{and} \quad y_2 = \tfrac{1}{\sqrt{2}}(x_1 + x_2)$$

In terms of y_1 and y_2, q takes the form

$$q = \mathbf{x}^T A\mathbf{x} = (P\mathbf{y})^T A(P\mathbf{y}) = \mathbf{y}^T(P^TAP)\mathbf{y} = \mathbf{y}^T D\mathbf{y} = 3y_1^2 - y_2^2$$

Note that $\mathbf{y} = P^T\mathbf{x}$ is obtained from $\mathbf{x}$ by a counterclockwise rotation of $\frac{\pi}{4}$ (see Theorem 2.4.6).

Observe that the quadratic form q in Example 8.2.6 can be diagonalized in other ways. For example

$$q = x_1^2 - 4x_1x_2 + x_2^2 = z_1^2 - \tfrac{1}{3}z_2^2$$

where $z_1 = x_1 - 2x_2$ and $z_2 = 3x_2$. We examine this more carefully in Section 8.9.

If we are willing to replace "diagonal" by "upper triangular" in the principal axes theorem, we can weaken the requirement that A is symmetric to insisting only that A has real eigenvalues.

Theorem 8.2.5: Triangulation Theorem

If A is an $n \times n$ matrix with n real eigenvalues, an orthogonal matrix P exists such that P^TAP is upper triangular.[4]

Proof. We modify the proof of Theorem 8.2.2. If $A\mathbf{x}_1 = \lambda_1\mathbf{x}_1$ where $\|\mathbf{x}_1\| = 1$, let $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$ be an orthonormal basis of $\mathbb{R}^n$, and let $P_1 = \left[\begin{array}{cccc} \mathbf{x}_1 & \mathbf{x}_2 & \cdots & \mathbf{x}_n \end{array}\right]$. Then P_1 is orthogonal and $P_1^TAP_1 = \left[\begin{array}{cc} \lambda_1 & B \\ 0 & A_1 \end{array}\right]$ in block form. By induction, let $Q^TA_1Q = T_1$ be upper triangular where Q is of size $(n-1)\times(n-1)$ and orthogonal. Then $P_2 = \left[\begin{array}{cc} 1 & 0 \\ 0 & Q \end{array}\right]$ is orthogonal, so $P = P_1P_2$ is also orthogonal and $P^TAP = \left[\begin{array}{cc} \lambda_1 & BQ \\ 0 & T_1 \end{array}\right]$ is upper triangular. □

The proof of Theorem 8.2.5 gives no way to construct the matrix P. However, an algorithm will be given in Section 11.1 where an improved version of Theorem 8.2.5 is presented. In a different direction, a version of Theorem 8.2.5 holds for an arbitrary matrix with complex entries (Schur's theorem in Section 8.7).

As for a diagonal matrix, the eigenvalues of an upper triangular matrix are displayed along the main diagonal. Because A and P^TAP have the same determinant and trace whenever P is orthogonal, Theorem 8.2.5 gives:

Corollary 8.2.1

If A is an $n \times n$ matrix with real eigenvalues $\lambda_1, \lambda_2, \dots, \lambda_n$ (possibly not all distinct), then $\det A = \lambda_1\lambda_2\dots\lambda_n$ and $\operatorname{tr} A = \lambda_1 + \lambda_2 + \dots + \lambda_n$.

This corollary remains true even if the eigenvalues are not real (using Schur's theorem).

Exercises for 8.2

Exercise 8.2.1 Normalize the rows to make each of the following matrices orthogonal.

a. $A = \left[\begin{array}{rr} 1 & 1 \\ -1 & 1 \end{array}\right]$

b. $A = \left[\begin{array}{rr} 3 & -4 \\ 4 & 3 \end{array}\right]$

c. $A = \left[\begin{array}{rr} 1 & 2 \\ -4 & 2 \end{array}\right]$

d. $A = \left[\begin{array}{rr} a & b \\ -b & a \end{array}\right]$, $(a, b) \neq (0, 0)$

---

6 CÍRCULOS E ESFERAS

6.1 EQUAÇÕES CANÔNICAS DE CÍRCULOS E ESFERAS

Um círculo é o conjunto de pontos no plano que estão a uma certa distância r de um ponto dado (a, b).

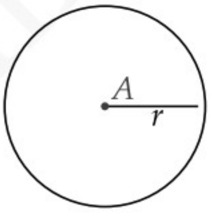

Figura 6.1: Círculo de centro A e raio r.

Desta forma temos que um ponto (x, y) pertence ao círculo de centro (a, b) e raio r se e somente se satisfaz a equação:

$$\sqrt{(x-a)^2 + (y-b)^2} = r$$

ou equivalentemente:

$$(x-a)^2 + (y-b)^2 = r^2$$

De modo análogo, a equação reduzida de uma esfera de centro (a, b, c) e raio r é

$$(x-a)^2 + (y-b)^2 + (z-c)^2 = r^2$$

Versão Preliminar

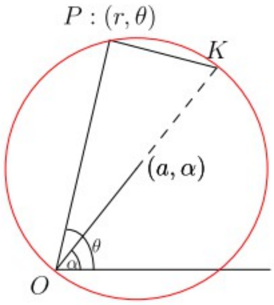

Figura 6.2: Esfera de Centro C e raio r.

Versão Preliminar

Exemplo 6.1 Determine a equação do círculo de centro $(-3,1)$ que

é tangente a reta $3x-4y-2=0$

Solução: Já conhecemos o centro e precisamos determinar o raio. Nesse caso o raio é a distância entre a reta e o ponto, já que a tangente a um círculo é perpendicular ao raio que liga o centro ao ponto de tangência. Logo:

$$r=\frac{|3(-3)-4\cdot 1-2|}{\sqrt{3^2+4^2}}=3$$

e assim a equação do círculo é:

$$(x+3)^2+(y-1)^2=9 \text{ ou } x^2+y^2+6x-2y+1=0$$

□

Exemplo 6.2 Determine a equação da esfera cujo diâmetro é o segmento que liga $(3,-1,2)$ a $(5,3,4)$.

Solução: Nesse caso aparentemente não conhecemos nem o centro nem o raio. Mas temos que o centro é o ponto médio do segmento e que o raio é metade do diâmetro. Logo:

$$r = \frac{1}{2}\sqrt{(5-3)^2 + (3+1)^2 + (4-2)^2} = \sqrt{6}$$

O ponto médio é $(4, 1, 3)$ e logo a equação da esfera é:

$$(x-4)^2 + (y-1)^2 + (z-3)^2 = 6$$

□

Exemplo 6.3 Identifique a curva cuja equação é:

$$x^2 + y^2 - 6x - 4y - 12 = 0$$

Solução: Identificaremos a curva completando quadrados. O termo $x^2 - 6x$ pode ser convertido num quadrado, se somarmos 9 e $y^2 - 4y$ pode ser convertido num quadrado somando 4. Desta forma, somaremos $4 + 9$ em cada lado da equação $x^2 + y^2 - 6x - 4y - 12 = 0$. Logo temos:

$$x^2 + y^2 - 6x - 4y - 12 = 0 \tag{6.1}$$

$$\Rightarrow (x^2 - 6x + 9) + (y^2 - 4y + 4) = 12 + 4 + 9 \tag{6.2}$$

$$\Rightarrow (x-3)^2 + (y-2)^2 = 5^2 \tag{6.3}$$

Logo a curva é um círculo de raio 5 e centro $(3, 2)$. □

Versão Preliminar

Versão Preliminar

Podemos generalizar o exemplo anterior:

Exemplo 6.4 Identifique a curva cuja equação é:

$$x^2 + y^2 + Ax + By + C = 0$$

Solução: Como no exemplo anterior, identificaremos a curva completando quadrados. O termo $x^2 + Ax$ pode ser convertido num quadrado, se somarmos $\dfrac{A^2}{4}$ e $y^2 + By$ pode ser convertido num quadrado somando $\dfrac{B^2}{4}$. Desta forma, somaremos $\dfrac{A^2}{4} + \dfrac{B^2}{4}$ em cada lado da equação:

$$x^2 + y^2 + Ax + By + C = 0 \tag{6.4}$$

$$\Rightarrow \left(x^2 + Ax + \frac{A^2}{4}\right) + \left(y^2 + By + \frac{B^2}{4}\right) = \frac{A^2}{4} + \frac{B^2}{4} - C \tag{6.5}$$

$$\Rightarrow \left(x + \frac{A}{2}\right)^2 + \left(y + \frac{B}{2}\right)^2 = \frac{A^2}{4} + \frac{B^2}{4} - C \tag{6.6}$$

Observamos que para a equação anterior ser a equação de um circulo, $r^2 = \dfrac{A^2}{4} + \dfrac{B^2}{4} - C$, e assim temos que ter $\dfrac{A^2}{4} + \dfrac{B^2}{4} - C > 0$.

No caso em que $\dfrac{A^2}{4} + \dfrac{B^2}{4} - C < 0$, o lugar geométrico descrito pela equação 6.6 é vazio, pois a equação não pode ser satisfeita pois a soma de quadrados é necessariamente negativa.

No caso em que $\dfrac{A^2}{4} + \dfrac{B^2}{4} - C = 0$, o lugar geométrico descrito pela equação 6.6 é o ponto $\left(-\dfrac{A}{2}, -\dfrac{B}{2}\right)$, pois se a soma de quadrados perfeitos é 0 cada termo da soma é zero. ☐

De modo análogo, podemos demonstrar que a equação

$$x^2 + y^2 + z^2 + Ax + By + Cz + D = 0$$

descreve uma esfera se $\frac{A^2}{4} + \frac{B^2}{4} + \frac{C^2}{4} - D > 0$, um ponto se $\frac{A^2}{4} + \frac{B^2}{4} + \frac{C^2}{4} - D = 0$ e o conjunto vazio se $\frac{A^2}{4} + \frac{B^2}{4} + \frac{C^2}{4} - D < 0$.

Exemplo 6.5 A superfície cuja equação é:

$$12 - 2x + x^2 + 4y + y^2 + 8z + z^2 = 0$$

é uma esfera. Encontre seu centro e raio.

Solução: Completando os quadrados temos

$$(x^2 - 2x + 1) + (y^2 + 4y + 4) + (z^2 + 8z + 16) - 1 - 4 - 16 + 12 = 0$$

Daí segue que:

$$(x - 1)^2 + (y + 2)^2 + (z + 4)^2 = 9$$

E logo o centro dessa esfera é $(1, -2, -4)$ e o raio é 3. ☐

6.1.1 Círculo por três pontos

É conhecido que três pontos não colineares determinam um único círculo. Assim sendo, fixados P_1, P_2 e P_3 não colineares podemos

Versão Preliminar

facilmente encontrar a equação do círculo que passa por tais pontos. Tal equação pode ser encontrada observando que a equação geral de um círculo é da forma

$$x^2 + y^2 + Ax + By + C = 0$$

e que um ponto pertence ao círculo se e somente se suas coordenadas satisfazem tal equação. A substituição de cada ponto resulta assim numa equação linear nas variáveis A, B, C e assim o fato dos três pontos pertencerem ao círculo nos fornecem um sistema linear em três equações e três variáveis A, B, C. Resolvendo tal sistema encontramos, então, a equação do círculo.

Exemplo 6.6 Determine a equação do círculo que passa pelos pontos $(-1, 2)$, $(0, 1)$ e $(-3, 2)$.

Solução: Substituindo os pontos na equação

temos o sistema:

$$\begin{cases} 5 - A + 2B + C = 0 \\ 1 + B + C = 0 \\ 13 - 3A + 2B + C \end{cases}$$

cujas solução é $A = 4, B = 0, C = -1$. E logo a equação é

$$x^2 + y^2 + 4x - 1 = 0.$$

Completando quadrado obtemos, então:

$$(x^2 + 4x + 4) + y^2 - 4 - 1 = 0.$$

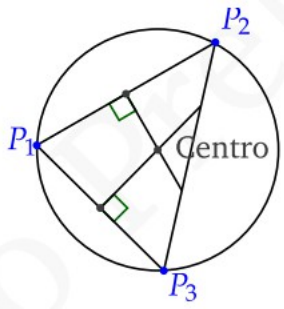
Versão Preliminar

Donde segue:

$$(x+2)^2 + y^2 = 5.$$

Desse modo vemos que o círculo que passa por tais pontos tem centro $(-2,0)$ e raio $\sqrt{5}$. $\square$

É possível encontrar a equação de um círculo por três pontos não colineares de uma outra maneira. Para esse fim consideramos o triângulo determinado pelos pontos P_1, P_2, P_3 e esse circunscrito na circunferência. Assim o seu centro é o circuncentro desse triângulo, isto é, o encontro das mediatrizes.



Exemplo 6.7 Determine a equação do círculo que passa pelos pontos $(-1,2)$, $(0,1)$ e $(-3,2)$.

Solução: A equação da reta passando pelos pontos $(-1,2)$, $(0,1)$ é $y-1=-x$, e como o ponto médio desses pontos é: $(-\frac{1}{2}, \frac{3}{2})$ temos que a mediatriz relativa a esse lado é: $y - \frac{3}{2} = x + \frac{1}{2}$ (lembrando

Versão Preliminar

que como a mediatriz é perpendicular ao lado seu coeficiente angular é igual a menos o inverso do coeficiente da reta).

De modo análogo a equação da reta passando pelos pontos $(0,1)$ e $(-3,2)$ é $y = -\frac{x}{3} + 1$ e a equação da mediatriz é: $3x = -6 + y$

temos o sistema:

$$\begin{cases} 3x = -6 + y \\ y - \frac{3}{2} = x + \frac{1}{2} \end{cases}$$

cujas solução é $x = -2, y = 0$, ou seja o centro da circunferência é $(-2,0)$. O raio pode ser calculado observando que este será a distância do centro $(-2,0)$ a um dos vértices do triângulo, por exemplo $(0,1)$. Assim $r^2 = 5$, e logo a equação é:

$$(x+2)^2 + y^2 = 5.$$

□

Versão Preliminar

Exemplo 6.8 Obtenha a equação da esfera que passa pelos pontos

$(0,0,1), (2,0,0), (1,1,1), (0,1,0)$ **Solução:** Impondo que os pontos pertençam a esfera temos o seguinte sistema linear:

$$\begin{aligned} &1 + C + D = 0 \\ &4 + 2A + D = 0 \\ &3 + A + B + C + D = 0 \\ &1 + B + D = 0 \end{aligned}$$

cuja solução é $A = -\frac{5}{3}, B = -\frac{1}{3}, C = -\frac{1}{3}, D = -\frac{2}{3}$ e assim a equação da esfera é:

$$x^2 + y^2 + z^2 - \frac{5x}{3} - \frac{y}{3} - \frac{z}{3} - \frac{2}{3} = 0$$

Completando quadrado obtemos:

$$\left(x^2 - \frac{5x}{3} + \left(\frac{5}{6}\right)^2\right) + \left(y^2 - \frac{y}{3} + \left(\frac{1}{6}\right)^2\right) +$$
$$+ \left(z^2 - \frac{z}{3} + \left(\frac{1}{6}\right)^2\right) - \left(\frac{5}{6}\right)^2 - \left(\frac{1}{6}\right)^2 - \left(\frac{1}{6}\right)^2 - \frac{24}{36} = 0.$$

Donde segue:

$$\left(x^2 - \frac{5}{6}\right)^2 + \left(y^2 - \frac{1}{6}\right)^2 + \left(z^2 - \frac{1}{6}\right)^2 = \frac{51}{36}.$$

□

Exercícios

Ex. 1.1 — Determine a equação dos seguintes círculos:

a) Centro $(-2, 5)$ e raio $r = 3$.

b) Centro $(1, 3)$ e raio $r = 2$

c) Centro a origem e raio $r = a$

d) Centro $(5, 2)$ e passando pelo ponto $(2, 3)$

e) Tangente ao eixo y na origem e raio a

f) Diâmetro $(5, 2)$ a $(-2, 10)$

Versão Preliminar

g) Centro $(3,-2)$ tangente a $2x-y=0$

h) Tangente a $2x-5y+1=0$ no ponto $(2,1)$ e raio 3 (duas respostas)

Ex. 1.2 — Identifique, dando o centro e o raio.

a) $x^2+y^2-4x+6y=12$

b) $x^2+y^2-2x-4y+5$

c) $x^2+y^2=2ax$

d) $4x^2-4x=5y-4y^2$

e) $x^2+y^2+z^2=2az$

Ex. 1.3 — Encontre a equação do círculo que passa pelos pontos $(4,0),(0,3)$ e a origem.

Ex. 1.4 — Encontre a equação dos seguintes círculos

a) Tangente aos eixos coordenados coordenados no segundo quadrante e com raio $r=4$.

b) Tangente ao eixo x, ao eixo y e a linha que intercepta o eixo x e o eixo y em 3 e 2 respectivamente.

Ex. 1.5 — Verifique que as equações abaixo descrevem esferas, em caso afirmativo identifique o centro e o raio:

a) $x^2+y^2+z^2-2x-4y+10=0$

Versão Preliminar

b) $x^2 - 6x + y^2 - 4y + z^2 + 14z + 58$

c) $x^2 + y^2 - 6y + z^2 + 4z + 16$

d) $x^2 + 2x + y^2 + 4y - z^2 + 6z - 29$

Ex. 1.6 — Dados $P_1 = (x_1, y_1, z_1)$ e $P_2 = (x_2, y_2, z_2)$ então a equação da esfera que tem P_1P_2 como diâmetro é

$$(x - x_1)(x - x_2) + (y - y_1)(y - y_2) + (z - z_1)(z - z_2) = 0$$

6.2 RETAS TANGENTES E PLANOS TANGENTES

Versão Preliminar

Uma reta é dita tangente a um círculo se a intersecção entre essa reta e o círculo for somente um ponto. Para uma reta tangente o seu vetor diretor é perpendicular ao vetor ligando o raio ao ponto de intersecção. Além disso a distância do centro do círculo a reta tangente é igual ao raio do círculo.

De modo análogo, dizemos que um plano é tangente a uma esfera se esse plano interceptar a esfera num único ponto. Nesse caso o vetor normal ao plano é paralelo ao vetor radial ligando o centro da esfera ao ponto onde o plano intercepta a esfera. E a distância do plano tangente ao centro da esfera é igual ao raio da mesma.

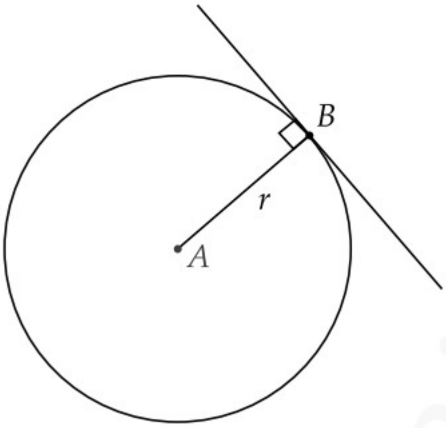


Figura 6.3: Reta tangente a um círculo

Versão Preliminar

Exemplo 6.9 Encontre a reta tangente ao círculo de equação $x^2 + y^2 - 2y - 4x = 0$ no ponto $(3,3)$

Solução: Completando quadrados podemos colocar a equação $x^2 + y^2 - 2y - 4x = 0$ na forma reduzida:

$$(x-2)^2 + (y-1)^2 = 0$$

Logo o centro do círculo tem coordenadas $(2,1)$. Logo, o vetor ligando o centro do círculo ao ponto $(3,3)$ é $\mathbf{i} + 2\mathbf{k}$ e assim o coeficiente angular da reta passando por estes pontos é igual a 2. Logo, o coeficiente da reta tangente é $-\frac{1}{2}$ (Por quê? Tente escrever a equação da reta tangente na forma padrão obtendo antes equações paramétricas para a mesma.). E assim a equação da reta tangente é:

$$y - 3 = -\frac{1}{2}(x-3)$$

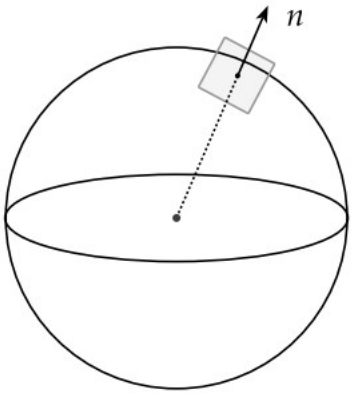

Figura 6.4: Plano tangente a uma esfera

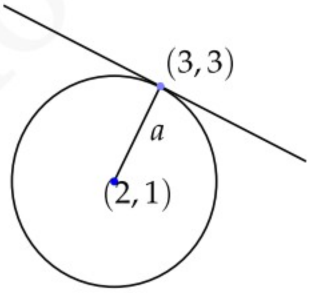
ou

$$x + 2y = 9.$$

□



Versão Preliminar

Podemos generalizar o exemplo anterior. Dado um círculo de equação

$$(x-a)^2 + (y-b)^2 = r^2$$

Vamos calcular a equação da reta tangente no ponto (x_1, y_1).

Para tanto, consideraremos o vetor ligando o centro do círculo ao ponto de tangencia: $(x_1 - a)\mathbf{i} + (y_1 - b)\mathbf{j}$. Consequentemente a inclinação da reta passando por esses pontos é: $\dfrac{y_1 - b}{x_1 - a}$ Logo o coeficiente angular da reta tangente é $-\dfrac{x_1 - a}{y_1 - b}$. E assim a equação da reta tangente é da forma

$$(y - y_1) = -\frac{x_1 - a}{y_1 - b}(x + x_1)$$

e logo

$$(y - y_1)(y_1 - b) = -(x_1 - a)(x - x_1)$$

e assim expandindo:

$$(x_1 - a)x + (y_1 - b)y = k$$

para alguma constante k. Somando $(x_1 - a)(-a) + (y_1 - b)(-b)$ em ambos os lados da equação obtemos:

$$(x_1 - a)(x - a) + (y_1 - b)(y - b) = k_2$$

para alguma constante k_2, que determinaremos agora. Se substituirmos $x = x_1$ e $y = y_1$ teremos que

$$k_2 = (x_1 - a)^2 + (y_1 - b)^2 = r^2$$

Versão Preliminar

e assim a equação da reta tangente no ponto (x_1, y_1) é

$$(x_1 - a)(x - a) + (y_1 - b)(y - b) = r^2.$$

Exemplo 6.10 Obtenha as equações dos planos tangentes a esfera

$-3 - 2x + x^2 + 4y + y^2 + 2z + z^2 = 0$ que são paralelos ao plano $x - 2y + 2z = 3$.

Solução: Completando quadrados temos que a equação da esfera pode ser escrita como:

$$(x-1)^2 + (y+2)^2 + (z+1)^2 = 9$$

Logo o centro dessa esfera é $(1, -2, -1)$ e o raio é 3.

A equação geral de um plano paralelo a $x - 2y + 2z = 3$ tem equação da forma: $x - 2y + 2z = d$

Como esse plano é tangente a esfera a distância do centro dessas esferas ao plano é igual ao raio dessa esfera. E assim:

$$d(C, \pi) = \frac{|1 - 2(-2) + 2(-1) - d|}{9} = 3$$

e logo $d = -6$ ou $d = 12$ e assim as equações dos planos são $x - 2y + 2z = -6$ e $x - 2y + 2z = 12$.

□

Versão Preliminar

Exercícios

Ex. 2.1 — Encontre a equação a reta tangente no ponto indicado:

a) $x^2 + y^2 = 25$, $(-3, 4)$

b) $x^2 + y^2 = 2x - 4y$, origem.

c) Encontre as retas tangentes ao circulo $x^2 + y^2 = 4x$ que passam pelo ponto $(3, 2)$.

d) Uma corda da circunferência $x^2 + y^2 = 25$ se encontra sobre a reta cuja equação é $x - 7y + 25 = 0$. Qual o comprimento dessa corda?

Ex. 2.2 — Para um triângulo qualquer encontrar:

a) a equação da circunferência circunscrita ao triângulo

b) a equação da circunferência inscrita ao triângulo

c) a equação da circunferência que passa pelos pontos médios dos lados do triângulo.

Ex. 2.3 — As equações dos lados de um triângulo são $9x + 2y + 13 = 0, 3x + 8y - 47 = 0$ e $x - y - 1 = 0$. Encontrar a equação da circunferência circunscrita.

Ex. 2.4 — Mostrar que as tangentes de inclinação m à circunferência $x^2 + y^2 = r^2$ são $y = mx \pm r\sqrt{1 + m^2}$.

Ex. 2.5 — Qual a equação da circûnferencia que passa pelos pontos $(1, 2), (3, 4)$ e que tem centro sobre o eixo y?

Versão Preliminar

Ex. 2.6 — Fixado a, quais devem ser os dois valores de b para que a reta $y = ax + b$ seja tangente ao círculo de centro na origem e raio r?

Ex. 2.7 — Uma circunferência de raio 5 é tangente a reta $3x - 4y - 1 = 0$ no ponto $(3, 2)$. Determinar sua equação (duas soluções).

Ex. 2.8 — Mostrar analiticamente que qualquer reta que passa pelo ponto $(-1, 5)$ não pode ser tangente a circunferência $x^2 + y^2 + 4x - 6y + 6 = 0$. Interprete o resultado geometricamente.

Ex. 2.9 — Encontre a equação dos círculos que passam pelos seguintes conjuntos de pontos. Diga qual o centro, o raio e desenhe.

a) $(3, 4), (-1, 2), (-2, 4)$
b) $(4, 2), (-2, 3), (-1, 6)$
c) $(a, 0), (b, 0), (0, c)$

Ex. 2.10 — Mostrar que o plano tangente à esfera $x^2 + y^2 + z^2 = r^2$ no ponto (a, b, c) tem equação $ax + by + cz = r^2$

Ex. 2.11 — Encontre a equação da esfera que passa pelos pontos $(0, 0, 1)$,$(1, 0, 0)$, $(0, 1, 0)$ e cujo centro esta no plano $x + y - z = 0$

Versão Preliminar

Ex. 2.12 — Encontre a esfera que tem centro na reta

$$r : \begin{cases} x = 2z - 3 \\ y = z - 1 \end{cases}$$

e passa pelos pontos $(6, -1, 3)$ e $(0, 7, 5)$

Ex. 2.13 — Calcule a distância do ponto $(2, 3, 4)$ à esfera $x^2 + 4x + y^2 - 2y + z^2 + 4$.

Ex. 2.14 — Determine a equação da esfera cujo centro é $(3, 2, -2)$ é que é tangente ao plano

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} + \begin{pmatrix} -3 \\ 1 \\ 0 \end{pmatrix} t + \begin{pmatrix} 2 \\ 0 \\ 1 \end{pmatrix} s$$

Ex. 2.15 — Determine a equação da esfera cujo centro se encontra sobre o eixo X e que passa pelos pontos $(3, -4, 2)$ e $(6, 2, -1)$.

Ex. 2.16 — A equação de uma esfera é $x^2 + y^2 + z^2 + 6y - 4z + 9 = 0$. Determinar a equação da esfera concêntrica que é tangente ao plano:

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} -1 \\ 0 \\ -1 \end{pmatrix} + \begin{pmatrix} \frac{1}{2} \\ 1 \\ 1 \end{pmatrix} s + \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} t$$

Versão Preliminar

Ex. 2.17 — Encontre os planos tangentes a esfera $x^2 + y^2 + (z-1)^2 = 1$ que são paralelos ao plano $4x - y + 3z = 2$

Ex. 2.18 — Encontre a equação dos planos que contem a reta r e são tangentes a esfera S:

$$r : \frac{x+6}{2} = y + 3 = z + 1$$

e $S : x^2 + y^2 + z^2 - 4x + 2y - 4z + 4 = 0$.

Versão Preliminar

6.3 CIRCUNFERÊNCIA EM COORDENADAS POLARES

CENTRADA NA ORIGEM O caso mais simples ocorre quando a circunferência está centrada na origem nesse caso a circunferência é o conjunto de pontos que distam uma constante a da origem ou seja a equação em coordenadas polares é

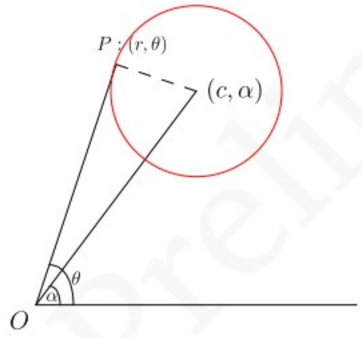
$$r = a.$$

É fácil de ver que essa equação coincide com a em equação em coordenadas cartesianas. Observe que, em coordenadas cartesianas,

$P = (x, y)$ pertence a tal círculo se e somente se: $x = a\cos\theta$ e $y = a \operatorname{sen}\theta$. Daí segue que:

$$x^2 + y^2 = a^2(\cos^2\theta + \operatorname{sen}^2\theta) = a^2.$$

PASSANDO PELA ORIGEM Dada uma circunferência de raio a e passando pela origem. As coordenadas polares do centro dessa circunferência são (a, α).



Considere o triângulo ΔOKP. Como $\overline{OK}$ é diâmetro da circunferência circunscrita ao triângulo vemos que ΔOKP é retângulo em P. Da definição de cosseno segue então:

$$r = 2a\cos\left(\theta - \alpha\right).$$

FORMA GERAL Dado uma circunferência de centro (c, α) e raio a, usando a lei dos cossenos temos que:

$$a^2 = r^2 + c^2 - 2rc\cos\left(\theta - \alpha\right)$$

vature and of geodesy for Riemann spaces. However, the concept of a differential manifold as presented in Chapter 3 did not appear until 1913 in the work of H. Weyl [59, I.§4]. According to Steenrod [53, p. v], general definitions for fiber bundles and vector bundles, which we introduced in part in Chapter 5, did not appear until the work of Whitney in 1935–1940.

Turning to physics, general relativity, one of the landmark achievements in science of the early 20th century, stands as the most visible application of Riemann manifolds to science. Starting from the principle that the speed of light in a vacuum is constant regardless of reference frame [20, p. 42], Einstein developed the theory of special relativity, defined in the absence of gravity. The "interpretation" of the law that "the gravitational mass of a body is equal to its inertial mass" [20, p. 65] and the intention to preserve the principle of the constancy of the speed of light led Einstein to understand spacetime as a curved space where "the geometrical properties of space are not independent, but [...] determined by matter" [20, p. 113]. Riemannian metrics, curvature, and the associated theorems for geodesics gave Einstein precisely the mathematical tools he needed to express his conception of a curvilinear spacetime.

The reader should be aware that other applications of manifolds to science do not (and should not) always require a metric structure. Applications of manifolds to either geometry or physics may require a different structure from or additional structure to a Riemann metric. For example, in its properly generalized context, Hamiltonian mechanics require the structure of what is called a symplectic manifold.

6.1 Riemannian Metrics

6.1.1 Definitions and Examples

Definition 6.1.1. Let M be a smooth manifold. A *Riemannian metric* on M is a tensor field g in $\mathrm{Sym}^2 TM^*$ that is positive definite. In more detail, at each point $p \in M$, a Riemannian metric determines an inner product on T_pM. A smooth manifold M together with a Riemannian metric g is called a *Riemannian manifold* and is denoted by the pair (M, g).

Over a coordinate patch of M with coordinate system $(x^1, \dots, x^n)$, as a section of $TM^{*\otimes 2}$, one writes the metric g as

$$g_{ij}\, dx^i \otimes dx^j,$$

where g_{ij} are smooth functions on M. (In this chapter, we regularly use Einstein's summation convention.) Since at each point, g is a symmetric tensor, $g_{ij} = g_{ji}$ identically. Furthermore, using the notation from Section 4.6, since g is a section of $\mathrm{Sym}^2 TM^*$, we write

$$g_{ij}\, dx^i\, dx^j. \tag{6.1}$$

The square root of the expression in Equation (6.1) is called the *line element* ds

associated to this metric. Many texts, in particular, physics texts, give the metric in reference to the line element by writing $ds^2 = g_{ij}\,dx^i\,dx^j$.

For vectors $X, Y \in T_pM$, we sometimes use the same notation as the first fundamental form ([6, Section 6.1]) and write $\langle X, Y\rangle_p$ for $g_p(X, Y)$, and it is also common to drop the subscript p whenever the point p is implied by context. By analogy with the dot product, the Riemannian metric allows one to define many common notions in geometry.

Definition 6.1.2. Let (M, g) be a Riemannian manifold. Suppose that X, Y are vectors in T_pM.

1. The *length* of X, denoted $\|X\|$, is defined by $\|X\| = \sqrt{g(X, X)}$.
2. The *angle* θ between X and Y is defined by
$$\cos\theta = \frac{g(X, Y)}{\|X\|\,\|Y\|}.$$
3. X and Y are called orthogonal if $g(X, Y) = 0$.

Whenever one introduces a new mathematical structure, one must discuss functions between any two instances of them and when two structures are considered equivalent. In the context of Riemannian manifolds, one still studies any smooth functions between two manifolds. However, two Riemannian manifolds are considered the same if they have the same metric. The following definition makes this precise.

Definition 6.1.3. Let M and N be two Riemannian manifolds. A diffeomorphism $f : M \to N$ is called an *isometry* if for all $p \in M$,

$$\langle X, Y\rangle_p = \langle df_p(X), df_p(Y)\rangle_{f(p)} \qquad \text{for all } X, Y \in T_pM.$$

Two Riemannian manifolds are called *isometric* if there exists an isometry between them.

From an intuitive perspective, an isometry is a transformation that bends (which also includes rigid motions) one manifold into another without stretching or cutting. Problem 6.1.6 asks the reader to show that the catenoid and the helicoid are isometric. Figure 6.1 shows intermediate stages of bending the catenoid into the helicoid. Though one might think this transformation incorporates some stretching because the longitudinal lines straighten out, the twist created in the helicoid strip "balances out" the flattening of the lines in just the right way so that one only needs to bend the surface.

Many examples of Riemannian metrics arise naturally as submanifolds of Riemannian manifolds.

Definition 6.1.4. Let $(N, \tilde{g})$ be a Riemannian manifold and M any smooth manifold. Let $f : M \to N$ be an immersion of M into N, i.e., f is differentiable and df_p

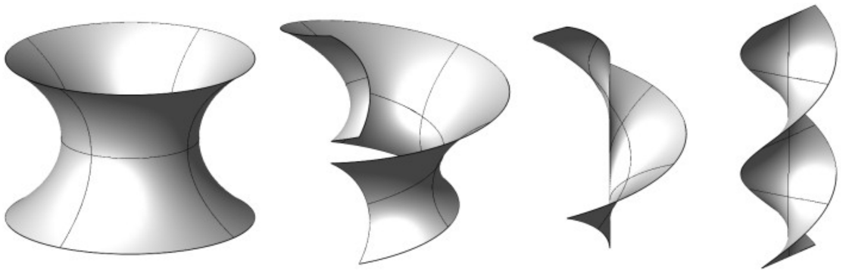

Figure 6.1: Bending the catenoid into the helicoid.

is injective for all p. The metric g on M *induced* by f (or "from N") is defined as the pull-back $g = f^*\tilde{g}$. In other words,

$$\langle X, Y\rangle_p = \langle df_p(X), df_p(Y)\rangle_{f(p)} \qquad \text{for all } p \in M \text{ and } X, Y \in T_pM.$$

The property that df_p is injective ensures that $\langle\, ,\, \rangle_p$ remains positive definite when induced on M.

Example 6.1.5 (Euclidean Spaces)**.** Consider the manifold $M = \mathbb{R}^n$, where $T_p(\mathbb{R}^n) = \mathbb{R}^n$ is naturally equipped with a Riemannian metric: the usual dot product. In particular,

$$g(\partial_i, \partial_j) = \delta_{ij} = \begin{cases} 1, & \text{if } i = j, \\ 0, & \text{if } i \neq j. \end{cases}$$

This metric is called the *Euclidean metric*.

Example 6.1.6 (First Fundamental Form)**.** A regular surface S is a 2-manifold embedded in $\mathbb{R}^3$, where the embedding map is simply the injection $i : S \to \mathbb{R}^3$. The first fundamental form (see Example 5.2.3) is precisely the metric on S induced by i from the Euclidean metric on $\mathbb{R}^3$. This connection gives us immediately a whole host of examples of Riemannian 2-manifolds that we take from the local theory of regular surfaces.

Proposition 6.1.7. *Let M be an m-dimensional manifold embedded in $\mathbb{R}^n$. If $\vec{F}(u_1, \dots, u_m)$ is a parametrization of a coordinate patch of M, then over this coordinate patch, the coefficients of the metric g on M induced from $\mathbb{R}^n$ are*

$$g_{ij} = \frac{\partial \vec{F}}{\partial u^i} \cdot \frac{\partial \vec{F}}{\partial u^j}.$$

Proof. Let $(x^1, \dots, x^n)$ be the coordinates on $\mathbb{R}^n$. Suppose that a coordinate patch (U, ϕ) of M has coordinates $(u_1, \dots, u_m)$ and that a parametrization of this coordinate patch is $\vec{F}(u_1, \dots, u_m) = \phi^{-1}(u_1, \dots, u_m)$. By Equation (3.14) the matrix of

$d\vec{F}$ in the given coordinate systems is

$$\left(\frac{\partial F^i}{\partial u^j}\right),$$

where $\vec{F} = (F^1, \dots, F^n)$.

Set $\langle\, , \rangle$ as the usual dot product in $\mathbb{R}^n$. Then at each point in U, the coefficients $g_{k\ell}$ of the metric g satisfy

$$\begin{aligned} g_{k\ell} &= g\left(\frac{\partial}{\partial u^k}, \frac{\partial}{\partial u^\ell}\right) = \left\langle d\vec{F}\left(\frac{\partial}{\partial u^k}\right), d\vec{F}\left(\frac{\partial}{\partial u^\ell}\right)\right\rangle = \frac{\partial F^i}{\partial u^k}\frac{\partial F^j}{\partial u^\ell}\left\langle \frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j}\right\rangle \\ &= \frac{\partial F^i}{\partial u^k}\frac{\partial F^j}{\partial u^\ell}\delta_{ij} = \frac{\partial \vec{F}}{\partial u^k}\cdot\frac{\partial \vec{F}}{\partial u^\ell}. \end{aligned}$$ □

We should emphasize at this point that a given manifold can be equipped with nonisometric Riemannian metrics. Problem 6.1.2 presents two different metrics on the 3-torus, each depending on a different embedding into some Euclidean space. In both cases, the 3-torus can be equipped with the same atlas, and so in both situations, the 3-torus is the same as a smooth manifold.

As another example, already in his seminal dissertation [47], Riemann introduced the following metric on the open unit ball in $\mathbb{R}^n$:

$$g_{ii} = \frac{4}{(1 - \|x\|^2)^2} \qquad \text{and} \qquad g_{ij} = 0 \text{ if } i \neq j. \tag{6.2}$$

As we will see, this is not isometric with the open unit ball equipped with the Euclidean metric.

Example 6.1.5 could be misleading in its simplicity. The reader might consider the possibility of defining a metric on any smooth manifold M by taking $\langle\, , \rangle_p$ as the usual dot product in each T_pM with respect to the coordinate basis associated to a particular coordinate system. The problem with this idea is that it does not define a smooth section in $\mathrm{Sym}^2\, TM^*$ over the whole manifold. Nonetheless, as the proof of the following proposition shows, we can use a partition of unity and stitch these bilinear forms together.

Proposition 6.1.8. *Every smooth manifold M has a Riemannian metric.*

Proof. Let M be a smooth manifold with atlas $\mathcal{A} = \{(U_\alpha, \phi_\alpha)\}_{\alpha\in I}$. For each $\alpha \in I$, label $\langle\, , \rangle^\alpha$ as the usual dot product with respect to the coordinate basis over U_α. Let $\{\psi_\alpha\}$ be a partition of unity that is subordinate to $\mathcal{A}$. For each $p \in M$, define the bilinear form $\langle\, , \rangle_p$ on T_pM by

$$\langle X, Y\rangle_p \overset{\text{def}}{=} \sum_{\alpha\in I} \psi_\alpha(p)\langle X, Y\rangle_p^\alpha \tag{6.3}$$

for any $X, Y \in T_pM$.

Since for each $p \in M$, only a finite number of $\alpha \in I$ have $\psi_\alpha(p) \neq 0$, then the sum in Equation (6.3) is finite. It is obvious by construction that $\langle X, Y \rangle_p$ is symmetric. To prove that $\langle\, , \rangle_p$ is positive definite, note that each $\langle X, Y \rangle_p^\alpha$ is. Let I' be the set of all indices $\alpha \in I$ such that $\psi_\alpha(p) \neq 0$. By definition of a partition of unity, $0 < \psi_\alpha(p) \leq 1$. Thus, for all $X \in T_pM$, clearly $\langle X, X \rangle_p \geq 0$. Furthermore, if $\langle X, X \rangle_p = 0$, then at least one summand in

$$\sum_{\alpha \in I'} \psi_\alpha(p) \langle X, X \rangle_p^\alpha$$

is 0. (In fact, all summands are 0.) Thus, there exists an $\alpha \in I$ with $\langle X, X \rangle_p^\alpha = 0$. Since $\langle\, , \rangle_p^\alpha$ is positive definite, then $X = 0$. Hence, $\langle X, X \rangle_p$ itself is positive definite. □

Though Equation (6.3) presents a Riemannian metric on any smooth manifold M, this is not in general easy to work with for specific calculations since it uses a partition of unity, which involves functions that are usually complicated. At any given point $p \in M$, Equation (6.3) does not involve one coordinate system around p but all of the atlas's coordinate neighborhoods of p.

More importantly, the Riemannian metric constructed in the above proof might not have any natural meaning.

Example 6.1.9 (Projective Space)**.** There is a natural metric on projective space $\mathbb{RP}^n$ that is induced from the Euclidean metric on $\mathbb{R}^{n+1}$. First, let g be the metric on $\mathbb{S}^n$ induced from Euclidean $\mathbb{R}^n$ as an embedded submanifold. Recall that the projection map $\pi : \mathbb{S}^n \to \mathbb{RP}^n$ as presented for $n = 2$ in Example 3.2.3 is a smooth function between manifolds. Define the metric $\tilde{g}$ on $\mathbb{RP}^n$ by

$$\tilde{g}_{\pi(p)}(v, w) = g_p\left((d\pi_p)^{-1}(v), (d\pi_p)^{-1}(w)\right), \tag{6.4}$$

for all $v, w \in T_{\pi(p)}\mathbb{RP}^n$. Note first that for all $p \in \mathbb{S}^n$, the linear transformation $d\pi_p$ is surjective between spaces of the same dimension, so is invertible. More importantly, $\tilde{g}$ is well-defined: If $A : \mathbb{S}^n \to \mathbb{S}^n$ is the antipodal map $A(p) = -p$, then $\pi \circ A = \pi$. Hence, $d\pi_p = d(\pi \circ A)_p = d\pi_{-p} \circ dA_p$. Hence

$$\begin{aligned} g_p &\left((d\pi_p)^{-1}(v), (d\pi_p)^{-1}(w)\right) \\ &= g_p\left((dA_p)^{-1}((d\pi_{-p})^{-1}(v)), (dA_p)^{-1}((d\pi_{-p})^{-1}(w))\right) \\ &= g_{-p}((d\pi_{-p})^{-1}(v), (d\pi_{-p})^{-1}(w)), \end{aligned}$$

where the second equality follows because $A : \mathbb{S}^n \to \mathbb{S}^n$ is an isometry. Consequently, in (6.4), the choice of p or $-p$ for the pre-image of $\pi(p)$ in $\mathbb{RP}^n$ is irrelevant.

6.1.2 Arclength and Volume

Using integration, the Riemannian metric allows for formulas that measure nonlocal properties, such as length of a curve and volume of a region on a manifold.

For example, consider a C^1 curve $\gamma : [a,b] \to M$ on a Riemannian manifold (M,g). At each point $\gamma(t)$ in M, the vector $\gamma'(t) = \frac{d\gamma}{dt}$ is a tangent vector, called the *velocity vector*. The Riemannian metric $g = \langle\, , \rangle$ allows one to calculate the length $\|\gamma'(t)\|$, which we call the *speed*. This motivates the following definition.

Definition 6.1.10. Let $\gamma : [a,b] \to M$ be a curve on a Riemannian manifold M of class C^1. The arclength of the curve γ is

$$\ell(\gamma) = \int_a^b \sqrt{\left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle_{\gamma(t)}}\, dt.$$

Proposition 6.1.11. *Let (M,g) be an oriented Riemannian manifold of dimension n. There exists a unique n-form, denoted dV, such that at all $p \in M$, it satisfies $dV_p(e_1, \dots, e_n) = 1$ for all bases $(e_1, \dots, e_n)$ in T_pM that are orthonormal with respect to $g_p(\, ,)$. Furthermore, over any coordinate patch U with coordinates $x = (x^1, \dots, x^n)$,*

$$dV = \sqrt{\det(g_{ij})}\, dx^1 \wedge \cdots \wedge dx^n, \tag{6.5}$$

where $g_{ij} = g(\partial_i, \partial_j) = \langle \partial/\partial x^i, \partial/\partial x^j \rangle$.

Proof. The content of this proposition is primarily linear algebra. By Proposition C.2.1, on each coordinate patch U_α, the form $dV|_{U_\alpha} = \omega_\alpha$ exists on each T_pM and is given by Equation (6.5). The existence of this n-form ω with the desired property explicitly requires that g_p be an inner product on T_pM. In order to define the form dV on the whole manifold, we refer to a partition of unity $\{\psi_\alpha\}$ subordinate to the atlas on M and define

$$dV = \sum_\alpha \psi_\alpha \omega_\alpha. \qquad \square$$

Definition 6.1.12. The form dV described in Proposition 6.1.11 is called the *volume form* of (M,g) and is denoted dV_M if there is a chance of confusion about the manifold. If M^m is a compact manifold, then the m-volume of M is the integral

$$\operatorname{Vol}(M) = \int_M dV. \tag{6.6}$$

If $i : M^m \to N^n$ is an embedded submanifold of a Riemannian manifold $(N, \tilde{g})$ then we can also calculate the m-volume of the submanifold M by equipping M with the metric $g = i^*\tilde{g}$, i.e., the metric induced from N. The reader should be aware that the volume form on M is not necessarily $i^*(dV_N)$. In particular, if $m < n$, then $i^*(dV_N)$ would be an n-form on M, but there are no n-forms on M. We illustrate this with a few examples.

Example 6.1.13 (Arclength)**.** Definition 6.1.10 should actually be a corollary of Proposition 6.1.11 and Definition 6.1.12. Let $(M, \tilde{g})$ be a Riemannian manifold and let $\gamma : [a, b] \to M$ be a curve of class C^1 on M. The induced metric g on γ is defined by

$$g_t(v, w) = \tilde{g}_{\gamma(t)} \left(\frac{d\gamma}{dt} v, \frac{d\gamma}{dt} w \right).$$

However, since a curve is one dimensional, both tangent vectors v and w are scalars. So

$$g_t(v, w) = \tilde{g}_{\gamma(t)}((d\gamma/dt), (d\gamma/dt))vw.$$

In the coordinate t on $[a, b]$, the domain of γ, the metric tensor can be represented by a 1×1 matrix $(\tilde{g}_{\gamma(t)}((d\gamma/dt), (d\gamma/dt)))$. Thus, the volume form on γ from the metric induced from M, is

$$dV = \sqrt{\tilde{g}_{\gamma(t)}((d\gamma/dt), (d\gamma/dt))}\, dt.$$

Definition 6.1.10 follows as a corollary.

Example 6.1.14 (Volume form on $\mathbb{S}^n$)**.** Consider the unit n-sphere $\mathbb{S}^n$ as a Riemannian manifold, equipped with the metric induced from its usual embedding in $\mathbb{R}^{n+1}$.

Consider the usual longitude-latitude parametrization of the sphere $\mathbb{S}^2$:

$$\vec{X}(u, v) = (\cos u \sin v, \sin u \sin v, \cos v) \quad \text{for} \quad (u, v) \in [0, 2\pi] \times [0, \pi].$$

Note that if we restrict the domain to $(0, 2\pi) \times (0, \pi)$, we obtain a dense open subset of $\mathbb{S}^2$. By Proposition 6.1.7, with respect to this coordinate system, the coefficients of the metric tensor are

$$g_{ij} = \begin{pmatrix} \sin^2 v & 0 \\ 0 & 1 \end{pmatrix}.$$

Since $\sin v \geq 0$ for $v \in [0, \pi]$, the volume form on $\mathbb{S}^2$ with respect to this coordinate system is $dV = \sin v\, du \wedge dv$. By Proposition 5.8.1, the volume of the sphere is calculated by

$$V = \int_{\mathbb{S}^2} dV = \int_0^{\pi} \int_0^{2\pi} \sin v\, du\, dv = 2\pi \big[-\cos v \big]_0^{\pi} = 4\pi.$$

We now calculate the volume form on $\mathbb{S}^n$ using an alternate approach. By Example 4.6.24, we see that the volume form on $\mathbb{R}^{n+1}$ is

$$e^{*1} \wedge \cdots \wedge e^{*(n+1)},$$

where $\{e_1, \ldots, e_{n+1}\}$ is the standard basis on $\mathbb{R}^{n+1}$. Furthermore, recall that as an alternating function,

$$e^{*1} \wedge \cdots \wedge e^{*(n+1)}(v_1, \ldots, v_{n+1}) = \det \begin{pmatrix} v_1 & \cdots & v_{n+1} \end{pmatrix}$$

for any $(n+1)$-tuple of vectors $(v_1, \ldots, v_{n+1})$.

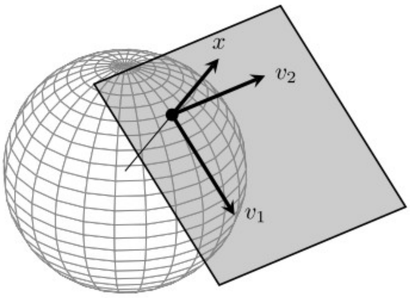

Figure 6.2: Volume form on the sphere.

Define a form $\omega \in \Omega^n(\mathbb{R}^{n+1})$, where for each $x \in \mathbb{R}^{n+1}$ and for any vectors u_i

$$\omega_x(u_1, \dots, u_n) = \det \begin{pmatrix} x & u_1 & \cdots & u_n \end{pmatrix}.$$

This is in fact, the same construction as the inner product on forms $i_x\omega$, but where we are taking advantage of the identification of $\mathbb{R}^{n+1}$ with its own tangent space. By the properties of the determinant, for each x, ω_x is an alternating n-multilinear function on $\mathbb{R}^{n+1}$, so ω is indeed an n-form. Using the Laplace expansion of the determinant, it is easy to show that

$$\omega = \sum_{i=1}^{n+1} (-1)^{i-1} x^i \, dx^1 \wedge \cdots \wedge \widehat{dx^i} \wedge \cdots \wedge dx^{n+1}, \tag{6.7}$$

where the $\widehat{\ }$ notation means to exclude the bracketed term. Using the forms η^j introduced in Equation (5.24), we can write $\omega = \sum_j x^j \eta^j$.

Now if $x \in \mathbb{S}^n$, then from the geometry of the sphere, x is perpendicular to $T_x\mathbb{S}^n$ as a subspace of $\mathbb{R}^{n+1}$ (equipped with the Euclidean metric). Thus, if $\{v_1, \dots, v_n\}$ forms a basis of $T_x\mathbb{S}^n$, then $\{x, v_1, \dots, v_n\}$ forms a basis of $\mathbb{R}^{n+1}$. See Figure 6.2. Furthermore, if the n-tuple $(v_1, \dots, v_n)$ is an orthonormal, positively-oriented basis of $T_x\mathbb{S}^n$, then $(x, v_1, \dots, v_n)$ is an orthonormal, positively-oriented basis of $\mathbb{R}^{n+1}$. But then the restriction of ω to $\mathbb{S}^n$ has the properties described in Proposition 6.1.11. Hence, if $f : \mathbb{S}^n \to \mathbb{R}^{n+1}$ is the usual embedding of the sphere in Euclidean space, then we obtain the volume form of $\mathbb{S}^n$ as

$$dV_{\mathbb{S}^n} = \omega\big|_{\mathbb{S}^n} = f^*(\omega).$$

In Section 5.7, we attempted to generalize with the single technique of integration on manifolds all the types of integration introduced in a standard calculus sequence. However, there were two types of integrals in the list at the beginning of the section that did not fit in the formalism we had developed for the integration of n-forms on n-dimensional smooth manifolds, namely:

- Line integrals of functions in $\mathbb{R}^n$.
- Surface integrals of a real-valued function defined over a closed and bounded region of a regular surface in $\mathbb{R}^3$.

Both of these types of integrals fit into the theory of integration volume forms on manifolds in the following ways.

For the line integral of functions in $\mathbb{R}^n$ over a piecewise-smooth curve C, let $\gamma : [a, b] \to \mathbb{R}^n$ be a parametrization of C. Let $\langle\, ,\, \rangle$ be the Euclidean form on $\mathbb{R}^n$ (i.e., the dot product). Then each smooth piece of γ is a one-dimensional submanifold of $\mathbb{R}^n$, equipped with the metric induced from $\mathbb{R}^n$. The volume form on γ is dV_γ so that for any smooth function f defined on a neighborhood of C,

$$\int_\gamma f\, dV_\gamma = \int_a^b f(t)\sqrt{\left\langle \frac{d\gamma}{dt}, \frac{d\gamma}{dt} \right\rangle_{\gamma(t)}}\, dt = \int_C f\, ds. \tag{6.8}$$

For surface integrals of a function f on a compact regular surface $\mathcal{S} \subset \mathbb{R}^3$, it is not hard to show (see Problem 6.1.1) that $dS = dV_{\mathcal{S}}$, where $dV_{\mathcal{S}}$ is the volume form on $\mathcal{S}$ equipped with the metric induced from the Euclidean metric. Thus, connecting the classical notation with the notation introduced in this section,

$$\int_{\mathcal{S}} f\, dS = \int_{\mathcal{S}} f\, dV_{\mathcal{S}}. \tag{6.9}$$

6.1.3 Raising and Lowering Indices

One interesting property of metrics on manifolds is that they give us a natural way to go back and forth between vectors and covectors.

Recall from Section 4.1 that for any real vector space V, the dual vector space V^* consists of all linear transformations $V \to \mathbb{R}$. If V is a vector space equipped with any bilinear form $\langle\, ,\, \rangle$, then this form defines a linear transformation into the dual V^* by

$$\begin{aligned} i : V &\longrightarrow V^*, \\ v &\longmapsto i_v \quad = (w \mapsto \langle v, w\rangle). \end{aligned}$$

If V is finite-dimensional and the bilinear form $\langle\, ,\, \rangle$ is nondegenerate, then the mapping $(v \mapsto i_v)$ is an isomorphism. We will assume from now on that $\langle\, ,\, \rangle$ is an inner product. The positive-definite implies the bilinear form is nondegenerate so the above mapping is an isomorphism. This isomorphism allows us to define a natural bilinear form $\langle\, ,\, \rangle^*$ on V^* by

$$\langle \eta, \tau\rangle^* = \langle i^{-1}(\eta), i^{-1}(\tau)\rangle.$$

Then $\langle\, ,\, \rangle^*$ is an element of $V \otimes V$, so is a tensor of type of $(2, 0)$. Furthermore, if the components of $\langle\, ,\, \rangle$ are c_{jk}, then the components of $\langle\, ,\, \rangle^*$ with respect to the associated basis are denoted by c^{jk}, where these are the entries of the inverse matrix C^{-1}, where $C = (c_{jk})$. (See Exercises 4.2.4 and 4.2.5 for where we prove these results.)

In coordinates, let $\mathcal{B} = \{u_1, \dots, u_n\}$ be a basis of V and let $\mathcal{B}^* = \{u^{*1}, \dots, u^{*n}\}$ be the associated cobasis. Let $C = (c_{jk})$ be the matrix of $\langle\, , \,\rangle$ with respect to $\mathcal{B}$, viz., $c_{jk} = \langle u_j, u_k\rangle$. Then

$$\langle v, w\rangle = [v]_{\mathcal{B}}^T C[w]_{\mathcal{B}} = c_{jk} v^j w^k. \tag{6.10}$$

This gives the coordinates of i_v with respect to $\mathcal{B}^*$ as $c_{jk}v^j$. Note that the indices for the components of i_v arise naturally as subscripts, consistent with our notation. Similarly, if $\lambda \in V^*$ is a functional on V, then $\lambda = \lambda_i u^{*i}$. If $\lambda = i_v$ for some $v \in V$, then

$$c^{k\ell}\lambda_k = c^{k\ell} a_{jk} v^j = c_{jk} a^{k\ell} v^j = \delta^\ell_j v^j = v^\ell. \tag{6.11}$$

We say that the process of mapping v to i_v "lowers the indices," while mapping λ to $i^{-1}(\lambda)$ "raises the indices."

Now consider a Riemannian manifold (M, g). If $X \in \mathfrak{X}(M)$ is a vector field on M, we define the covector field $X^\flat$ by

$$X^\flat(Y) \stackrel{\text{def}}{=} g(X, Y)$$

for all vector fields $Y \in \mathfrak{X}(M)$. On a coordinate patch, X has coordinates X^i. By the process described in the previous paragraphs, $X^\flat$ has components $g_{ij}X^i$. Mimicking musical notation, the function $\Gamma(TM) \to \Gamma(TM^*)$ that sends $X \mapsto X^\flat$ is call the *flat*, since it lowers the indices of the vector field X.

As we saw, a metric g^* on M also induces an inner product in $\operatorname{Sym}^2 T_pM$ defined by $g^*(\eta, \tau) = g(i^{-1}(\eta), i^{-1}(\tau))$ for any $\eta, \tau \in T_pM^*$. So if $\omega \in \Omega^1(M)$ is a covector field on M, we define the vector field $\omega^\sharp$ by

$$\eta(\omega^\sharp) \stackrel{\text{def}}{=} g^*(\eta, \omega)$$

for all covector fields $\eta \in \Omega^1(M)$. On a given coordinate patch, ω has component functions ω_i and the components of $\omega^\sharp$ are $g^{ij}\omega_i$. Keeping the musical analogy, we denote call this vector field the *sharp* of ω since the process raises the indices.

More generally, if T is any tensor field of type (p, q) on M, then

$$g_{i_\alpha k} T^{i_1\cdots i_p}_{j_1\cdots j_q} \qquad \text{and} \qquad g^{j_\beta l} T^{i_1\cdots i_p}_{j_1\cdots j_q}$$

define tensors fields of type $(p-1, q+1)$ and type $(p+1, q-1)$, respectively. It is common to still use the $\flat$ and $\sharp$ notation, here $T^\flat$ and $T^\sharp$, but one must indicate upon which index one performs the lowering or raising operations.

Recall that the trace of a matrix A is defined as the sum of the diagonal elements. If A has components A^i_j, then the trace is just A^i_i, using the Einstein summation convention of summing along i. Now A corresponds to a linear transformation

$T(\vec{v}) = A\vec{v}$ on a vector space V. Since the trace $\operatorname{Tr} A$ is also the sum of the eigenvalues, the trace remains unchanged under a change in basis in V.

Now, if A is a symmetric $(0,2)$-tensor, then $A^\sharp$ is a $(1,1)$-tensor, and the trace $\operatorname{Tr} A$ is defined in its usual linear algebraic sense. This process is common enough that we define the *trace with respect to* g of A to be

$$\operatorname{Tr}_g A \overset{\text{def}}{=} \operatorname{Tr} A^\sharp. \tag{6.12}$$

In coordinates, $\operatorname{Tr}_g A = g^{ij} A_{ij}$.

PROBLEMS

6.1.1. Recall the following formula from calculus. Let K be a compact set on a regular surface S in $\mathbb{R}^3$. Suppose that S is parametrized by $\vec{r}(u,v)$ and that under this parametrization, $K = \vec{R}(D)$ for some compact region D. Then the surface area of K on S is

$$\iint_K dS = \iint_D \|\vec{r}_u \times \vec{r}_v\| \, du \, dv.$$

Consider the regular surface S as a 2-manifold embedded in the Riemannian manifold of $\mathbb{R}^3$, equipped with the dot product as its usual metric. The parametrization $\vec{r}(u,v)$ describes the embedding of S in $\mathbb{R}^3$ in reference to the coordinates in a chart of S. Prove that the volume form on S of metric on S induced from the dot product in $\mathbb{R}^3$ is

$$dV_S = \|\vec{r}_u \times \vec{r}_v\| \, du \wedge dv.$$

This establishes the familiar surface area integral from Definition 6.1.12.

6.1.2. Consider the 3-torus $\mathbb{T}^3 = \mathbb{S}^1 \times \mathbb{S}^1 \times \mathbb{S}^1$. Calculate the induced metrics for the following two embeddings:

(a) Into $\mathbb{R}^6$ as the image of the parametrization

$$\vec{F}(u^1,u^2,u^3) = \left(\cos u^1, \sin u^1, \cos u^2, \sin u^2, \cos u^3, \sin u^3\right).$$

(b) Into $\mathbb{R}^4$ as the image of the parametrization $\vec{F}(u^1,u^2,u^3)$ given by

$$\Big((c + (b + a\cos u^1)\cos u^2)\cos u^3, (c + (b + a\cos u^1)\cos u^2)\sin u^3,$$
$$(b + a\cos u^1)\sin u^2, a\sin u^1\Big),$$

where $b > a > 0$ and $c > a + b$.

(c) Prove that these two Riemannian manifolds are not isometric.

[Hint: This gives two different metrics on the 3-torus that can be equipped with the same atlas in each case.]

6.1.3. We consider an embedding of $\mathbb{S}^1 \times \mathbb{S}^2$ in $\mathbb{R}^4$ by analogy with the embedding of the torus $\mathbb{S}^1 \times \mathbb{S}^1$ in $\mathbb{R}^3$. Place the sphere $\mathbb{S}^2$ with radius a at $(0,0,b,0)$ (where $b > a$) as a subset of the $x^1x^2x^3$-subspace, and rotate this sphere about the origin with a motion parallel to the x^3x^4-axis. Call this submanifold M and equip it with the metric induced from $\mathbb{R}^4$.

(a) Show that the described manifold M is an embedding as claimed.

(b) Find a parametrization $F : D \to \mathbb{R}^4$ where $D \subset \mathbb{R}^3$ such that, as sets of points $F(D) = M$, and $F(D^\circ)$ is an open subset of M that is homeomorphic to D°. (D° is the interior of the set D.)

(c) Calculate the coefficients g_{ij} of the metric on M in the coordinate patch defined by the above parametrization.

6.1.4. Let (M_1, g_1) and (M_2, g_2) be two Riemannian manifolds, and consider the product manifold $M_1 \times M_2$ with a $(0, 2)$-tensor field defined by

$$g(X_1 + X_2, Y_1 + Y_2) = g_1(X_1, Y_1) + g_2(X_2, Y_2).$$

(a) Show that g defines a metric on $M_1 \times M_2$.

(b) Let $(x^1, \ldots, x^n)$ be local coordinates on M_1 and $(x^{n+1}, \ldots, x^{n+m})$ be local coordinates on M_2 so that $(x^1, \ldots, x^{m+n})$ are local coordinates on $M_1 \times M_2$. Determine the components of the metric g on $M_1 \times M_2$ in terms of g_1 and g_2.

6.1.5. Repeat Problem 6.1.3 with $\mathbb{S}^1 \times S$, where S is a regular surface in $\mathbb{R}^3$ that does not intersect the plane $z = x^3 = 0$.

6.1.6. Consider the following two regular surfaces in $\mathbb{R}^3$. The catenoid parametrized by

$$F(\bar{u}^1, \bar{u}^2) = (\bar{u}^2 \cos \bar{u}^1, \bar{u}^2 \sin \bar{u}^1, \cosh^{-1} \bar{u}^2) \text{ for } (\bar{u}^1, \bar{u}^2) \in [0, 2\pi) \times [1, +\infty)$$

and the helicoid parametrized by

$$F(u^1, u^2) = (u^2 \cos u^1, u^2 \sin u^1, u^1) \text{ for } (u^1, u^2) \in [0, 2\pi) \times \mathbb{R}.$$

Prove that the helicoid and catenoid are isometric, and find an isometry between them.

6.1.7. Let M be a hypersurface of $\mathbb{R}^n$ (submanifold of dimension $n-1$), and equip M with Riemannian structure with the metric induced from $\mathbb{R}^n$. Suppose that an open set U of M is a graph of an $(n-1)$-variable function f, i.e., the parametrization of U is

$$x^1 = u^1, \ldots, x^{n-1} = u^{n-1}, x^n = f(u^1, \ldots, u^{n-1}), .$$

for $(u^1, \ldots, u^{n-1}) \in D$.

(a) Find the coefficients of the metric tensor g on M, and conclude that a formula for the $(n-1)$-volume of U is

$$\int_D \sqrt{1 + \|\text{grad } f\|^2} \, dV.$$

(b) Use this result to calculate the 3-volume of the surface in $\mathbb{R}^4$ given by $w = x^2 + y^2 + z^2$ for $x^2 + y^2 + z^2 \leq 4$.

6.1.8. Let M, N, and S be Riemannian manifolds, and let $f : M \to N$ and $h : N \to S$ be isometries.

(a) Show that f^{-1} is an isometry.

(b) Show that $h \circ f$ is an isometry.

(c) If you have seen some group theory, show that the set of isometries on a Riemannian manifold M forms a group.

6.1.9. Two metrics g and $\tilde{g}$ on a smooth manifold M are called *conformal* if there exists a smooth function $f \in C^{\infty}(M, \mathbb{R})$ such that $\tilde{g} = fg$. Prove that for all $p \in M$ and for all $X, Y \in T_pM$, the angle between X and Y with respect to $\tilde{g}$ is the same as the angle with respect to g.

6.1.10. Let (M, g) and $(N, \tilde{g})$ be Reimannian manifolds. A diffeomorphism $f : M \to N$ is called a conformal mapping if $f^*\tilde{g}$ is conformal to g. Repeat Problem 6.1.8 but replacing "isometry" with "conformal mapping." (See Problem 6.1.9.)

6.1.11. Let γ be a curve on a Riemannian manifold (M, g). Show precisely how the induced metric on γ generalizes Definition 6.1.10.

6.1.12. *Poincaré ball.* The Poincaré Ball is the open ball $\mathbb{B}^n_R$ in n dimensions of radius R equipped with the metric

$$\frac{4R^4}{(R^2 - \|x\|^2)^2} \left((dx^1)^2 + \cdots + (dx^n)^2 \right).$$

Note that this metric is conformal with the metric (see Problem 6.1.9) induced from the Euclidean metric in $\mathbb{R}^{n+1}$.

(a) Set $n = 2$ and $R = 1$. (This choice of parameters is called the unit Poincaré disk.) Calculate the area of the region $\mathcal{R}$ defined by $\|x\| \leq \frac{1}{2}$ and $0 \leq \theta \leq \pi/2$.

(b) Set $n = 3$ and $R = 2$. Calculate the length of the curve $\gamma(t) = (\cos t, \sin t, t/10)$ in the Poincaré ball for $0 \leq t \leq 4\pi$.

6.1.13. *Divergence Theorem.* Let (M, g) be an oriented, compact, Riemannian manifold with boundary. Given any vector field $X \in \mathfrak{X}(M)$ and any tensor field T of type (p, q), with $q \geq 1$, we define the contraction of X with T, denoted $i_X T$, as the tensor field of type $(p, q-1)$ that over any coordinate chart has components

$$X^l T^{i_1 \cdots i_p}_{l j_2 \cdots j_q}.$$

We define the *divergence operator* $\operatorname{div} : \mathfrak{X}(M) \to C^{\infty}(M)$ implicitly by

$$d(i_X \, dV) = (\operatorname{div} X) \, dV.$$

Prove the Divergence Theorem, which states that for any $X \in \mathfrak{X}(M)$

$$\int_M \operatorname{div} X \, dV = \int_{\partial M} g(X, N) \, d\tilde{V},$$

where N is the outward unit normal to ∂M and $d\tilde{V}$ is the volume form associated to the metric on ∂M induced from M.

6.1.14. We consider the sphere $\mathbb{S}^3$ of radius R as a submanifold in $\mathbb{R}^4$ with the induced Euclidean metric.

(a) Show that

$$F(u^1, u^2, u^3) = (R\cos u^1 \sin u^2 \sin u^3, R\sin u^1 \sin u^2 \sin u^3, R\cos u^2 \sin u^3, R\cos u^3),$$

where $(u^1, u^2, u^3) \in [0, 2\pi] \times [0, \pi]^2$ gives a parametrization for $\mathbb{S}^3$ that is homeomorphic to its image when restricted to the open set $V = (0, 2\pi) \times (0, \pi)^2$.

(b) Calculate the components of the metric tensor on the coordinate patch $F(V) = U$.

(c) Use part (b) to calculate the volume of a 3-sphere of radius R.

(d) Leaving R unspecified, consider the function $f(x^1, x^2, x^3, x^4) = (x^1)^2 + (x^2)^2 + (x^3)^2$ and calculate the volume integral $\int_{\mathbb{S}^3} f\, dV$. (Note that this integral would give the radius of gyration of the spherical shell of radius R about a principal axis – if such a thing existed in $\mathbb{R}^4$!)

6.1.15. Calculate the 5-volume of the 5-sphere $\mathbb{S}^5$ of radius R as a submanifold of $\mathbb{R}^6$.

6.1.16. (**ODE**) A loxodrome on the unit sphere $\mathbb{S}^2$ is a curve that makes a constant angle with all meridian lines. We propose to study analogues of loxodromes on $\mathbb{S}^3$. Consider the unit 3-sphere $\mathbb{S}^3$ with the parametrization from Problem 6.1.14. Set $R = 1$. We will call a loxodrome on $\mathbb{S}^3$ any curve γ such that γ' makes a constant angle of α_2 with $\frac{\partial}{\partial u^2}$ and a constant angle of α_3 with $\frac{\partial}{\partial u^3}$.

(a) Find equations that the components of γ must satisfy.

(b) Solve the differential equations we get in part (a). [Hint: Obtain u^1 and u^2 as functions of u^3. You might only be able to obtain one of these functions implicitly.]

6.1.17. Consider the function $r : \mathbb{R}^{n+1} - \{0\} \to \mathbb{S}^n$ given by $r(x) = x/\|x\|$.

(a) Using Example 6.1.14, prove that

$$\tilde{\omega} = r^*(dV_{\mathbb{S}^n}) = \frac{1}{\|x\|^{n+1}} \sum_{j=1}^{n+1} x^j \eta^j.$$

(b) Show that $\tilde{\omega}$ is closed but not exact in $\mathbb{R}^{n+1} - \{0\}$.

(c) Use $dV_{\mathbb{S}^n}$ to show that

$$\mathrm{Vol}(\mathbb{S}^n) = (n+1)\mathrm{Vol}(\mathbb{B}^{n+1}),$$

where $\mathbb{B}^{n+1}$ is the unit ball in $\mathbb{R}^{n+1}$.

6.1.18. Let M be a Riemannian manifold, and let $f : M \to M$ be an isometry on M. Prove that $f^*(dV_M) = \pm dV_M$. (The isometry f is called *orientation-preserving* if $f^*(dV_M) = dV_M$ and *orientation-reversing* if $f^*(dV_M) = -dV_M$.)

6.1.19. Suppose that J and K are disjoint, compact, oriented, connected, smooth submanifolds of $\mathbb{R}^{n+1}$ whose dimensions are greater than 0 and such that $\dim J + \dim K = n$. Define the function Ψ by

$$\begin{aligned} \Psi : J \times K &\longrightarrow \mathbb{S}^n \\ (x, y) &\longmapsto \frac{y - x}{\|y - x\|}. \end{aligned}$$

The *linking number* between J and K is defined as

$$\text{link}(J, K) = \frac{1}{\text{Vol}(\mathbb{S}^n)} \int_{J \times K} \Psi^*(dV_{\mathbb{S}^n}).$$

Prove Gauss's Linking Formula for the linking number of two closed space curves:

$$\text{link}(C_1, C_2) = \frac{1}{4\pi} \int_I \int_J \frac{\det(\vec{\alpha}(u) - \vec{\beta}(v), \vec{\alpha}'(u), \vec{\beta}'(v))}{\|\vec{\alpha}(u) - \vec{\beta}(v)\|^3} \, du \, dv. \tag{6.13}$$

[Note that a closed curve is homeomorphic to a circle $\mathbb{S}^1$ so $J \times K$ is homeomorphic to a torus. Hence, we can view Ψ as a function $\mathbb{T}^2 = \mathbb{S}^1 \times \mathbb{S}^1 \to \mathbb{S}^2$.]

The following exercises involve the Hodge star operation, which is introduced in Appendix C.3.

6.1.20. Let (M, g) be an oriented Riemannian manifold. Section C.3 defines the Hodge star operator on inner product spaces. Given a form $\eta \in \Omega^k(M)$, at each $p \in M$, the Hodge star operator defines an isomorphism $\star : \bigwedge^k T_pM^* \to \bigwedge^{n-k} T_pM^*$.

(a) Show that the Hodge star operator $\star$ is a vector bundle map $\bigwedge^k TM^* \to \bigwedge^{n-k} TM^*$ that leaves every base point fixed and that varies smoothly.

(b) Show that for all functions $f : C^\infty(M)$, the Hodge star operator is given by $\star f = f dV_g$.

6.1.21. Consider $\mathbb{R}^n$ as a manifold with the standard Euclidean metric.

(a) Calculate $\star dx^i$ for any $i = 1, \dots, n$.

(b) Set $n = 4$, and calculate $\star(dx^i \wedge dx^j)$.

6.1.22. Let (M, g) be an oriented Riemannian manifold. Prove the following identities for any vector field $X \in \mathfrak{X}(M)$.

(a) $\text{div}\, X = \star d \star X^\flat$, where div is the divergence operator defined in Problem 6.1.13.

(b) $i_X dV_g = \star X^\flat$.

6.1.23. Let (M, g) be a Riemannian manifold. Consider the operation that consists of $\star d \star d$.

(a) Show that $\star d \star d$ is an $\mathbb{R}$-linear operator $\Omega^k(M) \to \Omega^k(M)$ for $k < \dim M$.

(b) Let $M\mathbb{R}^n$ be a standard Euclidean space. Recalling that $\Omega^0(M) = C^\infty(M)$, show that for any smooth function f,

$$\star d \star df = \nabla^2 f,$$

where ∇^2 is the usual Laplacian $\nabla^2 = \dfrac{\partial^2}{\partial(x^1)^2} + \cdots + \dfrac{\partial^2}{\partial(x^n)^2}$.

(c) Find an expression in coordinates of $\star d \star df$ for smooth functions $f : \mathbb{S}^2 \to \mathbb{R}$, express in (u, v) longitude-latitude coordinates as used in Example 6.1.14.

6.2 Connections and Covariant Differentiation

6.2.1 Motivation

Despite all the "heavy machinery" we have developed in order to create a theory of analysis on manifolds, we are still unable to calculate or even define certain things that are simple in $\mathbb{R}^n$.

For example, if $\gamma : [a, b] \to M$ is a smooth curve on a smooth manifold, we have no way at present to talk about the acceleration of γ. Let $p \in M$, with $\gamma(t_0) = p$. In Definition 3.3.1, we presented the tangent vector $\gamma'(t_0)$ at p as the operator $D_\gamma : C^1(M) \to \mathbb{R}$ that evaluates

$$D_\gamma(f) = \frac{d}{dt} f(\gamma(t))\Big|_{t_0}.$$

In Section 3.3, we developed the linear algebra of expressions D_γ for curves γ through p. The vector space of such operators is what we called the tangent space T_pM.

Mimicking what one does in standard calculus, one could try to define the acceleration vector $\gamma''(t_0)$ at p as a limiting ratio as $t \to t_0$ of $\gamma'(t) - \gamma'(t_0)$ with $t - t_0$. However, what we just wrote does not make sense in the context of manifolds because $\gamma'(t)$ and $\gamma'(t_0)$ are not even in the same vector spaces and so their difference is not defined.

Another attempt to define the acceleration might follow Definition 3.3.1 and try to define $\gamma''(t_0)$ at p as the operator $D^{(2)}_\gamma : C^2(M) \to \mathbb{R}$, where

$$D^{(2)}_\gamma(f) = \frac{d^2}{dt^2} f(\gamma(t))\big|_{t_0}.$$

This operator is well defined and linear. However, $D^{(2)}_\gamma$ does not satisfy Leibniz's rule, and therefore, there does not exist another curve $\tilde{\gamma}$, with $\tilde{\gamma}(t_0) = p$ such that $D^{(2)}_\gamma = D_{\tilde{\gamma}}$. Hence, $D^{(2)}_\gamma \notin T_pM$. We could study properties for operators of the form $D^{(2)}_\gamma$ but, since the operators do not exist in any $TM^{\otimes p} \otimes TM^{*\otimes q}$, this is not the direction the theory of manifolds developed.

Another lack in our current theory is the ability to take partial derivatives or, more generally, directional derivatives of a vector field. Over $\mathbb{R}^n$, it is easy to define $\partial\vec{F}/\partial x^j$, where $\vec{F}$ is a vector field, and, under suitable differentiability conditions, $\partial\vec{F}/\partial x^j$ is again another vector field. In contrast, if X is a vector field over a smooth manifold M and U is a coordinate neighborhood of $p \in M$, one encounters the same problem with defining a vector $\partial_i X_p$ as one does in defining the acceleration of a curve.

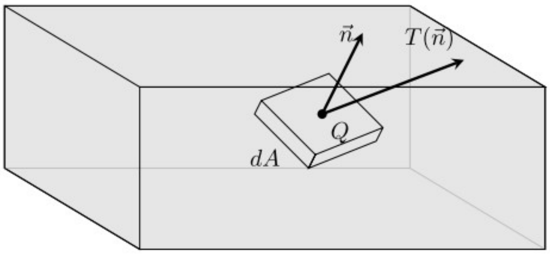

Figure 7.10: Stress tensor: an area element in a continuous medium.

7.5 Brief Introduction to General Relativity

As with the previous sections, the reader might consider it outlandish that we only allow one section to discuss general relativity. General relativity is a vast subject with contributions from a host of scientists and mathematicians, and it stands alongside quantum mechanics as one of the most revolutionary ideas in physics of the 20th century.

On the other hand, most textbooks on general relativity take a considerable amount of time to develop the techniques of analysis on manifolds, in particular, pseudo-Riemannian manifolds. However, these are precisely the mathematical methods we have developed in the previous chapters, so we are in a position to introduce some differential geometric concepts in general relativity as applications.

From the perspective of mathematical structures, general relativity builds on special relativity. The postulates of special relativity brought us to the notion of spacetime, which is a Minkowski space $\mathbb{R}^{3,1}$. In general relativity, we will want to consider our space as *locally Minkowski*, meaning that each tangent space is a Minkowski space. Hence, we model the universe as a pseudo-Riemannian manifold with signature $(3, 1)$. More importantly, the Einstein field equations propose a relationship between the presence of energy and the curvature of this spacetime manifold.

7.5.1 Stress-Energy Tensor

In the mechanics of elastic media, one encounters the concept of a stress tensor, which is a tensor-valued function defined at each point within the body or medium. Suppose the body is in equilibrium but subject to external forces and/or body forces (i.e., forces that act through the whole body). Then there must exist internal forces. Let Q be a point, $\vec{n}$ a vector based at Q, and consider the area element ΔA that is in the plane perpendicular to $\vec{n}$ and has area equal to $\|\vec{n}\|$ (see Figure 7.10). Let $\Delta\vec{F}$ be the overall internal forces distributed over the area element ΔA. The stress vector through the area element ΔA is the vector

$$\vec{T}(\vec{n}) = \lim_{\Delta A \to 0} \frac{\Delta \vec{F}}{\Delta A}. \tag{7.63}$$

It is not hard to show that the function $\vec{T}(\vec{n})$ is a linear function.[56, Section 10.6] Thus the stress tensor with respect to an orthogonal basis $\mathcal{B}$ based at the point Q is the matrix σ such that

$$\vec{T}(\vec{n}) = \sigma \big[\vec{n}\big]_{\mathcal{B}}.$$

Consider now a small rectangular parallelepiped with sides parallel to the coordinate planes. The stress acts on each face as depicted in Figure 7.11. Then the columns of σ are given by

$$\sigma \vec{e}_i = T(\vec{e}_i) = \begin{pmatrix} \sigma_{i1} \\ \sigma_{i2} \\ \sigma_{i3} \end{pmatrix}.$$

Minimal assumptions that are logical for physics (angular momentum in a medium cannot grow to be infinite at a point) imply that the stress tensor σ is symmetric.

As a simple example, in an ideal fluid, the stress on any small area element is composed only of pressure, and there is no shearing force. Consequently, the stress tensor is $\sigma = P\mathbf{I}$, where P is the pressure and $\mathbf{I}$ is the 3×3 identity matrix. (This restates the claim given in calculus texts on the applications of integration to hydrostatics when one says that "at any point in a liquid the pressure is the same in all directions."[55, p. 576]) The stress tensor arises also in the dynamics of viscous fluids where it is no longer necessarily diagonal. The stress tensor at a point "may be a function of the density and temperature, of the relative positions and velocities of elements near [the point], and perhaps also the previous history of the medium."[56, p. 434] This characterization describes the stress tensor as a function of many ambient quantities, but the reference to "relative positions" indicates that the stress tensor need not be diagonal.

Einstein's equation in general relativity involves the so-called *stress-energy tensor*. This tensor is different from the stress tensor but is based on the same concept. We assume that we are in a Minkowski space with metric $\mathbf{g}$ of signature $(3, 1)$.

As in special relativity, the four-velocity of a particle on a world line $\mathcal{P}$ parametrized by $\vec{x}$ is the tangent vector along $\mathcal{P}$ given by

$$\vec{U} = \frac{d\vec{x}}{d\tau}, \tag{7.64}$$

where, the proper time τ of an object along its world line is given in (7.20). From the theory of special relativity, by (7.22), the four-velocity is

$$\vec{U} = (U^0, U^1, U^2, U^3) = (\gamma c, \gamma v_x, \gamma v_y, \gamma v_z), \tag{7.65}$$

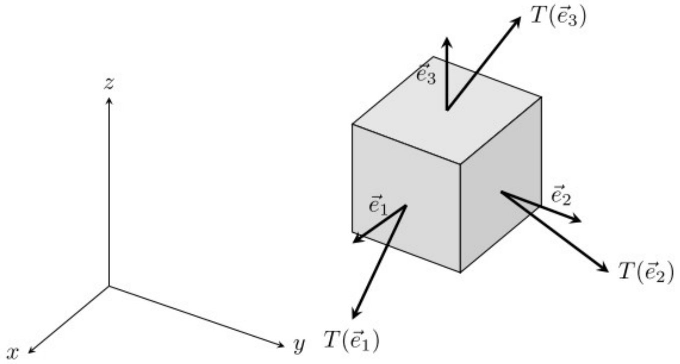

Figure 7.11: Action of stress on an infinitesimal coordinate cube.

where $\gamma = (1 - v^2/c^2)^{-1/2}$ and $\vec{v} = (dx/dt, dy/dt, dz/dt)$. In (7.23), we defined the momentum 4-vector of a particle of rest mass m by $\vec{p} = m\vec{u}$. Equally useful is the four-momentum covector given by

$$\mathbf{p} = \vec{p}^{\flat}. \tag{7.66}$$

In special relativity where the metric $\mathbf{g} = \eta$ is the standard Minkowski metric, the components of the momentum covector are

$$(p_0, p_1, p_2, p_3) = \left(-\frac{E}{c}, p_x, p_y, p_z \right), \tag{7.67}$$

where $(p_x, p_y, p_z) = m_0\gamma(v^1, v^2, v^3)$ is the relativistic 3-vector momentum.

Underlying the assumptions that define the stress-energy tensor, we assume that "spacetime contains a flowing river of 4-momentum"[41, p.130]. Any mass that is moving or anything with energy contributes to the 4-momentum. We could think of an individual particle, in which case the 4-momentum would only be defined on the particle's world line, or we could consider a system of many particles carrying this 4-momentum. In the latter case, we should think of the 4-momentum as a covector field on the spacetime manifold M, that is, as a 1-form.

Let $\mathbf{n}$ be any 1-form on M. Then at each point $Q \in M$, $\mathbf{n}_Q$ is perpendicular (using $\mathbf{g} = \langle \, , \rangle$ at Q) to a three-dimensional subspace of $T_Q M$. This subspace can be spanned by vectors A_Q, B_Q, and C_Q such that

$$\mathbf{n}_Q(u) = -\mathrm{Vol}_{\mathbf{g}}(u, A_Q, B_Q, C_Q), \tag{7.68}$$

where on the right-hand side we mean the 4-volume (with respect to $\mathbf{g}$) of the 4-parallelepiped spanned by $u, A_Q, B_Q, C_Q \in T_Q M$. Then the 3-volume of the 3-

parallelepiped A_Q, B_Q, C_Q is the length $\|\mathbf{n}\|$. In this way, every 1-form represents a volume element in $\mathbb{R}^4$.

We define the *stress-energy tensor* $\mathbf{T}$ of type $(2, 0)$ by $\mathbf{T}(\mathbf{p}, \mathbf{n})$ being the flux of the momentum covector $\mathbf{p}$ across a volume element represented by $\mathbf{n}$. At each point $Q \in M$, we have

$$\mathbf{T}(\mathbf{p}, \mathbf{n}) = \langle \mathbf{p}, \mathbf{n} \rangle_{\mathbf{g}}. \tag{7.69}$$

Over any coordinate chart (x^i), the components of $\mathbf{T}$ are

$$T^{\alpha\beta} = \mathbf{T}(dx^\alpha, dx^\beta)$$

to represent that flux of unit four-momentum in direction dx^α across a volume-element of constant β.

The stress-energy tensor $\mathbf{T}$ is also called the *energy-momentum tensor* because it contains information pertaining to the momentum flowing through space and the presence of static or moving energy in space. The name "stress-energy tensor" is commonly used since it is modeled off the stress tensor in mechanics of elastic media.

The following gives a summary of the information included in the stress-energy tensor. Assuming $j, k > 0$,

$$T^{00} = \text{density of energy (including mass)}, \tag{7.70}$$

$$T^{j0} = j\text{th component of the momentum density}, \tag{7.71}$$

$$T^{0k} = k\text{th component of the energy flux}, \tag{7.72}$$

$$\begin{aligned} T^{jk} &= (j,k)\text{th component of the momentum stress} \\ &= k\text{th component of the flux of the } j\text{th component of momentum.} \end{aligned} \tag{7.73}$$

The notion of *flux* in this context refers to a similar limit as in Equation (7.63) but in the situation where one is concerned with the movement of something (energy, fluid momentum, heat,...) through the infinitessimal area element $d\vec{A}$. In fact, with this particular concept of flux, one can define the stress-energy tensor in short by saying that T^{kj} is the kth component of the flux of the jth component of the 4-momentum.

We now state two facts about the stress-energy tensor that we do not fully justify here.

Proposition 7.5.1. *The (contravariant) stress-energy tensor* $\mathbf{T}$ *is symmetric.*

The symmetry in the components $1 \leq i, j \leq 3$ follows from the same physical reasoning for why the stress tensor in fluid dynamics is symmetric.

Proposition 7.5.2 (Einstein's Conservation Law). *The conservation of energy is equivalent to the identity*

$$\operatorname{div} \mathbf{T} = T^{\alpha\beta}{}_{;\beta} = 0.$$

Proof Sketch. Suppose that energy is conserved in a certain region of M. In other words, though energy and mass may move around, no energy or mass is created or annihilated in M. Then given any four-dimensional submanifold $\mathcal{V}$ with boundary $\partial\mathcal{V}$, the total flux of 4-momentum passing through $\partial\mathcal{V}$ must be 0. We can restate this as

$$\iiint_{\partial\mathcal{V}} \mathbf{T} \cdot d\mathbf{V}^{(3)} = 0,$$

where $d\mathbf{V}^{(3)}$ is the 3-volume element with direction along the outward-pointing normal vector to $\partial\mathcal{V}$. (We can view this as a volume 1-form.) By the product $\cdot$ we mean the contraction of $\mathbf{T}$ with the volume 1-form element $d\mathbf{V}^{(3)}$. Stokes' Theorem applied to pseudo-Riemannian manifolds gives

$$\iiiint_{\mathcal{V}} \operatorname{div} \mathbf{T} dV^{(4)} = \iiint_{\partial\mathcal{V}} \mathbf{T} \cdot d\mathbf{V}^{(3)} = 0.$$

Since this is true for all $\mathcal{V}$ as described above, using a limiting argument similar to that used to show Gauss' Law that $\operatorname{div} \vec{E} = 0$ for an electric field, a limiting argument establishes $\operatorname{div} \mathbf{T} = 0$ everywhere. ☐

Example 7.5.3 (Perfect Fluid Stress-Energy Tensor)**.** A perfect fluid is a fluid in which the pressure p is the same in any direction. The fluid must be free of heat conduction and viscosity and any process that can cause internal sheers. Using the interpretation of $\mathbf{T}$ from Equations (7.70)–(7.73), we see that $T^{jk} = 0$ if $j \neq k$ and $0 < j, k$. Furthermore, since the pressure is the same in all directions, $T^{jj} = p$ for $j = 1, 2, 3$. For components involving $j = 0$ or $k = 0$, we first have $T^{00} = \rho$, the energy density. This quantity includes mass density but also other types of energy such as compression energy. For the remaining off diagonal terms $T^{0j} = T^{j0}$, these are 0 because of the assumption that there is no heat conduction in the perfect fluid. Thus, the stress-energy tensor has components

$$T^{\alpha\beta} = \begin{pmatrix} \rho & 0 & 0 & 0 \\ 0 & p & 0 & 0 \\ 0 & 0 & p & 0 \\ 0 & 0 & 0 & p \end{pmatrix}. \tag{7.74}$$

If we suppose that an observer is in the Lorentz frame that is at rest with respect to the movement of the fluid, then the velocity has components $u^\alpha = (1, 0, 0, 0)$. With respect to the Minkowski metric η, we can write (7.74) as

$$T^{\alpha\beta} = (\rho + p)u^\alpha u^\beta + p\eta^{\alpha\beta}.$$

We can rewrite this in a coordinate-free way in any metric as

$$\mathbf{T} = p\mathbf{g}^{-1} + (p + \rho)\mathbf{u} \otimes \mathbf{u}, \tag{7.75}$$

where we have written $\mathbf{g}^{-1}$ for the contravariant tensor of type $(2, 0)$ associated to the metric tensor $\mathbf{g}$.

Example 7.5.4 (Electromagnetic Stress-Energy Tensor)**.** Directly using the interpretation of $\mathbf{T}$ given in Equations (7.70)–(7.73) and results from electromagnetism, which we do not recreate here, one can determine the components of the stress-energy tensor for the electromagnetic field in free space. If $F^{\mu\nu}$ are the components of the electromagnetic field tensor, then

$$\begin{aligned} T^{\alpha\beta} &= \frac{1}{\mu_0}\left(F^{\alpha\mu}g_{\mu\nu}F^{\beta\nu} - \frac{1}{4}g^{\alpha\beta}F^{\mu\nu}F_{\mu\nu}\right) \qquad \text{in SI units} \qquad (7.76)\\ &= \frac{1}{4\pi}\left(F^{\alpha\mu}g_{\mu\nu}F^{\beta\nu} - \frac{1}{4}g^{\alpha\beta}F^{\mu\nu}F_{\mu\nu}\right) \qquad \text{in CGS units} \qquad (7.77)\end{aligned}$$

where $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{N/A^{-2}}$ is a constant sometimes called the vacuum permeability.

As the context requires, we may need the stress-energy tensor to be of type $(2, 0)$ as defined, of type $(1, 1)$ or of type $(0, 2)$. To pass between any of these, we raise or lower the indices as needed using the metric.

7.5.2 Einstein Field Equations

The Einstein field equations (EFE) are the heart of general relativity. They stem from the juxtaposition of the two following principles:

1. Every aspect of gravity is a description of the spacetime geometry.
2. Mass (energy) is the source of gravity.

The metric tensor $\mathbf{g}$ encapsulates all the information about the geometry of the spacetime. The metric $\mathbf{g}$ has the associated Levi-Civita connection ∇, the Riemann curvature tensor $\mathbf{R}$ of type $(1, 3)$, the Ricci curvature tensor $\mathbf{Rc}$, and the scalar curvature function R, defined in Chapter 6. (Note: In math texts on Riemannian geometry, one often denotes by S the scalar curvature while texts on general relativity invariably denote it by R. Using the bold font $\mathbf{R}$ to indicate the curvature tensor alleviates any confusion between the scalar and tensor curvature.)

On the other hand, the stress-energy tensor describes the spacetime content of mass-energy. In fact, any observer with 4-velocity $\vec{U}$ measures the density of mass-energy as

$$\rho = \mathbf{u} \cdot \mathbf{T} \cdot \mathbf{u} = T_{\alpha\beta}u^{\alpha}u^{\beta}.$$

In order to put together the two above principles, we should be able to write the tensor $\mathbf{T}$ exclusively in terms of the components of the metric tensor $\mathbf{g}$. The conservation of energy states that $\operatorname{div}\mathbf{T} = 0$. Also, if $\mathbf{T}$ is to serve as a measure of the curvature of spacetime, we propose that it should explicitly involve only components of $\mathbf{R}$ and of $\mathbf{g}$ (no derivatives of any of these terms) and it should be linear in the components of $\mathbf{R}$. It turns out that under these restrictions, there are only a few options for a geometric description of $\mathbf{T}$. In Problem 7.5.2, we show that for purely mathematical reasons, these constraints impose that

$$T_{\alpha\beta} = C\left(R_{\alpha\beta} - \frac{1}{2}Rg_{\alpha\beta} + \Lambda g_{\alpha\beta}\right), \tag{7.78}$$

where $R_{\alpha\beta}$ are the components of the Ricci curvature tensor, R is the scalar curvature, and Λ and C are real constants. This leads to Einstein's field equations.

Let $\mathbf{G}$ be the Einstein curvature tensor described in Definition 6.5.4. General relativity is summarized in this following equation. The presence of mass-energy deforms spacetime according to

$$\mathbf{G} + \Lambda\mathbf{g} = \frac{8\pi G}{c^4}\mathbf{T} \qquad \text{in SI units,} \tag{7.79}$$

where $G = 6.67 \times 10^{-11}\,\mathrm{m}^3\mathrm{s}^{-2}\mathrm{kg}^{-1}$ is the gravity constant and Λ is the *cosmological constant*. If we assume that empty (devoid of energy) spacetime is flat, then

$$\mathbf{G} = \frac{8\pi G}{c^4}\mathbf{T}. \tag{7.80}$$

Equation (7.80) is called collectively the *Einstein field equations* (EFE), and the formulas in (7.79) are the Einstein field equations with cosmological constant. These equations are as important in astrophysics as Newton's second law of motion is in classic mechanics. Though we do not give the calculation here, the constant $8\pi G/c^4$, called *Einstein's constant* is chosen so that (1) when the gravitational field is weak and (2) velocities are small compare to the speed of light, the theory reduces to the Newtonian theory of gravitation in approximation.

In Equation (2) of Einstein's original paper on general relativity [19], Einstein made the assumption that $\mathbf{G}$ vanishes when spacetime is empty of mass-energy. This corresponds to the mathematical assumption that $\Lambda = 0$. However, Equation (7.80) predicts a dynamic universe. This result did not appeal to Einstein and, at the time, there existed no astronomical evidence to support this. In 1917, he introduced the constant Λ because it allows for a static universe. Physically, $\Lambda \neq 0$ would imply the presence of an otherwise unexplained force that counteracts gravity or a sort of negative pressure.

When Hubble discovered that the universe is expanding, the cosmological constant no longer appeared to be necessary and many physicists did away with it. In fact, in his autobiography, George Gamow relays that Einstein told Gamow that he considered the introduction of the cosmological constant as "the biggest blunder of my life." [26] However, the possibility of a small nonzero Λ has resurfaced and regularly enters into the conversations around the current most vexing problems in physics, namely, the nature of dark energy and the effort to unify gravity and quantum mechanics.

We should note the Einstein field equations (EFE) are very complicated. Finding a solution to the EFE means finding the metric tensor $\mathbf{g}$ that satisfies (7.80), which consists of 10 second-order, nonlinear, partial differential equations of 10 functions $g_{ij}(x^0, x^1, x^2, x^3)$, with $0 \leq i \leq j \leq 3$. Then, determining the trajectory of a particle or of radiation amounts to determining the geodesics in this metric. Surprisingly, under some circumstances, especially scenarios that involve a high level of symmetry, it is possible to provide an exact solution.

Whole books have been written about consequences of solutions to (7.80) or (7.79) that deviate from Newtonian mechanics. After the introduction of general relativity, some scientists balked at such mathematical complexity. Yet experiment has repeatedly confirmed predictions in favor of general relativity over Newtonian mechanics. The approach taken here to justify the Einstein field equations cited mathematical esthetics, the condition of being divergence-free, and linear in the components of the curvature tensor **R**. During the 20th century, scientists arrived at (7.79) from other, more physical principles. Of note, in [36], Lovelock showed that the Einstein field equations arise as the unique second-order equations that can follow from the Euler-Lagrange equations of a Lagrange density involving g_{ij} and its derivatives up to second order. Furthermore, there exist natural generalizations to Einstein's theory of general relativity. However, any theory that can unify gravity and quantum mechanics should be able to derive (7.79) as an approximation.

7.5.3 Schwarzschild Metric

We finish this section with one of the earliest proven consequences of general relativity, i.e., the Schwarzschild metric which is an exact solution to Einstein's field equations. Instead of simply showing that the Schwarzschild metric satisfies EFE, we show how the metric was discovered.

One of the main contexts in which one can expect to see the effects of general relativity against Newtonian mechanics is in the context of astronomy. The simplest dynamical problem in astronomy involves calculating the orbit of a single planet around the sun. One can hope that the EFE for the effect of the sun on the space around it will become simple under the following two assumptions (approximations):

1. The sun is a spherically symmetric distribution of mass-energy density.
2. Outside of the sun, the stress-energy tensor should vanish.

The spherical symmetry implies that the components of the metric tensor should be given as functions of x^0 and r alone, where $r^2 = (x^1)^2 + (x^2)^2 + (x^3)^2$. Since we are looking only for solutions outside the sun, we are looking for solutions in a vacuum. Thus $\mathbf{T} = 0$, from which we deduce that $\mathbf{G} = 0$. Thus, $\operatorname{Tr}_{\mathbf{g}} \mathbf{G} = 0$. However,

$$\operatorname{Tr}_{\mathbf{g}} \mathbf{G} = \operatorname{Tr}_{\mathbf{g}} \left(\mathbf{Rc} - \frac{1}{2} R \mathbf{g} \right) = R - \frac{1}{2} R \cdot 4 = -R,$$

where this follows from (6.56) and the fact that $\operatorname{Tr}_{\mathbf{g}} \mathbf{g} = \dim M = 4$. Thus, $R = 0$ and the fact that $\mathbf{G} = 0$ implies that we are looking for spherically symmetric solutions to the equation

$$R_{\alpha\beta} = 0. \tag{7.81}$$

Since we are looking for solutions in a vacuum, it seems as though we have lost information, but, as we shall see, that is not the case.

The following derivation follows the treatment in [54]. We leave some of the details as exercises for the reader.

A judicious choice of coordinates and a few coordinate transformations will simplify the problem. We first start with the coordinates

$$(\bar{x}^0, x^1, x^2, x^3) = (\bar{x}^0, \bar{r}, \theta, \varphi),$$

where $\bar{x}^0 = ct$ for some timelike variable t, $\bar{r}^2 = (x^1)^2 + (x^2)^2 + (x^3)^2$ and where θ and φ are given in the physics style of defining spherical coordinates, i.e., so that φ is the longitudinal angle and θ is the latitude angle measured down from a "positive" vertical direction. We know that the standard line element in spherical coordinates is

$$ds^2 = d\bar{r}^2 + \bar{r}^2 d\theta^2 + \bar{r}^2 \sin^2\theta d\varphi^2.$$

Though we are not working with the Euclidean metric, spherical symmetry does imply that the metric tensor in the space coordinates is orthogonal and that no perpendicular direction to the radial direction is singled out. Thus, the metric tensor has the form

$$g_{\alpha\beta} = \begin{pmatrix} g_{00}(\bar{x}^0, \bar{r}) & g_{01}(\bar{x}^0, \bar{r}) & g_{02}(\bar{x}^0, \bar{r}) & g_{03}(\bar{x}^0, \bar{r}) \\ g_{10}(\bar{x}^0, \bar{r}) & g_{11}(\bar{x}^0, \bar{r}) & 0 & 0 \\ g_{20}(\bar{x}^0, \bar{r}) & 0 & f(\bar{x}^0, \bar{r})^2 & 0 \\ g_{30}(\bar{x}^0, \bar{r}) & 0 & 0 & f(\bar{x}^0, \bar{r})^2 \sin^2\theta \end{pmatrix}, \tag{7.82}$$

where f is any smooth function. We actually have some choice on θ and φ because they are usually given in reference to some preferred x-axis and z-axis. We choose θ and φ (which may change over time with respect to some fixed Cartesian frame) so that $g_{20} = g_{30} = 0$, and then the metric looks like

$$g_{\alpha\beta} = \begin{pmatrix} g_{00}(\bar{x}^0, \bar{r}) & g_{01}(\bar{x}^0, \bar{r}) & 0 & 0 \\ g_{10}(\bar{x}^0, \bar{r}) & g_{11}(\bar{x}^0, \bar{r}) & 0 & 0 \\ 0 & 0 & f(\bar{x}^0, \bar{r})^2 & 0 \\ 0 & 0 & 0 & f(\bar{x}^0, \bar{r})^2 \sin^2\theta \end{pmatrix}. \tag{7.83}$$

We make the coordinate transformation $r = f(\bar{x}^0, \bar{r})$ and all the other coordinates remain the same. In this coordinate system, the metric looks like

$$g_{\alpha\beta} = \begin{pmatrix} g_{00}(\bar{x}^0, r) & g_{01}(\bar{x}^0, r) & 0 & 0 \\ g_{10}(\bar{x}^0, r) & g_{11}(\bar{x}^0, r) & 0 & 0 \\ 0 & 0 & r^2 & 0 \\ 0 & 0 & 0 & r^2 \sin^2\theta \end{pmatrix}. \tag{7.84}$$

Finally, we can orthogonalize the metric tensor by a suitable coordinate transformation of $x^0 = ct = h(\bar{x}^0, r)$, with r staying fixed (see Problem 7.5.4). Since we know that the metric has signature $(3,1)$, we can write the metric in the coordinate system $(x^0, r, \theta, \varphi)$ as

$$g_{\alpha\beta} = \begin{pmatrix} -e^{\nu(x^0,r)} & 0 & 0 & 0 \\ 0 & e^{\lambda(x^0,r)} & 0 & 0 \\ 0 & 0 & r^2 & 0 \\ 0 & 0 & 0 & r^2 \sin^2\theta \end{pmatrix}, \tag{7.85}$$

where λ and ν are smooth functions. The metric in Equation (7.85) is an orthogonal metric that is spherically symmetric in the space variables.

Using the notation $\dot{u} = \partial u/\partial x^0$ and $u' = \partial u/\partial r$, we can show (see Problem 7.5.5) that the independent nonzero Christoffel symbols for the Levi-Civita connection are

$$\Gamma^0_{00} = \frac{1}{2}\dot{\nu}, \qquad \Gamma^0_{01} = \frac{1}{2}\nu', \qquad \Gamma^0_{11} = \frac{1}{2}\dot{\lambda}e^{\lambda-\nu}, \quad \Gamma^1_{00} = \frac{1}{2}\nu' e^{\nu-\lambda}, \tag{7.86}$$

$$\Gamma^1_{01} = \frac{1}{2}\dot{\lambda}, \qquad \Gamma^1_{11} = \frac{1}{2}\lambda', \qquad \Gamma^1_{22} = -re^{-\lambda}, \quad \Gamma^1_{33} = -r\sin^2\theta e^{-\lambda}, \tag{7.87}$$

$$\Gamma^2_{12} = \frac{1}{r}, \qquad \Gamma^2_{33} = -\sin\theta\cos\theta, \quad \Gamma^3_{13} = \frac{1}{r}, \qquad \Gamma^3_{23} = \cot\theta. \tag{7.88}$$

Though it is a little long to calculate (see Problem 7.5.6), we then determine that the only nonzero components of the Ricci tensor are

$$\begin{aligned} R_{00} &= e^{\nu-\lambda}\Big(\frac{\nu''}{2} + \frac{(\nu')^2}{4} - \frac{\nu'\lambda'}{4} + \frac{\nu'}{r}\Big) - \frac{\ddot{\lambda}}{2} - \frac{\dot{\lambda}^2}{4} + \frac{\dot{\lambda}\dot{\nu}}{4}, \\ R_{01} &= R_{10} = \frac{\dot{\lambda}}{r}, \\ R_{11} &= -\frac{\nu''}{2} - \frac{(\nu')^2}{4} + \frac{\nu'\lambda'}{4} + \frac{\lambda'}{r} + e^{\lambda-\nu}\Big(\frac{\ddot{\lambda}}{2} + \frac{\dot{\lambda}^2}{4} - \frac{\dot{\lambda}\dot{\nu}}{4}\Big), \\ R_{22} &= -e^{-\lambda}\Big(1 + \frac{r}{2}(\nu' - \lambda')\Big) + 1, \\ R_{33} &= \sin^2\theta\, R_{22}. \end{aligned} \tag{7.89}$$

Since we are trying to solve $R_{\alpha\beta} = 0$, we obtain conditions on the functions λ and ν. Since $R_{01} = 0$, we deduce immediately that $\dot{\lambda} = 0$, which means that λ is a function of r alone. Also, since $\partial R_{22}/\partial t = 0$, we find that $\partial \nu'/\partial t = 0$. Therefore, we can write the function ν as

$$\nu = \nu(r) + f(t)$$

for some function $f(t)$.

We now make one final coordinate change. In the metric line element, t appears only in the summand $e^{\nu} d(x^0)^2 = e^{\nu(r)} e^{f(t)} d(ct)^2$. So by choosing the variable $\bar{t}$ in such a way that

$$\frac{d\bar{t}}{dt} = e^{f(t)/2}$$

and then renaming $\bar{t}$ to just t, we obtain a metric which is independent of any timelike variable. (The variable $\bar{t}$, relabeled as t, is not necessarily time anymore so we cannot necessarily call a solution with $t = 0$ as a solution static.)

We can now assume there is no t dependence. Simplifying the expression $R_{00} + e^{\nu-\lambda}R_{11}$ leads to

$$\frac{1}{r}(\lambda' + \nu') = 0.$$

This implies that $\lambda(r) = -\nu(r) + C$ for some constant C. Without loss of generality, we can assume that $C = 0$ since we have not specified λ or ν. Thus, we set $\lambda(r) = -\nu(r)$. Then $R_{22} = 0$ in (7.89) implies that

$$e^{-\lambda}(1 - r\lambda') = 1.$$

Now setting $h(r) = e^{-\lambda(r)}$, this last equation becomes

$$h' + \frac{h}{r} = \frac{1}{r}.$$

This is a linear, first-order, ordinary, differential equation whose general solution is

$$h(r) = e^{-\lambda(r)} = 1 - \frac{2M}{r},$$

where M is a constant of integration. One can verify directly that $R_{11} = R_{00} = 0$ in Equation (7.89) are satisfied by this solution and therefore give no additional conditions. Therefore, the spherically symmetric vacuum solution to the EFE gives a metric with line element

$$ds^2 = -\left(1 - \frac{2M}{r}\right)c^2 dt^2 + \left(1 - \frac{2M}{r}\right)^{-1} dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta d\varphi^2. \qquad (7.90)$$

This is called the Schwarzschild metric. This metric provided the first exact solution to the Einstein field equations. Though it is still complicated, this metric can be compared in fundamental importance to the solution in mechanics to the differential equations $d^2\vec{x}/dt^2 = -m\vec{g}$. Many of the verifiable predictions of general relativity arise from this metric.

In order to understand (7.90), we need to have some sense of the meaning of the constant M. Obviously, if $M = 0$, then the Schwarzschild metric is simply the flat Minkowski metric for spacetime.

To derive an interpretation for $M \neq 0$, we study some consequences of (7.90) for small velocities. If the velocity v is much smaller than the speed of light, i.e., $v \ll c$, then special relativity tells us that proper time is approximately coordinate time $\tau \cong t = x^0/c$. Furthermore, from (7.65) we can approximate the velocity of any particle as $\vec{U} = (c, 0, 0, 0)$. Plugging these into the geodesic equation

$$\frac{d^2x^i}{d\tau^2} = -\Gamma^i_{jk}\frac{dx^j}{d\tau}\frac{dx^k}{d\tau},$$

we obtain the approximate relationship

$$\frac{d^2x^i}{dt^2} = -\Gamma^i_{00}c^2 = \frac{c^2}{2}g^{il}\frac{\partial g_{00}}{\partial x^l}, \tag{7.91}$$

where the second equality follows from the formula for Christoffel symbols and the fact that the functions g_{ij} are not x^0 dependent. However, since $\mathbf{g}$ is diagonal and g_{00} depends only on r, we find that the only nonzero derivative is

$$\frac{d^2r}{dt^2} = -\frac{c^2}{2}\left(1 - \frac{2M}{r}\right)\frac{\partial}{\partial r}\left(1 - \frac{2M}{r}\right) = -\frac{Mc^2}{r^2}\left(1 - \frac{2M}{r}\right).$$

We must compare this to the formula for gravitational attraction in Newtonian mechanics, namely,

$$\frac{d^2r}{dt^2} = -\frac{GM_S}{r^2}$$

where M_S is the mass of the attracting body (and G is the gravitational constant). Thus, we find as a first approximation that the constant of integration M is

$$M \cong \frac{GM_S}{c^2}. \tag{7.92}$$

Hence, M is a constant multiple of the mass of the attracting body. The constant $2M$ has the dimensions of length, and one calls $r_G = 2M$ the *Schwarzschild radius*. The formula for it is

$$r_G = \frac{2G}{c^2} \cdot M_S = (1.48 \times 10^{-27}\ \text{m/kg})M_S.$$

The Schwarzschild radius is 2.95 km for the sun and 8.8 mm for the Earth. Evidently, for spherically symmetric objects that one encounters in common experience, the Schwarzschild radius is much smaller than the object's actual radius. In fact, if a spherically symmetric object has radius R_S and mass M_S, then

$$r_G < R_S \Longleftrightarrow \frac{2G}{c^2}M_S < R_S.$$

A sphere with $r_G > R_S$ would need to have an enormous density. Furthermore, this situation would seem to be physically impossible for the following reason. It is understood that the Schwarzschild metric holds only in the vacuum outside of the body (planet or star). However, if $r_G > R_S$, then the Schwarzschild radius would correspond to a sphere outside of the spherical body where the Schwarzschild metric has a singularity $g_{11} = 1/0$. For this reason, some physicists initially claimed this to be a result of the successive approximations or simply a physically impossible situation.

The history of science has occasionally shown that singularities in the equations do not immediately imply that the scenario is impossible. The possibility of traveling at the speed of sound was thought to be impossible because of the consequences for the Doppler effect equation. Now, military jets regularly fly faster than the speed of sound. Similarly, in recent decades, physicists regularly study objects considered to be so dense that $2GM_S/c^2 > R_S$. Such objects are called *black holes*. For a time, the existence of black holes remained in the realm of hypothesis, but now astronomers are convinced they have observed many such objects, and astrophysicists have worked out many of their dynamic properties.

PROBLEMS

7.5.1. Show that we can rephrase the explanation for Equation (7.68) by saying that for any three vectors A, B, and C in $T_P M$,

$$(\star \mathbf{n}_P)(A, B, C) = \mathrm{Vol}_{\mathbf{g}}(\mathbf{n}_P^\sharp, A, B, C),$$

where $\mathrm{Vol}_{\mathbf{g}}$ is the volume form with respect to the metric $\mathbf{g}$.

7.5.2. Let $\mathbf{L}$ be a symmetric tensor of type $(0, 2)$ consisting of components that are constructible from those of $\mathbf{R}$ and Tg and are linear in the components of the Riemann curvature tensor $\mathbf{R}$.

(a) Show that $\mathbf{L}$ can only have the form

$$L_{\alpha\beta} = aR_{\alpha\beta} + bRg_{\alpha\beta} + \lambda g_{\alpha\beta},$$

where $R_{\alpha\beta}$ are the components of the Ricci curvature tensor, R is the scalar curvature, and a, b, and λ are real constants. [Hint: Consider Bianchi identities.]

(b) Show that $\operatorname{div} \mathbf{L} = 0$ if and only if $b = -\frac{1}{2}a$.

(c) If $\mathbf{g} = \eta$, the standard Minkowski metric, show that $\mathbf{L} = 0$ if and only if $\lambda = 0$.

7.5.3. Calculate the curvature tensor and the Ricci curvature tensor for the Schwarzschild metric.

7.5.4. Find the "suitable" coordinate transformation h that allows one to pass from Equation (7.84) to Equation (7.85).

7.5.5. Prove that Equation (7.87) is correct.

7.5.6. Prove Equation (7.89).

7.5.7. *Light Propagation in the Schwarzschild Metric.* In the Schwarzschild metric, light travels along the null-geodesics, i.e., where $ds^2 = 0$.

(a) Explain why setting $\theta = 0$ does not lose any generality to finding the null-geodesics.

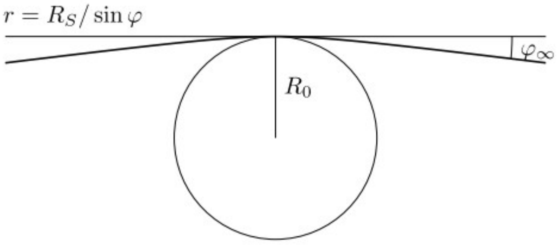

Figure 7.12: Deviation of light near a massive body.

(b) Prove that if one sets $u = 1/r$, then $ds^2 = 0$ implies that

$$\frac{d^2u}{d\varphi^2} + u = 3Mu^2. \tag{7.93}$$

(c) Deduce that in the vicinity of a black hole, light travels in a circle precisely at the radius $r = \frac{3}{2}r_G$.

(d) Solve Equation (7.93) for $M = 0$. This corresponds to empty space (no mass present). Call this solution $u_0(\varphi)$.

(e) Now look for general solutions u to Equation (7.93) by setting $u = u_1 + u_0$. Then $u_1(\varphi)$ must satisfy

$$\frac{d^2u_1}{d\varphi^2} + u_1 = \frac{3M}{R_0}\sin^2(\varphi - \varphi_0).$$

Solve this differential equation explicitly, and find the complete solution to Equation (7.93).

(f) In the complete solution, show that $M = 0$ (empty space) corresponds to traveling along a straight line $u = \frac{1}{R_0}\sin(\varphi - \varphi_0)$, where R_0 is the distance from the line to the origin.

(g) Show that the general solution to Equation (7.93) is asymptotically a line.

(h) We now consider Eddington's famous experiment to measure the deviation of light by the sun. Consider a geodesic $\mathcal{G}$ in the Schwarzschild metric that passes right alongside the sun, i.e., passes through the point $r = R_S$ and $\varphi = 0$. Define φ_∞ as the limiting angle of deviation between the line $r = R_S/\sin\varphi$ and the geodesic $\mathcal{G}$ (see Figure 7.12). The sun bends the light away from the straight line by a total of $2\varphi_\infty$. Using (at a judicious point) the approximation that $\sin\varphi \cong \varphi$, prove that the total deviation of light is

$$2\varphi_\infty = \frac{4GM_S}{R_S c^2},$$

where M_S is the mass of the sun and R_S is the sun's radius.

APPENDIX A

Point Set Topology

Though mathematicians, when developing a new area of mathematics, may define and study any object as they choose, the "natural" notion of a surface in $\mathbb{R}^3$ requires a rather intricate definition (Definition 3.1.1). Though at first somewhat unwieldy, this definition and also the definition for a differentiable manifold are necessary to appropriately generalize calculus and geometry to non-Euclidean spaces.

On the other hand, numerous concepts from geometry and calculus can be generalized not by formulating more constrained definitions but by expanding the context in which we define these concepts. The first wider context presented in this appendix is that of a metric space, a set equipped with some notion of distance. Many concepts from Euclidean geometry, including continuity, have natural generalizations to metric spaces. As it turns out, many useful concepts for analysis, like continuity, limit of sequences, or connectedness, arise in the yet more general context of topological spaces, where instead of a distance function, we have a looser notion of "nearness."

Though topology is a vast branch of mathematics, this appendix presents just the basic notions that support this book's presentation of differential geometry. A reader might encounter many of these concepts in a typical analysis course. We refer the reader to [27] for a gentle but thorough introduction to point set topology and to [43] and [2] for an introduction to topology that includes homology, the fundamental group, algebraic topology, and the classification of surfaces.

A.1 Metric Spaces

A.1.1 Metric Spaces: Definition

A metric space is a set that comes with the notion of "distance" between two points, where this distance function involves a few numerical conditions that mimic geometry in Euclidean spaces.

Definition A.1.1. Let X be any set. A *metric* on X is a function $D : X \times X \to \mathbb{R}^{\geq 0}$ such that

1. equality: $D(x, y) = 0$ if and only if $x = y$;
2. symmetry: $D(x, y) = D(y, x)$ for all $x, y \in X$;
3. triangle inequality: $D(x, y) + D(y, z) \geq D(x, z)$ for all $x, y, z \in X$.

A pair (X, D) where X is a set with a metric D is called a *metric space*.

Example A.1.2 (Euclidean Spaces). The Euclidean space $\mathbb{R}^n$ is a metric space where D is the usual Euclidean distance formula between two points, namely, if $P = (p_1, p_2, \ldots, p_n)$ and $Q = (q_1, q_2, \ldots, q_n)$, then

$$D(P, Q) = \sqrt{\sum_{i=1}^{n} (q_i - p_i)^2}.$$

Many notions in usual geometry (circles, parallelism, midpoint...) depend vitally on this particular distance formula. Furthermore, if $n = 1$, this formula simplifies to the usual distance formula on the real line $\mathbb{R}$, namely,

$$d(x, y) = |y - x|.$$

To prove that $(\mathbb{R}^n, D)$ is indeed a metric space, we must verify the three axioms in Definition A.1.1. The first holds because

$$D(P, Q) = 0 \Longleftrightarrow \sum_{i=1}^{n} (q_i - p_i)^2 = 0,$$

which is equivalent to $(q_i - p_i)^2 = 0$ for all $1 \leq i \leq n$, and hence $q_i = p_i$ for all $1 \leq i \leq n$. The second obviously holds, and we prove the third axiom as follows. The Cauchy-Schwarz inequality on the vectors $\overrightarrow{PQ}$ and $\overrightarrow{QR}$ gives

$$\overrightarrow{PQ} \cdot \overrightarrow{QR} \leq \overrightarrow{PQ} \cdot \overrightarrow{QR}| \leq \|\overrightarrow{PQ}\| \, \|\overrightarrow{QR}\|$$

so

$$2 \sum_{i=1}^{n} (q_i - p_i)(r_i - q_i) \leq 2 \sqrt{\sum_{i=1}^{n} (q_i - p_i)^2} \sqrt{\sum_{i=1}^{n} (r_i - q_i)^2}.$$

Using the property that $2ab = (a + b)^2 - a^2 - b^2$ with $a = q_i - p_i$ and $b = r_i - q_i$, we get

$$\sum_{i=1}^{n} (r_i - p_i)^2 \leq 2 \sqrt{\sum_{i=1}^{n} (q_i - p_i)^2} \sqrt{\sum_{i=1}^{n} (r_i - q_i)^2} + \sum_{i=1}^{n} (q_i - p_i)^2 + \sum_{i=1}^{n} (r_i - q_i)^2.$$

Hence,

$$\sum_{i=1}^{n} (r_i - p_i)^2 \leq \left(\sqrt{\sum_{i=1}^{n} (q_i - p_i)^2} + \sqrt{\sum_{i=1}^{n} (r_i - q_i)^2} \right)^2$$

from which it follows that $D(P,Q)+D(Q,R)\geq D(P,R)$.

Of course, the triangle inequality is used in Definition A.1.1 precisely because it is one of the fundamental properties of the Euclidean distance function. However, we needed to verify the triangle inequality based on the formula given for the Euclidean metric, and the example illustrates what is required in order to establish the three axioms.

Example A.1.3. There exists a variety of other metrics on Euclidean space, and we illustrate a few of these alternate metrics for $\mathbb{R}^2$. Let $P=(x_1,y_1)$ and $Q=(x_2,y_2)$. We leave to the reader the proofs that the following functions are metrics on $\mathbb{R}^2$:

$$\begin{aligned} D_1(P,Q) &= |x_2-x_1|+|y_2-y_1|, \\ D_3(P,Q) &= \sqrt[3]{|x_2-x_1|^3+|y_2-y_1|^3}, \\ D_\infty(P,Q) &= \max\big\{|x_2-x_1|,|y_2-y_1|\big\}. \end{aligned}$$

Example A.1.4 (Six Degrees of Kevin Bacon)**.** A humorous example of a metric space is the set of syndicated actors A equipped with the function D defined as follows. Consider the graph whose set of vertices is A and has an edge between two actors a_1 and a_2 if they acted in a movie together. Define $D(a_1,a_2)$ as 0 if $a_1=a_2$ and, otherwise, as the minimum number of edges it takes to create a path connecting a_1 and a_2. The pair (A,D) is a metric space.

The party game called "Six Degrees of Kevin Bacon" asks players to find $D(a_1,a_2)$ given any pair (a_1,a_2).

Having a notion of distance in a set, we may want to consider the subset of all points that are within a certain distance of a fixed point.

Definition A.1.5. Let (X,D) be a metric space, and let $p\in X$ be a point. We define the *open ball* of radius r around p as the set

$$B_r(p)=\{y\in X \mid D(p,y)<r\}.$$

The reader who is new to topology should note that the terminology "open ball" might be initially misleading since the set $B_r(p)$ only takes the shape of an actual ball (disk, sphere, etc.) in the case of the Euclidean metric on $\mathbb{R}^n$.

Example A.1.6. Consider the metric D_1 from Example A.1.3 above, and let $O=(0,0)$. The ball of radius 1 around the origin O using the metric D_1 is the set

$$B_1(O)=\{(x,y)\in\mathbb{R}^2 \mid |x|+|y|<1\}.$$

Notice that the equation $|x|+|y|=1$ has a locus that is symmetric about the x-axis and about the y-axis. So to determine its locus we only need to see what happens in the first quadrant. In the first quadrant, the equation $|x|+|y|=1$ becomes $x+y=1$, which is a line segment from $(1,0)$ to $(0,1)$. Thus, the open ball $B_1(O)$ is the open square with corners at $\{(1,0),(0,1),(-1,0),(0,-1)\}$.

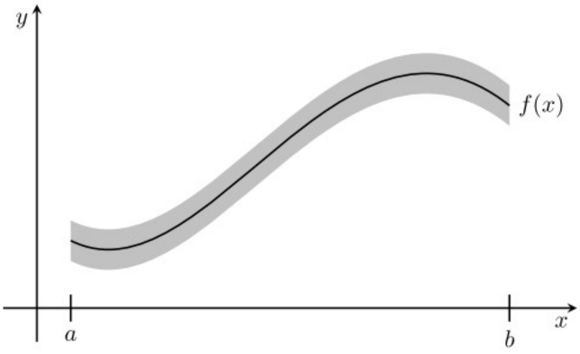

Figure A.1: Example A.1.7: a collar around $f(x)$.

Example A.1.7. Metric spaces can encompass a much wider range than the above examples have illustrated so far. Let $X = C^0([a,b])$ be the set of continuous real functions defined on the closed interval $[a,b]$, or let $X = F_{\text{bounded}}([a,b])$ be the set of all bounded functions on interval $[a,b]$. (A theorem of calculus tells us that any function f continuous over $[a,b]$ is bounded so $C^0([a,b]) \subset F_{\text{bounded}}([a,b])$.) Define the function $D : X \times X \to \mathbb{R}^{\geq 0}$ as

$$D(f,g) = \text{lub}\{|g(x) - f(x)| \, : \, x \in [a,b]\},$$

where lub refers to the least upper bound of a subset of reals.

The open ball of radius r around a function f is the set of all the functions $g \in X$ such that $|f(x) - g(x)| < r$ for all $x \in [a,b]$, or in other words,

$$f(x) - r < g(x) < f(x) + r \qquad \text{for all } x \in [a,b].$$

In this context, we call the region $f(x) - r < y < f(x) + r$ with $a \leq x \leq b$ the *r-collar* of $f(x)$. See Figure A.1.

Above, we introduced the notion of an open ball in any metric space. Though this appendix introduces notions that primarily support an overview of point-set topology, the notion of distance between two points allows us to generalize concepts from geometry to any metric space (X, D). We list here below a few of these concepts, which exist in any metric space but do not generalize further to topological spaces.

- A point $C \in X$ is said to be *between* two points A and B if $D(A,B) = D(A,C) + D(C,B)$. When D is the Euclidean metric on $\mathbb{R}^n$, this equality occurs for a degenerate triangle and only in the case when C lies on the segment $\overline{AB}$. It is in this sense that this definition directly generalizes the notion of betweenness from Euclidean geometry.

- The *bisector* of two points A and B is the set of points

$$\{P \in X \mid D(P, A) = D(P, B)\}.$$

  This is the usual definition for the segment bisector in Euclidean geometry but in other metric spaces this set may look quite different.

- If $A, B \in X$ and $c \in \mathbb{R}$ with $2c > D(A, B)$, then the set of points

$$\{M \in X \mid D(A, M) + D(B, M) = 2c\}$$

  is the ellipse with foci A and B and with half axis c.

- Let $S \subset X$ be a subset. We define the *diameter* of S to be

$$\operatorname{diam} S = \operatorname{lub}\{D(x, y) \mid x, y \in S\}.$$

- A subset S of X is called *bounded* if $\operatorname{diam} S < \infty$.

- Let S_1 and S_2 be two subsets of the metric space X. Then the distance between S_1 and S_2 is

$$D(S_1, S_2) = \operatorname{glb}\{D(x, y) \mid x \in S_1,\ y \in S_2\},$$

  where glb is the greatest lower bound. The distance between a point $x \in X$ and a subset $A \subset X$ is $D(\{x\}, A)$. We observe that this definition of distance between subsets does not establish a metric on $\mathcal{P}(X)$, the set of subsets of X. Indeed, for any two subsets S_1 and S_2 in X such that $S_1 \neq S_2$ and $S_1 \cap S_2 \neq 0$, the distance between them is $D(S_1, S_2) = 0$, and hence, even the first axiom for metric spaces fails. However, in geometry, the notion of distance between sets, especially disjoint sets, is quite useful.

A.1.2 Open and Closed Sets

In the study of real functions, we often use the notions of open intervals and closed intervals. In this context, we simply say that a bounded interval is open if it does not include its endpoints and closed if it includes both of them; a similar definition is given for an unbounded interval. Then a subset of $\mathbb{R}$ is called open if it is a disjoint union of open intervals. In contrast, in $\mathbb{R}^n$ or in a metric space, given the wide range of possibilities for the shape of sets, we cannot legitimately talk about endpoints, though we could attempt to make sense of the concept of "including its boundary points." Regardless, a different definition for openness and closedness is required.

Definition A.1.8. Let (X, D) be a metric space. A subset $U \subseteq X$ is called *open* if for all $p \in U$ there exists $r > 0$ such that the open ball $B_r(p) \subset U$. A subset $F \subseteq X$ is called *closed* if the complement $F^c \overset{\text{def}}{=} X - F$ is open.

Intuitively, this definition states that a subset U of a metric space is called open if around every point there is an open ball, perhaps with a small radius, that is completely contained in U. Note that we may wish to consider more than one metric at the same time on the same set X. In this case, we will refer to a D-open set.

Proposition A.1.9. *Let (X, D) be a metric space. Then*

1. *X and $\emptyset$ are both open;*
2. *the intersection of any two open sets is open;*
3. *the union of any collection of open sets is open.*

Proof. For part 1, if $p \in X$, then any open ball satisfies $B_r(p) \subset X$. Also, since $\emptyset$ is empty, the criteria for openness holds trivially for $\emptyset$.

To prove part 2, let U_1 and U_2 be two open sets and let $p \in U_1 \cap U_2$. Since U_1 and U_2 are open, there exist r_1 and r_2 such that $B_{r_1}(p) \subset U_1$ and $B_{r_2}(p) \subset U_2$. Take $r = \min(r_1, r_2)$. Then $B_r(p) \subseteq B_{r_1}(p) \subset U_1$ and $B_r(p) \subseteq B_{r_2}(p) \subset U_2$ so $B_r(p) \subset U_1 \cap U_2$. Thus, $U_1 \cap U_2$ is open.

Finally, consider a collection of open sets U_α where α is an index taken from some indexing set I, which is not necessarily finite. Define

$$U = \bigcup_{\alpha \in I} U_\alpha \,.$$

For any $p \in U$, there exists some $\alpha_0 \in I$ such that $p \in U_{\alpha_0}$. Since U_{α_0} is open, there exists r such that $B_r(p) \subset U_{\alpha_0}$, and thus, $B_r(p) \subset U$. Consequently, U is open. ☐

Using Proposition A.1.9(2), it is easy to show that any intersection of a finite number of open sets is again open. In contrast, part 3 states that the union of any collection of open subsets of X is again open, regardless of whether this collection is finite or not. This difference between unions and intersections of open sets is not an insufficiency of this proposition but rather a fundamental aspect of open sets in a metric space. In fact, as the following simple example shows, the infinite intersection of open sets need not be open.

Example A.1.10. For each integer $n \geq 1$, consider the open intervals $I_n = \left(0, 1 + \frac{1}{n}\right)$, and define

$$S = \bigcap_{n=1}^{\infty} I_n \,.$$

Obviously, $I_{n+1} \subsetneq I_n$, and so the intervals form a decreasing, nested chain. Since $\lim_{n\to\infty} \frac{1}{n} = 0$, we expect S to contain $(0, 1)$, but we must determine whether it

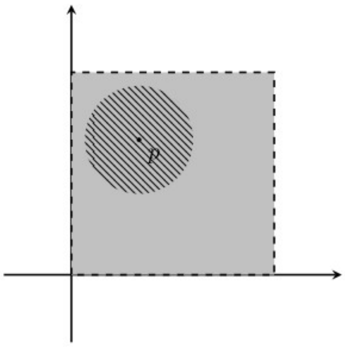

Figure A.2: Example A.1.11.

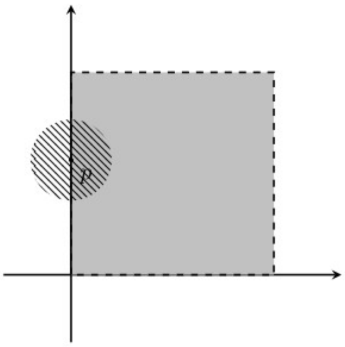

Figure A.3: Example A.1.12.

contains anything more. If $r > 1$, then if n is large enough so that $\frac{1}{n} < r - 1$, we have $r \notin I_n$. On the other hand, for all $n \in \mathbb{Z}^{\geq 1}$, $\frac{1}{n} > 0$, so $1 < 1 + \frac{1}{n}$. Hence, $1 \in I_n$ for all $n \in \mathbb{Z}^{\geq 1}$, and thus, $1 \in S$. Thus, we conclude that $S = (0, 1]$. This shows that the infinite intersection of open sets need not be open.

Example A.1.11. As a more down-to-earth example, we wish to show that according to this definition, the set $S = \{(x, y) \in \mathbb{R}^2 \,|\, 0 < x < 1 \text{ and } 0 < y < 1\}$ is open in $\mathbb{R}^2$ equipped with the Euclidean metric. Let $p = (x_0, y_0)$ be a point in S. Since $p \in S$, we see that $x_0 > 0$, $1 - x_0 > 0$, $y_0 > 0$, and $1 - y_0 > 0$. Since the closed distance from a point p to any line L is along a perpendicular to L, then the closest distance between p and any of the lines $x = 0$, $x = 1$, $y = 0$, and $y = 1$ is $\min\{x_0, 1 - x_0, y_0, 1 - y_0\}$. Consequently, if r is any positive real number such that

$$r \leq \min\{x_0, 1 - x_0, y_0, 1 - y_0\},$$

then $B_r(p) \subset S$. (See Figure A.2.)

Example A.1.12. In contrast to the previous example, consider the set

$$T = \{(x, y) \in \mathbb{R}^2 \,|\, 0 \leq x < 1 \text{ and } 0 < y < 1\},$$

where again we assume $\mathbb{R}^2$ is equipped with the Euclidean metric. The work in Example A.1.11 shows that for any point $p = (x_0, y_0)$, with $0 < x_0 < 1$ and $0 < y_0 < 1$, there exists a positive radius r such that $B_r(p) \subset S \subset T$. Thus, consider now points $p \in T$ with coordinates $(0, y_0)$. For all positive r, the open ball $B_r(p)$ contains the point $(-r/2, y_0)$, which is not in T. Hence, no open ball centered around points $(0, y_0)$ is contained in T, and hence T, is not open. (See Figure A.3.)

It is very common in proofs and definitions that rely on topology to refer to an open set that contains a particular point. Here is the common terminology.

Definition A.1.13. Let p be a point in a metric space (X, D). An *open neighborhood* (or simply *neighborhood*) of p is any open set of X that contains p.

Closed sets satisfy properties quite similar to those described in Proposition A.1.9, with a slight but crucial difference.

Proposition A.1.14. *Let (X, D) be a metric space. Then*

1. *X and $\emptyset$ are both closed;*
2. *the union of any two closed sets is closed;*
3. *the intersection of any collection of closed sets is closed.*

Because a set is defined as closed if its complement is open and because of DeMorgan laws for sets, this proposition is actually a simple corollary of Proposition A.1.9. Therefore, we leave the details of the proof to the reader.

Note that in any metric space, the whole set X and the empty set $\emptyset$ are both open and closed. Depending on the particular metric space, these are not necessarily the only subsets of X that are both open and closed.

Proposition A.1.15. *Let (X, D) be a metric space, and let $x \in X$. The singleton set $\{x\}$ is a closed subset of X.*

Proof. To prove that $\{x\}$ is closed, we must prove that $X - \{x\}$ is open. Let y be a point in $X - \{x\}$. Since $x \neq y$, by the axioms of a metric space, $D(x, y) > 0$. Let $r = \frac{1}{2}D(x, y)$. The real number r is positive, and we consider the open ball $B_r(y)$. Since $D(x, y) > r$, then $x \notin B_r(y)$, and hence, $B_r(y) \subset X - \{x\}$. Hence, we have shown that $X - \{x\}$ is open and thus that $\{x\}$ is closed. ☐

The notion of distance between sets provides an alternate characterization of closed sets in metric spaces. Recall that for any subset $A \subset X$, $x \in A$ implies that $D(x, A) = 0$. The following proposition shows that the converse holds precisely for closed sets.

Proposition A.1.16. *Let (X, D) be a metric space. A subset F is closed if and only if $D(x, F) = 0$ implies $x \in F$.*

Proof. Suppose first that F is closed. If $x \notin F$, then $x \in X - F$, which is open, so there exists an open ball $B_r(x)$ around x contained entirely in $X - F$. Hence, the distance between any point $a \in F$ and x is greater than the radius $r > 0$, thus, $D(x, F) > 0$, and in particular, $D(x, F) \neq 0$. Thus, $D(x, F) = 0$ implies that $x \in F$.

We now prove the converse. Suppose that F is a subset of X such that $D(x, F) = 0$ implies that $x \in F$. Then for all $x \in X - F$, we have $D(x, F) > 0$. Take the positive number $r = \frac{1}{2}D(x, F)$, and consider the open ball $B_r(x)$. Let p be any point in F and a any point in $B_r(x)$. Form the triangle inequality

$$D(p, x) \leq D(p, a) + D(a, x) \iff D(p, a) \geq D(p, x) - D(a, x).$$

The least possible value for $D(p,a)$ occurs when $D(p,x)$ is the least possible and when $D(a,x)$ is the greatest possible, that is when $D(p,x)=D(x,F)$ and $D(a,x)=r$. Thus, we find that $D(p,a)\geq r>0$. Hence, for all $a\in B_r(x)$, we have $D(F,a)>0$ and thus $B_r(x)\cap F=\emptyset$. Therefore, $B_r(x)\subset X-F$ so $X-F$ is open and F is closed. □

Proposition A.1.16 indicates that given any subset A of a metric space X, one can obtain a closed subset of X by adjoining all the points with 0 distance from A. This motivates the following definition.

Definition A.1.17. Let (X,D) be a metric space, and let $A\subset X$ be any subset. Define the *closure* of A as

$$\operatorname{Cl} A=\{x\in X \mid D(x,A)=0\}.$$

Proposition A.1.18. *Let (X,D) be a metric space and A any subset of X.* $\operatorname{Cl} A$ *is the smallest closed set containing A. In other words,*

$$\operatorname{Cl} A=\bigcap_{A\subset F,\ F\ \mathit{closed}} F\ .$$

Proof. (Left as an exercise for the reader. See Problem A.1.20.) □

A.1.3 Sequences

In standard calculus courses, one is introduced to the notion of a sequence of real numbers along with issues of convergence and limits. The definition given in such courses for when we say a sequence converges to a certain limit formalizes the idea of all terms in the sequence ultimately coming arbitrarily close to the limit point. Consequently, since limits formalize a concept about closeness and distance, the natural and most general context for convergence and limits is in a metric space.

Definition A.1.19. Let (X,D) be a metric space and let $\{x_n\}_{n\in\mathbb{N}}$ be a sequence in X. The sequence $\{x_n\}$ is said to converge to the limit $\ell\in X$ if for all $\varepsilon\in\mathbb{R}^{>0}$ there exists $N\in\mathbb{N}$ such that if $n>N$, then $D(x_n,\ell)<\varepsilon$ (i.e., $x_n\in B_\varepsilon(\ell)$). If $\{x_n\}$ converges to ℓ, then we write

$$\lim_{n\to\infty} x_n=\ell.$$

Note that we can restate Definition A.1.19 to say that $\{x_n\}$ converges to ℓ if for all positive $\varepsilon\in\mathbb{R}^{>0}$, only finitely many elements of the sequence $\{x_n\}$ are not in the open ball $B_\varepsilon(\ell)$.

Example A.1.20. Consider the sequence $\{x_n\}_{n\geq 1}$ in $\mathbb{R}^3$ given by $x_n=(3,\frac{1}{n+2},\frac{2n}{n+1})$. We prove that $\{x_n\}$ converges to $(3,0,2)$. We know that as sequences of real numbers,

$$\lim_{n\to\infty}\frac{1}{n+2}=0 \qquad \text{and} \qquad \lim_{n\to\infty}\frac{2n}{n+1}=2.$$

Pick any positive ε. Choose N_1 such that $n > N_1$ implies that $\frac{1}{n+2} < \frac{\varepsilon}{\sqrt{2}}$, and choose N_2 such that $n > N_2$ implies that $\left|\frac{2n}{n+1} - 2\right| < \frac{\varepsilon}{\sqrt{2}}$. Using the Euclidean distance

$$D(x_n, (3,0,2)) = \sqrt{(3-3)^2 + \left(\frac{1}{n+2} - 0\right)^2 + \left(\frac{2n}{n+1} - 2\right)^2},$$

one sees that if $n > N = \max(N_1, N_2)$, then

$$D(x_n, (3,0,2)) < \sqrt{\frac{\varepsilon}{2} + \frac{\varepsilon}{2}} = \varepsilon.$$

This proves that $\lim x_n = (3,0,2)$.

Note that we could have proved directly that $\lim x_n = (3,0,2)$ by considering the limit of $D(x_n, (3,0,2))$ as a sequence of real numbers and proving that this converges to 0.

Example A.1.21. Consider the set X of bounded, real-valued functions defined over the interval $[0,1]$ equipped with the metric defined in Example A.1.7. For $n \geq 1$, consider the sequence of functions given by

$$f_n(x) = \begin{cases} 1 - nx, & \text{for } 0 \leq x \leq \frac{1}{n}, \\ 0, & \text{for } \frac{1}{n} \leq x \leq 1. \end{cases}$$

Figure A.4 shows the functions for $n = 1, 2, 3$. One might suspect that the limit of this sequence $f_n(x)$ would be the function

$$f(x) = \begin{cases} 1, & \text{if } x = 0, \\ 0, & \text{for } x > 0, \end{cases}$$

but this is not the case. Let $r = \frac{1}{4}$, and consider the r-collar around $f(x)$. There is no n such that $f_n(x)$ lies within the $\frac{1}{4}$-collar around $f(x)$. (See Figure A.5.) Consequently, $f_n(x)$ does not converge to $f(x)$ in the metric space (X, D). Note, however, that for all $x \in [0,1]$, as sequences of real numbers $\lim_{n\to\infty} f_n(x) = f(x)$. We say that $f_n(x)$ converges *pointwise*.

Proposition A.1.22. *Let (X, D) be a metric space. Any sequence $\{x_n\}$ can converge to at most one limit point.*

Proof. Suppose that

$$\lim_{n\to\infty} x_n = \ell \qquad \text{and} \qquad \lim_{n\to\infty} x_n = \ell'.$$

Let ε be any positive real number. There exists N_1 such that $n > N_1$ implies that $D(x_n, \ell) < \frac{\varepsilon}{2}$, and there exists N_2 such that $n > N_s$ implies that $D(x_n, \ell') < \frac{\varepsilon}{2}$. Thus, taking some $n > \max(N_1, N_2)$, we deduce from the triangle inequality that

$$D(\ell, \ell') \leq D(x_n, \ell) + D(x_n, \ell') \leq \frac{\varepsilon}{2} + \frac{\varepsilon}{2} = \varepsilon.$$

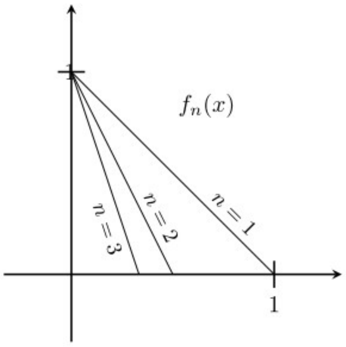

Figure A.4: Sequence of functions.

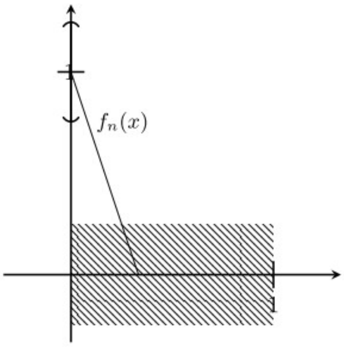

Figure A.5: $\frac{1}{4}$-collar around $f(x)$.

Thus, since $D(\ell, \ell')$ is less than any positive real number, we deduce that $D(\ell, \ell') = 0$ and hence that $\ell = \ell'$. ☐

In any metric space, there are plenty of sequences that do not converge to any limit. For example, the sequence $\{a_n\}_{n\geq 1}$ of real numbers given by $a_n = (-1)^n + \frac{1}{n}$ does not converge toward anything but, in the long term, alternates between being very close to 1 and very close to -1. Referring to the restatement of Definition A.1.19, one can loosen the definition of limit to incorporate the behavior of such sequences as the one just mentioned.

Definition A.1.23. Let (X, D) be a metric space, and let $\{x_n\}$ be a sequence in X. A point $p \in X$ is called an *accumulation point* of $\{x_n\}$ if for all real $\varepsilon > 0$, an infinite number of elements x_n are in $B_\varepsilon(p)$. The accumulation set of $\{x_n\}$ is the set of all accumulation points.

Example A.1.24. Consider again the real sequence $a_n = (-1)^n + \frac{1}{n}$. Let ε be any positive real number. If $n > \frac{1}{\varepsilon}$ and n is even, then $a_n \in B_\varepsilon(1)$. If $n > \frac{1}{\varepsilon}$ and n is odd, then $a_n \in B_\varepsilon(-1)$. Hence, 1 and -1 are accumulation points. However, for any r different than 1 or -1, suppose we choose a ε such that $\varepsilon < \min(|r-1|, |r+1|)$. If n is large enough, then

$$\frac{1}{n} < \big|\min(|r-1|, |r+1|) - \varepsilon\big|,$$

and for such n, we have $a_n \notin B_\varepsilon(r)$. Thus, 1 and -1 are the only accumulation points of $\{a_n\}$. In the terminology of Definition, A.1.23, the accumulation set is $\{-1, 1\}$.

A.1.4 Continuity

For the same reason as for the convergence of sequences, the notion of continuity, first introduced in the context of real functions over an interval, generalizes naturally to the category of metric spaces. Here is the definition.

Definition A.1.25. Let (X, D) and (Y, D') be two metric spaces. A function $f : X \to Y$ is called *continuous at* $a \in X$ if for all $\varepsilon \in \mathbb{R}^{>0}$, there exists $\delta \in \mathbb{R}^{>0}$ such that $D(x, a) < \delta$ implies that $D(f(x), f(a)) < \varepsilon$. The function f is called *continuous* if it is continuous at all points $a \in X$.

Example A.1.26. As a first example of Definition A.1.25, consider the function $f : \mathbb{R}^2 \to \mathbb{R}$ given by $f(x, y) = x + y$, where we assume $\mathbb{R}^2$ and $\mathbb{R}$ are equipped with the usual Euclidean metrics. Consider some point $(a_1, a_2) \in \mathbb{R}^2$. Let $\varepsilon > 0$ be any positive real number. Choosing $\delta = \frac{\varepsilon}{2}$ will suffice, as we now show. First note that

$$D((x, y), (a_1, a_2)) = \sqrt{(x - a_1)^2 + (y - a_2)^2} < \frac{\varepsilon}{2}$$

implies that

$$|x - a_1| < \frac{\varepsilon}{2} \qquad \text{and} \qquad |y - a_2| < \frac{\varepsilon}{2}.$$

But if this is so, then

$$|f(x, y) - f(a_1, a_2)| = |x + y - (a_1 + a_2)| < |x - a_1| + |y - a_2| < \frac{\varepsilon}{2} + \frac{\varepsilon}{2} = \varepsilon.$$

Thus, f is continuous.

Example A.1.27. Definition A.1.25 allows one to study the continuity of functions in much more general contexts, as we show with this example. Let X be a proper subset of $\mathbb{R}^n$, and let $\vec{p}$ be a point in $\mathbb{R}^n - X$. We view X as a metric space by restricting the Euclidean metric to it. Let $\mathbb{S}^{n-1}$ be the unit sphere in $\mathbb{R}^n$ also with its metric coming from the Euclidean one in $\mathbb{R}^n$. Define a function $f : X \to \mathbb{S}^{n-1}$ by

$$f(\vec{x}) = \frac{\vec{x} - \vec{p}}{\|\vec{x} - \vec{p}\|}.$$

We will show that f is continuous.

Let $\vec{a} \in X$. The Euclidean metric is $D(\vec{x}, \vec{a}) = \|\vec{x} - \vec{a}\|$. Hence

$$\begin{aligned} D(f(\vec{a}), f(\vec{x})) &= \left\| \frac{\vec{a} - \vec{p}}{\|\vec{a} - \vec{p}\|} - \frac{\vec{x} - \vec{p}}{\|\vec{x} - \vec{p}\|} \right\| \\ &= \sqrt{\left(\frac{\vec{a} - \vec{p}}{\|\vec{a} - \vec{p}\|} - \frac{\vec{x} - \vec{p}}{\|\vec{x} - \vec{p}\|} \right) \cdot \left(\frac{\vec{a} - \vec{p}}{\|\vec{a} - \vec{p}\|} - \frac{\vec{x} - \vec{p}}{\|\vec{x} - \vec{p}\|} \right)} \\ &= \sqrt{2 - 2\frac{(\vec{a} - \vec{p}) \cdot (\vec{x} - \vec{p})}{\|\vec{a} - \vec{p}\| \, \|\vec{x} - \vec{p}\|}} \\ &= \sqrt{2 - 2\cos\alpha}, \end{aligned}$$

where α is the angle between the vectors $(\vec{a}-\vec{p})$ and $(\vec{x}-\vec{p})$. However, from the trigonometric identity $\sin^2\theta = (1-\cos 2\theta)/2$, we deduce that

$$D(f(\vec{a}), f(\vec{x})) = 2\sin\left(\frac{\alpha}{2}\right).$$

If $\vec{x}$ and $\vec{a}$ are close enough, then $(\vec{a}-\vec{p})$ and $(\vec{x}-\vec{p})$ form an acute angle, and hence, if d is the height from $\vec{a}$ to the segment between $\vec{p}$ and $\vec{x}$, we have

$$D(f(\vec{x}), f(\vec{a})) = 2\sin\left(\frac{\alpha}{2}\right) \leq 2\sin\alpha = 2\frac{d}{\|\vec{p}-\vec{a}\|} \leq 2\frac{\|\vec{x}-\vec{a}\|}{\|\vec{p}-\vec{a}\|}.$$

Therefore, choosing δ small enough so that the angle between $(\vec{a}-\vec{p})$ and $(\vec{x}-\vec{p})$ is acute and $\delta < \frac{1}{2}\|\vec{p}-\vec{a}\|\,\varepsilon$, we conclude that

$$\|\vec{x}-\vec{a}\| < \delta \Longrightarrow D(f(\vec{x}), f(\vec{a})) < \varepsilon,$$

proving that f is continuous at all points $\vec{a} \in X$.

Proposition A.1.28. *Let (X, D), (Y, D'), and (Z, D'') be metric spaces. Let $f : X \to Y$ and $g : Y \to Z$ be functions such that f is continuous at a point $a \in X$ and g is continuous at $f(a) \in Y$. Then the composite function $g \circ f : X \to Z$ is continuous at a.*

Proof. Since f is continuous at a, for all $\varepsilon_1 \in \mathbb{R}^{>0}$, there exists $\delta_1 \in \mathbb{R}^{>0}$ such that $D(x, a) < \delta_1$ implies that $D(f(x), f(a)) < \varepsilon_1$. Since g is continuous at $f(a)$, for all $\varepsilon_2 \in \mathbb{R}^{>0}$, there exists $\delta_2 \in \mathbb{R}^{>0}$ such that $D(y, f(a)) < \delta_2$ implies that $D\big(g(y), g(f(a))\big) < \varepsilon_2$. Therefore, given any $\varepsilon > 0$, set $\varepsilon_2 = \varepsilon$ and choose ε_1 so that $\varepsilon_1 < \delta_2$. Then

$$D(x, a) < \delta_1 \Rightarrow D(f(x), f(a)) < \varepsilon_1 < \delta_2 \Rightarrow D\big(g(f(x)), g(f(a))\big) < \varepsilon,$$

showing that $g \circ f$ is continuous at a. □

Using the concepts of open sets, we can give alternate formulations for when a function between metric spaces is continuous.

Proposition A.1.29. *Let (X, D) and (Y, D') be two metric spaces, and let $f : X \to Y$ be a function. The function f is continuous if and only if for all open subsets $U \subset Y$, the set*

$$f^{-1}(U) = \{x \in X \mid f(x) \in U\}$$

is an open subset of X.

Proof. First suppose that f is continuous. Let U be an open subset of Y, and let x be some point in $f^{-1}(U)$. Of course $f(x) \in U$. Since U is open, there exists a real

$\varepsilon > 0$ such that $B_\varepsilon(f(x)) \subset U$. Since f is continuous, there exists a $\delta > 0$ such that $y \in B_\delta(x)$ implies that $f(y) \in B_\varepsilon(f(x))$. Hence,

$$f(B_\delta(x)) \subset B_\varepsilon(f(x)) \subset U,$$

and thus, $B_\delta(x) \subset f^{-1}(U)$.

Conversely, suppose that $f^{-1}(U)$ is an open set in X for every open set U in Y. Let $f(x)$ be a point in U, and let ε be a positive real number. Then

$$f^{-1}\big(B_\varepsilon(f(x))\big)$$

is an open set in X. Since $x \in f^{-1}\big(B_\varepsilon(f(x))\big)$ is open, there exists some δ such that $B_\delta(x) \subset f^{-1}\big(B_\varepsilon(f(x))\big)$. Thus, $f(B_\delta(x)) \subset B_\varepsilon(f(x))$, and therefore, f is continuous. ☐

The following proposition is an equivalent formulation to Proposition A.1.29 but often more convenient for proofs.

Proposition A.1.30. *Let (X, D) and (Y, D') be two metric spaces and let $f : X \to Y$ be a function. The function f is continuous if and only if for all open balls $B_r(p)$ in Y, the set $f^{-1}(B_r(p))$ is an open subset of X.*

Proof. (Left as an exercise for the reader. See Problem A.1.27.) ☐

Much more could be included in an introduction to metric spaces. However, many properties of metric spaces and continuous functions between them hold simply because of the properties of open sets (Proposition A.1.9) and the characterization of continuous functions in terms of open sets (Proposition A.1.29). This fact motivates the definition of topological spaces.

PROBLEMS

A.1.1. Prove that D_1, D_3, and D_∞ from Example A.1.3 are in fact metrics on $\mathbb{R}^2$.

A.1.2. In the following functions on $\mathbb{R}^2 \times \mathbb{R}^2$, which axioms fail to make the function into a metric?

(a) $D_1((x_1, y_1), (x_2, y_2)) = |x_1| + |x_2| + |y_1| + |y_2|$.

(b) $D_2((x_1, y_1), (x_2, y_2)) = -\big((x_2 - x_1)^2 + (y_2 - y_1)^2\big)$.

(c) $D_3((x_1, y_1), (x_2, y_2)) = |x_2 - x_1| \cdot |y_2 - y_1|$.

(d) $D_4((x_1, y_1), (x_2, y_2)) = |x_2^2 - x_1^2| + |y_2 - y_1|$.

A.1.3. Let (X_1, D_1) and (X_2, D_2) be metric spaces. Consider the Cartesian product $X = X_1 \times X_2$. Prove that the following function is a metric on X:

$$D((p_1, p_2), (q_1, q_2)) = D(p_1, q_1) + D(p_2, q_2).$$

A.1.4. Let $X = \mathcal{P}_{\text{fin}}(\mathbb{Z})$ be the set of all finite subsets of the integers. Recall that the symmetric difference between two sets A and B is $A \triangle B = (A - B) \cup (B - A)$. Define the function $D : X \times X \to \mathbb{R}^{\geq 0}$ by

$$D(A, B) = |A \triangle B|,$$

the cardinality of $A \triangle B$. Prove that D is a metric on X.

A.1.5. In Euclidean geometry, the median line between two points p_1 and p_2 in $\mathbb{R}^2$ is defined as the set of points that are of equal distance from p_1 and p_2, i.e.,

$$M = \{q \in \mathbb{R}^2 \mid D(q, p_1) = D(q, p_2)\}.$$

What is the shape of the median lines in $\mathbb{R}^2$ for D_1, D_2, and D_∞ from Example A.1.3?

A.1.6. Prove that if (X, D) is any metric space, then $D(x, y)^n$ where n is any positive integer, is also metric on X.

A.1.7. Let (X, D) be a metric space, and let S be any subset of X. Prove that (S, D) is also a metric space. (The metric space (S, D) is referred to as the *restriction of D to S*.)

A.1.8. Let $\mathbb{S}^2$ be the unit sphere in $\mathbb{R}^3$, i.e.,

$$\mathbb{S}^2 = \{(x, y, z) \in \mathbb{R}^3 \mid x^2 + y^2 + z^2 = 1\}.$$

Sketch the open balls on $\mathbb{S}^2$ obtained by the restriction of the Euclidean metric to $\mathbb{S}^2$ (see Problem A.1.7). Setting the radius $r < 2$, for some point $p \in \mathbb{S}^2$, describe $B_r(p)$ algebraically by the equation $x^2 + y^2 + z^2 = 1$ and some linear inequality in x, y, and z.

A.1.9. Prove that Example A.1.7 is in fact a metric space.

A.1.10. Consider the metric space $(\mathbb{R}^2, D_1)$, where D_1 is defined in Example A.1.3.

(a) Let A and B be two points in $\mathbb{R}^2$. Prove that the set of points between A and B is the rectangle with vertical or horizontal edges with A and B as opposite corners.

(b) Determine the bisector of the points A and B in this metric.

A.1.11. Find the distance between the following pairs of sets in $\mathbb{R}^2$:

(a) $A = \{(x, y) \mid x^2 + y^2 < 1\}$ and $B = \{(x, y) \mid (x - 3)^2 + (y - 2)^2 < 1\}$.

(b) $A = \{(x, y) \mid xy = 1\}$ and $B = \{(x, y) \mid xy = 0\}$.

(c) $A = \{(x, y) \mid xy = 2\}$ and $B = \{(x, y) \mid x^2 + y^2 < 1\}$.

A.1.12. Prove that a subset A of a metric space (X, D) is bounded if and only if $A \subset B_r(p)$ for some $r \in \mathbb{R}^{\geq 0}$ and $p \in X$.

A.1.13. *Infinite Intersections and Unions.* Let $A_n = [n, +\infty)$ and let $B_n = [\frac{1}{n}, \sin n]$. Find

$$\text{(a)}\ \bigcup_{n=0}^{\infty} A_n, \qquad \text{(b)}\ \bigcap_{n=0}^{\infty} A_n, \qquad \text{(c)}\ \bigcup_{n=2}^{\infty} B_n. \tag{A.1}$$

A.1.14. Define the metric D on $\mathbb{R}^2$ as follows. For any $p = (p_x, p_y)$ and $q = (q_x, q_y)$, let $D(p,q) = \sqrt{4(p_x - q_x)^2 + (p_y - q_y)^2}$. Prove that this is in fact a metric. What is the shape of a unit ball $B_r\big((x,y)\big)$? What is the shape of the "median" between two points? [Hint: see Problem A.1.5.]

A.1.15. Are the following subsets of the plane (using the usual Euclidean metric) open, closed, or neither:

(a) $\{(x,y) \in \mathbf{R}^2 : x^2 + y^2 < 1\}$.

(b) $\{(x,y) \in \mathbf{R}^2 : x^2 + y^2 \geq 1\}$.

(c) $\{(x,y) \in \mathbf{R}^2 : x + y = 0\}$.

(d) $\{(x,y) \in \mathbf{R}^2 : x + y \neq 0\}$.

(e) $\{(x,y) \in \mathbf{R}^2 : x^2 + y^2 \leq 1 \text{ or } x = 0\}$.

(f) $\{(x,y) \in \mathbf{R}^2 : x^2 + y^2 < 1 \text{ or } x = 0\}$.

(g) The complement A^c where $A = \{(x,y) \in \mathbf{R}^2 \mid x = 0 \text{ and } -1 \leq y \leq 1\}$.

A.1.16. Let L be a line in the plane $\mathbb{R}^2$. Prove that $\mathbb{R}^2 - L$ is open in the Euclidean metric and in the three metrics presented in Example A.1.3.

A.1.17. Let $X = \mathbb{R}^2$, and define D_2 as the Euclidean metric and D_1 as $D_1((x_1,y_1),(x_2,y_2)) = |x_2 - x_1| + |y_2 - y_1|$. Prove that any D_2-open ball contains a D_1-open ball and is also contained in a D_1-open ball. Conclude that a subset of $\mathbb{R}^2$ is D_2-open if and only if it is D_1-open.

A.1.18. Prove that the set $\{\frac{1}{n} \mid n \in \mathbb{Z}^{>0}\}$ is not closed in $\mathbb{R}$ whereas the set $\{\frac{1}{n} \mid n \in \mathbb{Z}^{>0}\} \cup \{0\}$ is.

A.1.19. Consider a metric space (X, D), and let x and y be two distinct points of X. Prove that there exists a neighborhood U of x and a neighborhood V of y such that $U \cap V = \emptyset$. (In general topology, this property is called the *Hausdorff property*, and this exercise shows that all metric spaces are Hausdorff.)

A.1.20. Prove Proposition A.1.18.

A.1.21. Let A be a subset of a metric space (X, D). Suppose that every sequence $\{x_n\}$ in A that converges in X converges to an element of A. Prove that A is closed.

A.1.22. Let $\{x_n\}_{n\in\mathbb{N}}$ be a sequence in a metric space (X, D). Prove that the closure of the set of elements $\{x_n\}$ is $\{x_n \mid n \in \mathbb{N}\}$ together with the accumulation set of the sequence $\{x_n\}$.

A.1.23. Using Definition A.1.25, prove that the real function $f(x) = 2x - 5$ is continuous over $\mathbb{R}$.

A.1.24. Using Definition A.1.25, prove that

(a) the real function $f(x) = x^2$ is continuous over $\mathbb{R}$;

(b) the real function of two variables $f(x,y) = 1/(x^2 + y^2 + 1)$ is continuous over all $\mathbb{R}^2$ (using the usual Euclidean metric).

A.1.25. Let (X, D) and (Y, D') be metric spaces, and let $f : X \to Y$ be a continuous function. Prove that if a sequence $\{x_n\}$ in X converges to a limit point ℓ, then the sequence $\{f(x_n)\}$ in Y converges to $f(\ell)$.

A.1.26. Let $f : X \to Y$ be a function from the metric space (X, D) to the metric space (Y, D'). Suppose that f is such that there exists a positive real number λ, with

$$\frac{D'(f(x_1), f(x_2))}{D(x_1, x_2)} \leq \lambda \qquad \text{for all } x_1 \neq x_2,$$

i.e., that the stretching ratio for f is bounded. Show that f is continuous.

A.1.27. Prove Proposition A.1.30.

A.1.28. Let $X = \mathbb{R}^m$ and $Y = \mathbb{R}^n$ equipped with the usual Euclidean metric. Prove that any linear transformation from X to Y is continuous.

A.2 Topological Spaces

A.2.1 Definitions and Examples

Definition A.2.1. A *topological space* is a pair (X, τ) where X is a set and where τ is a set of subsets of X satisfying the following:

1. X and $\emptyset$ are in τ.
2. For all U and V in τ, $U \cap V \in \tau$.
3. For any collection $\{U_\alpha\}_{\alpha \in I}$ of sets in τ, the union $\bigcup_{\alpha \in I} U_\alpha$ is in τ.

The elements in τ are called open subsets of X and a subset $F \subset X$ is called closed if $X - F$ is open, i.e., if $X - F \in \tau$.

As an alternate terminology we talk about τ satisfying the above three properties as a *topology* on X. In the introduction to this appendix, we promised that topology attempts to provide a mental model that generalizes the notion of nearness. The following concept is key to this way of thinking.

Definition A.2.2. Let (X, τ) be a topological space and let $x \in X$. Any $U \in \tau$ such that $x \in U$ is called a *neighborhood* of x.

If we work with more than one topology on the same underlying set X, we refer to τ-open and τ-closed subsets to avoid ambiguity.

As with the properties of open sets in metric spaces, in criterion (3) of Definition A.2.1, the indexing set I need not be countable, and hence, we should not assume that the collection $\{U_\alpha\}_{\alpha \in I}$ can be presented as a sequence of subsets.

Example A.2.3. According to Proposition A.1.9, if (X, D) is a metric space, it is also a topological space, where we use the topology τ to be the open sets as defined by Definition A.1.8. Historically, it was precisely Proposition A.1.9 along with the discovery by mathematicians that collections of sets with the properties described in this proposition arise naturally in numerous other contexts that led to the given definition of a topological space.

Example A.2.4 (Euclidean topology). Consider the metric space $(\mathbb{R}^2, D)$, where D is the Euclidean metric. The topology induced on $\mathbb{R}^n$ according to Example A.2.3 is called the Euclidean topology.

Example A.2.5 (Discrete topology). Let X be any set. Setting $\tau = \mathcal{P}(X)$ to be the set of all subsets of X is a topology on X called the *discrete topology* on X. In the discrete topology, all subsets of X are both closed and open.

Example A.2.6 (Trivial topology). On the opposite end of the spectrum from, setting $\tau = \{X, \emptyset\}$ also satisfies the axioms of a topology, and this is called the *trivial topology* on X. These two examples represent the largest and the smallest possible examples of topologies on a set X.

Example A.2.7. Let $X = \{a, b, c\}$ be a set with three elements. Consider the set of subsets $\tau = \{\emptyset, \{a\}, \{a, b\}, X\}$. A simple check shows that τ is a topology on X, namely that τ satisfies all the axioms for a topology. Notice that $\{a\}$ is open, $\{c\}$ is closed (since $\{a, b\}$ is open) and that $\{b\}$ is neither open nor closed. By Proposition A.1.15, there is no metric D on X such that the D-open sets of X are the open sets in the topology of τ. We say that (X, τ) is not metrizable.

It is not always easy to specify a subset of $\mathcal{P}(X)$ that satisfy the axioms for a topology on X. The concept of a basis makes this possible and Proposition A.2.9 gives a practical characterization of a basis.

Definition A.2.8. Let (X, τ) be a topological space. A collection of open sets $\mathcal{B} \subset \tau$ is called a *basis* of the topology if every open set is a union of elements in $\mathcal{B} \subset \tau$.

Proposition A.2.9. *Let (X, τ) be a topological space, and suppose that $\mathcal{B}$ is a basis. Then:*

1. *the elements of $\mathcal{B}$ cover X;*
2. *if $B_1, B_2 \in \mathcal{B}$, then for all $x \in B_1 \cap B_2$ there exists $B_3 \in \mathcal{B}$ such that $x \in B_3 \subset B_1 \cap B_2$.*

Conversely, if any collection $\mathcal{B}$ of open sets satisfies the above two properties, then there exists a unique topology on X for which $\mathcal{B}$ is a basis. (This topology is said to be generated *by $\mathcal{B}$.)*

Proof. (Left as an exercise for the reader.) ☐

This characterization allows one to easily describe topologies by presenting a basis of open sets.

Example A.2.10. By Definition A.1.8, in a metric space, the topology associated to a metric has the set of open balls as a basis.

Example A.2.11. Let $X = \mathbb{R}^2$, and consider the collection $\mathcal{B}$ of sets of the form

$$U = \{(x, y) \in \mathbb{R}^2 \mid x > x_0 \text{ and } y > y_0\},$$

where x_0 and y_0 are constants. This collection $\mathcal{B}$ satisfies both of the criteria in Proposition A.2.9, hence there exists a unique topology τ on $\mathbb{R}^2$ with $\mathcal{B}$ as a basis. It is easy to see that τ is different from the usual Euclidean topology. Note that for any open set $U \in \tau$, if $(a, b) \in U$, then the half-infinite ray

$$\{(a + t, b + t) \mid t \geq 0\}$$

is a subset of U. This is not a property of the Euclidean topology on $\mathbb{R}^2$, so this gives a topology different from the Euclidean topology.

Proposition A.2.12. *Let (X, τ) be a topological space. Then the following are true about the τ-closed sets of X:*

1. *X and $\emptyset$ are closed.*
2. *The union of any two closed sets is closed.*
3. *The intersection of any collection of closed sets is closed.*

Proof. Part 1 is obviously true since both X and $\emptyset$ are open.

For part 2, let F_1 and F_2 be any two closed subsets of X. Then ${F_1}^c$ and ${F_2}^c$ are open sets. Thus ${F_1}^c \cap {F_2}^c$ is open. However, by the DeMorgan laws,

$${F_1}^c \cap {F_2}^c = (F_1 \cup F_2)^c.$$

Thus, since $F_1 \cup {F_2}^c$ is open, $F_1 \cup F_2$ is closed.

For part 3, let $\{F_\alpha\}$, where α is in some indexing set I, be a collection of closed subsets. The collection $\{{F_\alpha}^c\}$ is a collection of open sets. Therefore, $\bigcup_\alpha {F_\alpha}^c$ is open. Thus,

$$\bigcap_{\alpha \in I} F_\alpha = \left(\bigcup_{\alpha \in I} {F_\alpha}^c \right)^c$$

is closed. □

A converse to this proposition turns out to be useful for defining certain classes of topologies on sets.

Proposition A.2.13. *Let X be a set. Suppose that a collection $\mathcal{C}$ of subsets of X satisfies the following properties:*

1. *X and $\emptyset$ are in $\mathcal{C}$.*
2. *The union of any two sets in $\mathcal{C}$ is again in $\mathcal{C}$.*
3. *The intersection of any collection of sets in $\mathcal{C}$ is again in $\mathcal{C}$.*

Then the set of all complements of sets in $\mathcal{C}$ form a topology on X.

Proof. (Left as an exercise for the reader.) ☐

Example A.2.14. Let X be any set. Consider the collection $\mathcal{C}$ of subsets of X that include X, $\emptyset$, and all finite subsets of X. The collection $\mathcal{C}$ satisfies all three criteria in Proposition A.2.13, so X, $\emptyset$, and the complements of finite subsets of X form a topology on X. This is often called the *finite complement* topology.

We now present a topology on $\mathbb{R}^n$ that has more open sets than the finite complement topology but fewer than the usual Euclidean topology.

Example A.2.15. Let $X = \mathbb{R}^n$. Let $\mathcal{C}$ be the collection of all finite unions of affine subspaces of $\mathbb{R}^n$, where by affine subspace we mean any set of points that is the solution set to a set of linear equations in $x_1, x_2, \ldots, x_n$ (i.e., points, lines, planes, etc.). Taking the empty set of linear equations or an inconsistent set of linear equations, we obtain X and $\emptyset$ as elements of $\mathcal{C}$. Since the union operation of sets is associative, a finite union of finite unions of affine spaces is again just a union of affine spaces.

To establish that the third criterion in A.2.13 holds for $\mathcal{C}$, we must prove that the intersection of any collection of finite unions of affine spaces is a finite union of affine spaces. Note first that if the intersection of two affine subspaces A_1 and A_2 is a strict subspace of both A_1 and A_2, then $\dim A_1 \cap A_2$ is strictly less than $\dim A_1$ and $\dim A_2$. Let $\{F_\alpha\}_{\alpha \in I}$ be a collection of sets in $\mathcal{C}$, and let $\{\alpha_i\}_{i \in \mathbb{N}}$ be a sequence of indices. Given the sequence $\{\alpha_i\}$, create a sequence of "intersection" trees according to the following recursive definition. The tree T_0 is the tree with a base node, and an edge for each $A_{\alpha_0, j}$ in

$$F_{\alpha_0} = \bigcup_j A_{\alpha_0, j} \ ,$$

with a corresponding leaf for each $A_{\alpha_0, j}$. For each tree T_i, construct T_{i+1} from T_i as follows. Writing

$$F_{\alpha_i} = \bigcup_j A_{\alpha_i, j} \ ,$$

for each leaf F of T_i and for each j such that $F \cap A_{\alpha_i, j} \neq F$, adjoin an edge labeled by $A_{\alpha_i, j}$ to F and label the resulting new leaf by $F \cap A_{\alpha_i, j}$.

As constructed, for each k, the leaves of the tree T_k are labeled by intersections of affine spaces so that

$$\bigcap_{i=0}^{k} F_{\alpha_i}$$

is the union of the leaves of T_k. Since only a finite number of edges gets added to every leaf, for all $i \geq 0$, there can be only a finite number of vertices at a fixed distance from the base node. Furthermore, since any nontrivial intersection $A \cap B$ of affine spaces has dimension

$$\dim(A \cap B) \leq \min(\dim A, \dim B) - 1$$

and since the ambient space is $\mathbb{R}^n$, each branch (descending path) in any tree T_i can have at most $n+1$ edges. In conclusion, for all T_i, there can only be a finite number of leaves. Thus,

$$\bigcap_{i=0}^{\infty} F_{\alpha_i}$$

is a finite union of intersections of affine spaces. Since this holds for all sequences $\{\alpha_i\}$ in I, this then proves that

$$\bigcap_{\alpha \in I} F_{\alpha}$$

is a finite union of intersections of affine spaces.

This rather lengthy proof shows that the collection $\mathcal{C}$ of finite unions of affine spaces in $\mathbb{R}^n$ satisfies the criteria of Proposition A.2.13. Consequently, the set τ of subsets of $\mathbb{R}^n$ that are complements of a finite union of affine spaces forms a topology on $\mathbb{R}^n$.

Example A.2.15, along with the result of Problem A.2.3, shows that given a set X, it is possible to have two topologies τ and τ' on X such that $\tau \subsetneq \tau'$, or in other words, that every τ-open set in X is τ'-open but not vice versa. This leads to a useful notion.

Definition A.2.16. Let X be a set and let τ and τ' be two topologies on X. If $\tau \subseteq \tau'$, then we say that τ' is *finer* than τ and that τ is *coarser* than τ'. If in addition $\tau \neq \tau'$, we say that τ' is *strictly finer* than τ and that τ is *strictly coarser* than τ'.

As a few examples, consider $X = \mathbb{R}^n$. Then the finite complement topology (Example A.2.14) is coarser than the topology defined in Example A.2.15, which is in turn coarser than the Euclidean topology.

In Section A.1.2, Proposition A.1.18 proved that the closure of a subset A (as defined by Definition A.1.17) of a metric space (X, D) is the intersection of all closed subsets of X containing A. This formulation of the closure of a set does not rely explicitly on the the metric D and carries over without changes to topological spaces. The closure of a subset $A \subset X$ is an example of a *topological operator*, three of which we mention here.

Definition A.2.17. Let (X, τ) be a topological space and A a subset of X. We define

1. the *closure* of A, written $\operatorname{Cl} A$, as the intersection of all closed sets in X containing A;
2. the *interior* of A, written A°, as the union of all open sets of X contained in A;
3. the *frontier* of A, written $\operatorname{Fr} A$, as the set of all $x \in X$ such that for every neighborhood U of x intersects A and A^c nontrivially, i.e., $U \cap A \neq \emptyset$ and $U \cap A^c \neq \emptyset$.

We leave some of the basic properties of the above topological operators to the exercises but present one common characterization of closed sets.

Proposition A.2.18. *Let* (X, τ) *be a topological space, and let* A *be any subset of* X*. The set* A *is closed if and only if* $A = \operatorname{Cl} A$*.*

Proof. If A is closed, then A is among the closed sets $F \subset X$ that contain A, and there is no smaller closed subset containing A. Hence $A = \operatorname{Cl} A$. Conversely, if $A = \operatorname{Cl} A$, then since the intersection of any collection of closed sets is closed, $\operatorname{Cl} A$ is closed, so A is closed. □

Another useful characterization of closed sets relies not on a topological operator but on properties of its limit points.

Definition A.2.19. Let A be any subset of a topological space (X, τ). A *limit point* of A is any point $p \in X$ such that $U \cap (A - \{p\})\ ne\emptyset$ for every open neighborhood U of p.

In the vocabulary of sequences in a metric space, if the subset A is a sequence $\{x_n\}$, then in Definition A.1.23, we would call the limit points of A the accumulation points of A. For this reason, some authors use the alternate terminology of accumulation point for limit points of a subset A in a topological space. The discrepancy in terminology is unfortunate, but in topology, the majority of authors use the vocabulary of Definition A.2.19.

Proposition A.2.20. *Let* A *be a subset of a topological space* X*. The set* A *is closed if and only if it contains all of its limit points.*

Proof. Assume first that A is closed. The complement $X - A$ is open and hence is a neighborhood of each of its points. Therefore, there is no point in $X - A$ that is a limit point of A. Hence, A contains all its limit points.

Assume now that A contains all of its limit points. Let $p \in X - A$. Since p is not a limit point of A, there exists an open neighborhood U of p such that $U \cap A = \emptyset$. Thus, $X - A$ is a neighborhood of each of its points, and hence, it is open. Thus, A is closed. □

Finally, we mention one last term related to closures.

Definition A.2.21. Let (X, τ) be a topological space. A subset A of X is called *dense* in X if $\operatorname{Cl} A = X$.

By Proposition A.2.20 a set A is dense in X if every point of X is a limit point of A. We give a few common examples of dense subsets.

Example A.2.22. Let $I = [a, b]$ be a closed interval in $\mathbb{R}$, and equip I with the topology induced from the Euclidean metric on $\mathbb{R}$. The open subsets in this topology on I are of the form $U \cap I$, where U is an open subset of $\mathbb{R}$. Furthermore, the open interval (a, b) is dense in I.

Proposition A.2.23. *The set $\mathbb{Q}$ of rational numbers is dense in $\mathbb{R}$.*

Proof. A precise proof of this statement must rely on a definition of real numbers, as constructed from the rationals. One may find this definition in any introductory analysis text. However, using a high school understanding of real numbers as numbers with an infinite decimal expansion that is not periodic, we can supply a simple proof of this fact.

Let $x_0 \in \mathbb{R}$ be any real number, and let U be an open neighborhood of x_0. By definition, there exists a positive real $\varepsilon > 0$ such that $(x_0 - \varepsilon, x_0 + \varepsilon) \in U$. Let $N = 1 - \lfloor \log_{10} \varepsilon \rfloor$. Consider q the fraction that represents the decimal approximation of x_0 that stops at N digits after the decimal period. Then, $q \in \mathbb{Q}$ and $q \in U$. Hence, x_0 is a limit point of $\mathbb{Q}$. □

Knowing that $\mathbb{Q}$ is a countable and dense subset of $\mathbb{R}$, we can introduce a property of the Euclidean topology that is a key part of the definition of a topological manifold.

Definition A.2.24. A topological space (X, τ) is called *second countable* if there exists a basis of τ that is countable.

Example A.2.25. The Euclidean space $\mathbb{R}^n$ is second countable. Consider the collection $\mathcal{B}$ of open balls whose centers have rational coordinates and of rational radius. This collection is in bijection with $\mathbb{Q}^n \times \mathbb{Q}^{>0}$. Since the Cartesian product of countable sets is countable, $\mathbb{B}$ is countable. It is not hard to see that this collection satisfies the conditions of Proposition A.2.9, so this $\mathcal{B}$ is a countable basis of $\mathbb{R}^n$.

A.2.2 Continuity

When working with topological spaces (X, τ) and (Y, τ'), we are usually not interested in studying the properties of just any function between $f : X \to Y$ because a function without any special properties will not necessarily relate the topology on X to that on Y or vice versa. In Section A.1.4, Proposition A.1.29 provided a characterization of continuous functions between metric spaces only in terms of the open sets in the metric space topology. This motivates the definition of continuity for functions between topological spaces.

Definition A.2.26. Let (X, τ) and (Y, τ') be two topological spaces, and let $f : X \to Y$ be a function. We call f continuous (with respect to τ and τ') if for every open set $U \subset Y$, the set $f^{-1}(U)$ is open in X.

Example A.2.27. Proposition A.1.29 shows that any function called continuous between two metric spaces (X, D) and (Y, D') is continuous with respect to the topologies induced by the metrics on X and Y.

In previous contexts (e.g., functions from $\mathbb{R}^n$ to $\mathbb{R}^m$, and functions between metric spaces), we first defined the notion of continuity at a point and then expanded to continuous over a domain. In this case, as in all texts on topology, we first defined continuity over a whole domain. However, there is a natural definition for continuity at a point.

Definition A.2.28. Let $f : X \to Y$ be as in the previous definition. We call f continuous at $x \in X$, if for every neighborhood V of $f(x)$, there is a neighborhood U of x with $f(U) \subset V$.

The following proposition shows why this definition of continuity at a point is natural.

Proposition A.2.29. *Let (X, τ) and (Y, τ') be topological spaces, and let $f : X \to Y$ be a function. Then f is continuous if and only if f is continuous at all $x \in X$.*

Proof. First, suppose that f is continuous. Then for all $f(x) \in Y$ and for all open neighborhoods V of $f(x)$, $f^{-1}(V)$ is open in X. Furthermore, $x \in f^{-1}(V)$ so $f^{-1}(V)$ is an open neighborhood of x. Also, since $f(f^{-1}(V)) = V$ for any set, we see that setting $U = f^{-1}(V)$ proves one direction.

Second, assume that f is continuous at all $x \in X$. Let V be any open set in Y. If V contains no image $f(x)$, then $f^{-1}(V) = \emptyset$, which is open in X. Therefore, assume that V contains some image $f(x)$. Let $W = f^{-1}(V)$. According to the assumption, for all $x \in W$ there exists open neighborhoods U_x of x such that $f(U_x) \subset V$. Since $f(U_x) \subset V$, then $U_x \subset f^{-1}(V) = W$. But then

$$W \subset \bigcup_{x \in W} U_x \subset W^\circ,$$

and since $W^\circ \subset W$ always, we conclude that $W = W^\circ$, which implies (see Problem A.2.7) that W is open. This shows that f is continuous. ☐

Proposition A.2.30. *Let (X, τ), (Y, τ'), and (Z, τ'') be three topological spaces. If $f : X \to Y$ and $g : Y \to Z$ are continuous functions, then $g \circ f : X \to Z$ is also a continuous function.*

Proof. (Left as an exercise for the reader.) ☐

For metric spaces, a continuous function is one that preserves “nearness” of points. Though topological spaces are not necessarily metric spaces, a continuous function $f : X \to Y$ between topological spaces preserves nearness in the sense that if two images $f(x_1)$ and $f(x_2)$ are in the same open set V, then there is an open set U that contains both x_1 and x_2, with $f(U) \subset V$.

In set theory, we view two sets as “the same” if there exists a bijection between them: they are identical except for how we label the specific elements. For topological spaces to be considered “the same,” not only do the underlying sets need to be in bijection, but this bijection must preserve the topology. This is the concept of a homeomorphism.

Definition A.2.31. Let (X, τ) and (Y, τ') be two topological spaces, and let $f : X \to Y$ be a function. The function f is called a *homeomorphism* if

1. f is a bijection;
2. $f : X \to Y$ is continuous;
3. $f^{-1} : Y \to X$ is continuous.

If there exists a homeomorphism between two topological spaces, we call them *homeomorphic*.

Example A.2.32. Any two squares S_1 and S_2, as subsets of $\mathbb{R}^2$ with the Euclidean metric, are homeomorphic. For $i = 1, 2$, let t_i be the translation that brings the center of S_i to the origin, R_i a rotation that makes the edges of $t_i(S_i)$ parallel to the x- and y-axes, and let h_i be a scaling (homothetie) that changes $R_i \circ t_i(S_i)$ into the square with vertices $\{(-1,-1), (-1,1), (1,1), (1,-1)\}$. It is easy to see that translations are homeomorphisms of $\mathbb{R}^2$ to itself. Furthermore, by Problem A.1.28, we see that R_i and h_i are continuous, and since they are invertible linear transformations, their inverses are continuous as well. Thus, R_i and h_i are homeomorphisms. Thus, the function

$$f = t_2^{-1} \circ R_2^{-1} \circ h_2^{-1} \circ h_1 \circ R_1 \circ t_1$$

is a homeomorphism of $\mathbb{R}^2$ into itself that sends S_1 to S_2. Thus, S_1 and S_2 are homeomorphic.

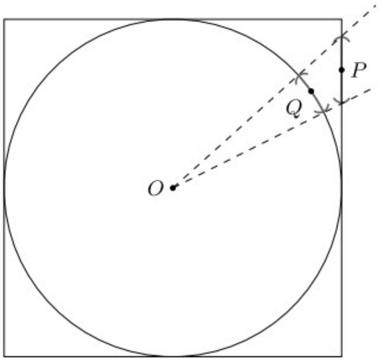

Figure A.6: A homeomorphism between a circle and a square from Example A.2.33.

Example A.2.33. Any circle and any square, as subsets of $\mathbb{R}^2$, are homeomorphic. We must present a homeomorphism between a circle and a square. By Example A.2.32 we see that any two squares are homeomorphic. By a similar argument, any two circles are homeomorphic. So without loss of generality, consider the consider the unit circle S and the unit square T, both with center $(0, 0)$. (See Figure A.6.)

Let $f : T \to S$ be the function defined by $f(x) = x/\|x\|$, where x is viewed as a point in $\mathbb{R}^2$. It is clear that this is a continuous function on its domain, $\mathbb{R}^2 - \{(0,0)\}$ so it is continuous on the subset T. For $\theta \in \mathbb{R}$, consider the function $g(\theta) = \max(|\sin\theta|, |\cos\theta|)$ and then the curve $\gamma : [0, 2\pi] \to \mathbb{R}^2$ parametrized by $\gamma(t) = (\cos(t)/g(t), \sin(t)/g(t))$. It is not hard to verify that this curve traces out the unit square T. Identifying a point on the circle with its angle, we can think of γ as a function $S \to T$. It is not hard to see that g is continuous and that γ is as well. Furthermore, $(f \circ \gamma)(p) = p$ for all $p \in S$ and also $(\gamma \circ f)(q) = q$ for all $q \in T$. Hence, f is a homeomorphism between the unit square and the unit circle.

Figure A.6 shows corresponding points P and Q as well as corresponding neighborhoods of these points.

Example A.2.34. The above two examples only begin to illustrate how different homeomorphic spaces may look. In this example, we prove that any closed, simple, parametrized curve γ in $\mathbb{R}^n$ is homeomorphic to the unit circle $\mathbb{S}^1$ (in $\mathbb{R}^2$). Let $\vec{x} : [0, l] \to \mathbb{R}^n$ be a parametrization by arclength for the curve γ such that $\vec{x}(t_1) = \vec{x}(t_2)$ implies that $t_1 = 0$ and $t_2 = l$, assuming $t_1 < t_2$. The function $f : \gamma \to \mathbb{S}^1$ defined by

$$f(P) = \Big(\cos\Big(\frac{2\pi}{l}\vec{x}^{-1}(P)\Big), \sin\Big(\frac{2\pi}{l}\vec{x}^{-1}(P)\Big)\Big) \tag{A.2}$$

produces the appropriate homeomorphism. Note that $\vec{x}^{-1}$ is not well defined only at the point $\vec{x}(0)$ because $\vec{x}^{-1}(\vec{x}(0)) = \{0, l\}$. However, using either 0 or l in Equation (A.2) is irrelevant.

Example A.2.35. In contrast to the previous example, consider the closed, regular curve γ parametrized by $\vec{x} : [0, 2\pi] \to \mathbb{R}^2$ with

$$\vec{x}(t) = (\cos t, \sin 2t).$$

The curve γ traces out a figure eight of sorts and is not simple because $\vec{x}(\pi/2) = (0,0) = \vec{x}(3\pi/2)$ (and $\vec{x}'(\pi/2) \neq \vec{x}'(3\pi/2)$). We show that it is not homeomorphic to a circle $\mathbb{S}^1$. Call $P = (0,0)$.

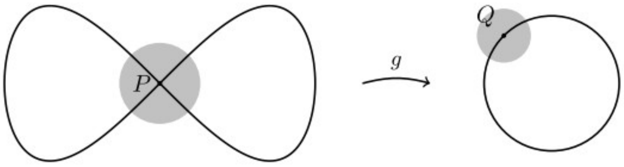

Figure A.7: Figure eight not homeomorphic to a circle.

There does exist a surjective continuous map f of γ onto the circle $\mathbb{S}^1$, namely, using the parametrization $\vec{x}(t)$,

$$f(\vec{x}(t)) = (\cos 2t, \sin 2t)$$

which amounts to folding the figure eight back onto itself so that the circle is covered twice. However, there exists no continuous bijection $g : \gamma \to \mathbb{S}^1$. To see this, call $Q = g(P)$, and let U be a small open neighborhood of Q. If g is a bijection, it has exactly one preimage for every element $x \in U$. Thus, $g^{-1}(U)$ is the image of a nonintersecting parametrized curve. However, every open neighborhood of P includes two segments of curves. Thus, the circle and γ are not homeomorphic.

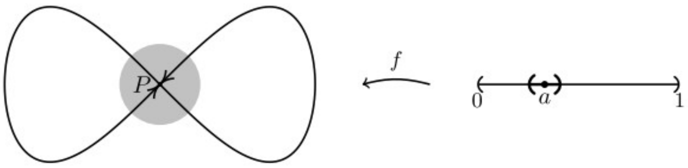

Figure A.8: Figure eight not homeomorphic to a segment.

Example A.2.36. Consider the same regular, closed parametrized curve as in the previous example. The function $f : (0,1) \to \gamma_2$ defined by $f(t) = \vec{x}\big(2\pi t - \frac{\pi}{2}\big)$ is a bijection. Furthermore, f is continuous since it is continuous as a function $(0,1) \to \mathbb{R}^2$. However, the inverse function is not continuous and in fact no continuous bijection $g : (0,1) \to \gamma_2$ can have a continuous inverse.

Let $a \in (0,1)$ be the real number such that $f(a) = P$, the point of self-intersection on γ_2. Take an open segment U around a. The image $f(U)$ is a portion of γ_2 through P (see the heavy lines in Figure A.8). However, this portion $f(U)$ is not an open subset of γ_2 since every open neighborhood of P includes $f((0,\varepsilon_1))$ and $f((1-\varepsilon_2,1))$. Thus there exists no homeomorphism between the open interval and the figure eight.

We conclude this section on continuity by mentioning one particular result, the proof of which exceeds the scope of this appendix.

Theorem A.2.37. *The Euclidean spaces* $\mathbb{R}^n$ *and* $\mathbb{R}^m$ *are homeomorphic if and only if* $m = n$.

This theorem states that Euclidean spaces can only be homeomorphic if they are of the same dimension. This might seem obvious to the casual reader but this fact hides a number of subtleties. First of all, the notion of dimension of a set in topology is not at all a simple one. Secondly, we must be careful to consider space-filling curves, such as the Peano curve, which is a continuous surjection of the closed interval $[0,1]$ onto the closed unit square $[0,1] \times [0,1]$. (See [28], Section 3-3, for a construction.) The construction for space-filling curves can be generalized to find continuous surjections of $\mathbb{R}^n$ onto $\mathbb{R}^m$ even if $n < m$. However, Theorem A.2.37 implies that no space-filling curve is bijective and has a continuous inverse. That Euclidean spaces of different dimensions are not homeomorphic means that they are distinct from the perspective of topology.

A.2.3 Derived Topological Spaces

Given any topological space (X, τ), there are a number of ways to create a new topological space. We present two common ways – subset topology and quotient spaces – which are used throughout this book.

Definition A.2.38. Let (X, τ) be a topological space, and let S be any subset of X. We define the *subset topology* τ' on S by calling a subset $A \subset S$ open if and only if there exists an open subset U of X such that $A = S \cap U$.

The subset topology is sometimes called the topology induced on S from X. There is an alternate way to characterize it.

Proposition A.2.39. *Let (X, τ) be a topological space, and let $S \subset X$. Let $i : S \to X$ be the inclusion function. The subset topology on S is the coarsest topology such that i is a continuous function.*

Proof. Given any subset A of X, we have $i^{-1}(A) = A \cap S$. If i is continuous, then for all open subsets $U \subset X$, the set $i^{-1}(U) = U \cap S$ is open. However, according to Definition A.2.38, the subset topology on S has no other open subsets and therefore is coarser than any other topology on S, making i continuous. ☐

Example A.2.40. Consider $\mathbb{R}$ equipped with the usual topology. Let $S = [a, b]$ be a closed interval. If $a < c < b$, in the subset topology on S, the interval $[a, c)$ is open. To see this, take any real $d < a$. Then

$$[a, c) = (d, c) \cap [a, b],$$

and (d, c) is open in $\mathbb{R}$.

A second and often rather useful way to create new topological spaces is to induce a topology on a quotient set.

Definition A.2.41. Let X be a set, and let R be an equivalence relation on X. The set of equivalence classes of R is denoted by X/R and is called the *quotient set* of X by R.

The concept of a quotient set arises in many areas of mathematics (congruence classes in number theory, quotient groups in group theory, quotient rings in ring theory, etc.) but also serves as a convenient way to define interesting objects in topology and geometry. We provide a few such examples before discussing topologies on quotient sets.

Example A.2.42 (Real Projective Space)**.** The typical construction of the real projective space is given in Example 3.1.6. We present two other equivalent constructions.

Let X be the set of all lines in $\mathbb{R}^{n+1}$, and let R be the equivalence relation of parallelism on X. We can therefore discuss the set of equivalence classes X/R. Each line in X is uniquely parallel to a line that passes through the origin, and hence, X/R may be equated with the set of lines passing through the origin. This set is called the *real projective space* of dimension n and is usually denoted by $\mathbb{RP}^n$.

As an alternate characterization for $\mathbb{RP}^n$, consider the unit n-sphere $\mathbb{S}^n$ in $\mathbb{R}^{n+1}$ and centered at the origin. Each line through the origin intersects $\mathbb{S}^n$ at two antipodal points. Therefore, $\mathbb{RP}^n$ is the quotient set of $\mathbb{S}^n$ with respect to the equivalence relation, in which two points are called equivalent if they are antipodal (form the ends of a diameter through $\mathbb{S}^n$).

Example A.2.43 (Grassmannian)**.** Let X_r be the set of all r dimensional vector subspaces in $\mathbb{R}^n$, and let R be the equivalence relation of parallelism between hyperplanes. The set of equivalence classes is called a Grassmannian and is denoted $\mathbb{G}(r, n)$. Again, since each r-dimensional hyperplane is uniquely parallel to one hyperplane through the origin, $\mathbb{G}(r, n)$ is the set of r-hyperplanes through the origin.

Of particular interest to geometry is the question of how to give a topology to X/R if X is equipped with a topology. Proposition A.2.39 illustrates how to make a reasonable definition.

Definition A.2.44. Let (X, τ) be a topological space and let R be an equivalence relation on X. Define $f : X \to X/R$ as the function that sends an element in X to its equivalence class; f is called the *quotient map* (or sometimes *identification map*). We call *quotient topology* (or *identification topology*) on X/R the finest topology that makes f continuous.

The above definition for the quotient topology does not make it too clear what the open sets of X/R should be. The following proposition provides a different characterization.

Proposition A.2.45. *Let (X, τ) be a topological space, let R be an equivalence relation on X and let f be the quotient map. The quotient topology on X/R is*

$$\tau' = \{U \in \mathcal{P}(X/R) \mid f^{-1}(U) \in \tau\}.$$

Proof. Let τ' be a topology on X/R such that $f : X \to X/R$ is continuous. Then for all open sets $U \in \tau'$, we must have $f^{-1}(U)$ be open in X. Note first that $f^{-1}(\emptyset) = \emptyset$ and $f^{-1}(X/R) = X$, which are both open in X.

From basic set theory, for any function $F : A \to B$ and any collection $\mathcal{C}$ of subsets of B, we have

$$F^{-1}\Big(\bigcup_{S\in\mathcal{C}} S\Big) = \bigcup_{S\in\mathcal{C}} F^{-1}(S) \qquad \text{and} \qquad F^{-1}\Big(\bigcap_{S\in\mathcal{C}} S\Big) = \bigcap_{S\in\mathcal{C}} F^{-1}(S).$$

(See Section 1.3 in [48].) Therefore, if U_1 and U_2 are such that $f^{-1}(U_1) \cap f^{-1}(U_2)$ is open, then $f^{-1}(U_1 \cap U_2)$ is open. Also, for any collection of sets $\{U_\alpha\}_{\alpha\in I}$ in X/R,

$$f^{-1}\Big(\bigcup_{\alpha\in I} U_\alpha\Big) = \bigcup_{\alpha\in I} f^{-1}(U_\alpha)$$

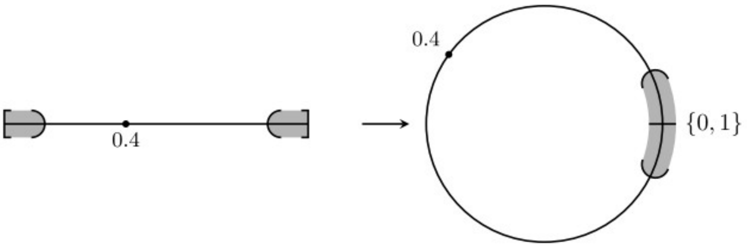

Figure A.9: Open set around $\{0,1\}$.

so if the right-hand side is open, then so is the left-hand side. Consequently, the collection of subsets $\mathcal{B}$ of X/R such that $U \in \mathcal{B}$ if and only if $f^{-1}(U) \in \tau$ is a topology on X/R. However, any finer topology on X/R would include some subset $S \subset X/R$ such that $f^{-1}(S)$ would not be open in X and, hence, would make f not continuous. □

Example A.2.46 (Circles)**.** Let I be the interval $[0,1]$ equipped with the topology induced from $\mathbb{R}$. Consider the equivalence relation that identifies 0 with 1, and everything else inequivalent. The identification space I/R is homeomorphic to a circle. We may use the function $f : I/R \to \mathbb{S}^1$ defined by

$$f(t) = (\cos 2\pi t, \sin 2\pi t),$$

which is well-defined since $f(0) = f(1)$, so whether we take 0 or 1 for the equivalence class $\{0,1\}$, we obtain the same image. This function f is clearly bijective.

To prove that f is continuous, let $P \in \mathbb{S}^1$, and let $x \in I/R$. If $P \neq (1,0)$, then any open neighborhood U of P contains an open interval of angles $\theta_1 < \theta < \theta_2$, where $0 < \theta_1 < \theta_2 < 2\pi$ and the angle θ_0 corresponding to P satisfies $\theta_1 < \theta_0 < \theta_2$. Then

$$f\Big(\frac{\theta_1}{2\pi}, \frac{\theta_2}{2\pi}\Big)$$

contains P and is a subset of U. On the other hand, if $P = (1,0)$, any open neighborhood U' of P in $\mathbb{S}^1$ contains an open arc of angles $\theta_1 < \theta < \theta_2$, with $\theta_1 < 0 < \theta_2$. Then if $g : I \to I/R$ is the quotient map,

$$f \circ g \left(\left[0, \frac{\theta_2}{2\pi}\right) \cup \left(1 - \frac{\theta_1}{2\pi}, 1\right] \right)$$

contains P and is contained in U'. Furthermore, by definition, $g([0,\theta_2/2\pi) \cup (1 - \theta_1/2\pi, 1])$ is open in I/R since $[0,\theta_2/2\pi) \cup (1 - \theta_1/2\pi, 1]$ is open in the subset topology of $[0,1]$. By Proposition A.2.29, f is continuous.

Using a similar argument, it is not hard to show that f^{-1} is continuous, concluding that I/R is homeomorphic to $\mathbb{S}^1$.

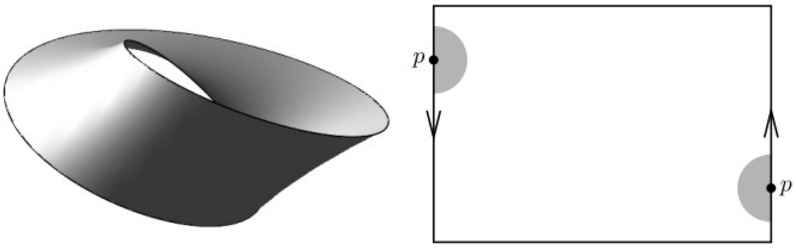

Figure A.10: Möbius strip.

Example A.2.47. Consider the real projective space $\mathbb{RP}^n$ given as the quotient space $\mathbb{S}^n/\sim$ where $\sim$ is the equivalence relation on $\mathbb{S}^n$ where $p_1 \sim p_2$ if and only if they are antipodal to each other, i.e., form a diameter of the sphere. The unit sphere $\mathbb{S}^n$ naturally inherits the subspace topology from $\mathbb{R}^{n+1}$. Definition A.2.44 provides the induced topology for $\mathbb{RP}^n$.

Example A.2.48 (Möbius Strip)**.** Let $I = [0,1] \times [0,1]$ be the unit square with the topology induced from $\mathbb{R}^n$. Define the identification (equivalence relation $\sim$) between points by $(0,y) \sim (1,1-y)$, for all $y \in [0,1]$ and no other points are equivalent to any others. The topological space obtained is called the *Möbius strip*. In $\mathbb{R}^3$, the Möbius strip can be viewed as a strip of paper twisted once and with ends glued together. Figure A.10 shows an embedding of the Möbius strip in $\mathbb{R}^3$, as well as a diagrammatic representation of the Möbius strip. In the diagrammatic representation, the arrows indicate that the opposite edges are identified but in inverse direction. The shaded area shows a disk around a point p on the identified edge.

A.2.4 Compactness

In any calculus course, we encounter the Extreme Value Theorem, a result in analysis that forms an essential ingredient to Rolle's Theorem, hence the Mean Value Theorem, and therefore the Fundamental Theorem of Calculus.

Theorem A.2.49 (Extreme Value Theorem)**.** *Let $f : [a,b] \to \mathbb{R}$ be a continuous real-valued function. Then f attains a maximum and a minimum over the interval $[a,b]$.*

As topology developed, a variety of attempts were made to generalize the idea contained in this fact. In the context of metric spaces, the key properties that would allow for a generalization are that the interval $[a,b]$ is closed and bounded. Though closed is a concept in topology, the notion of being bounded does not have an equivalent notion. It turns out that in topological spaces, the notion of *compactness* provides this desired generalization.

2> > 6

Definition A.2.50. Let (X, τ) be a topological space. Let $\mathcal{U} = \{U_i\}_{i \in I}$ be a collection of open sets in X. We call $\mathcal{U}$ an *open cover* of X if

$$X = \bigcup_{i \in I} U_i.$$

If $J \subset I$, the collection $\mathcal{V} = \{V_j\}_{j \in J}$ is called a *subcover* of $\mathcal{U}$ if $\mathcal{V}$ is itself an open cover of X.

Definition A.2.51. A topological space (X, τ) is called *compact* if every open cover of X has a finite subcover.

Remark A.2.52. A subset A of X is called compact if it is compact when equipped with the subspace topology induced from (X, τ). This is equivalent to the property that whenever there exists a collection of $\mathcal{U} = \{U_i\}_{i \in I}$ of open sets with $A \subset \bigcup_{i \in I} U_i$, there exists a finite subset $J \subset I$ with $A \subset \bigcup_{i \in J} U_j$.

Some examples of compact spaces are obvious, such as that any finite subset of a topological space is compact. However, the following theorem justifies, at least in part, the given definition of compactness.

Theorem A.2.53 (Heine-Borel)**.** *A closed and bounded interval* $[a, b]$ *of* $\mathbb{R}$ *is compact.*

Proof. (A variety of proofs exist for the Heine-Borel Theorem. The following proof is called the "creeping along" proof.)

Let $\mathcal{U} = \{U_\alpha\}_{\alpha \in I}$ be an open cover of $[a, b]$. Define the subset of $[a, b]$ by

$$E = \{x \in [a, b] \mid [a, x] \text{ is contained in a finite subfamily of } \mathcal{U}\}.$$

Obviously, E is an interval, but a priori we do not know whether it is open or closed or even nonempty. We will show that $b \in E$ to establish the theorem.

Now $a \in E$ because there exists some U_{α_0} such that $a \in U_{\alpha_0}$. Let $c = \text{lub } E$. Clearly $a \leq c \leq b$. Suppose that $c < b$. Since $\mathcal{U}$ covers $[a, b]$, there exists some index β such that $c \in U_\beta$, and therefore there exists ε such that $(c - \varepsilon, c + \varepsilon) \subset U_\beta$. Since c is the least upper bound of E, any $x \in (c - \varepsilon, c)$ is in E. Therefore, there exists a finite set $\{\alpha_1, \alpha_2, \ldots, \alpha_n\}$ such that

$$[a, x] \subset \bigcup_{i=1}^{n} U_{\alpha_i}.$$

But then the finite union of open sets

$$(c - \varepsilon, c + \varepsilon) \cup \bigcup_{i=1}^{n} U_{\alpha_i}$$

contains the point $c + \varepsilon/2$, contradicting the assumption that $c < b$ and $c = \text{lub } E$. Thus $c = b$, and $b \in E$. $\square$

Compactness is an important property of topological spaces, and we refer the reader to Chapter 3 in [2], Section 6.6 in [15], or Chapter 7 in [27] for complete treatments. For the purposes of this book however, we are primarily interested in two results, namely Theorem A.2.57 and Theorem A.2.58, and a few necessary propositions to establish them. We will not prove Theorem A.2.57 completely but again refer the reader to the above sources.

Proposition A.2.54. *Let (X, τ) be a topological space, and let K be a compact subset of X. Every closed subset of K is compact.*

Proof. Let $F \subset K$ be a closed set. Then $X - F$ is open. If $\mathcal{U}$ is an open cover of F, then $\mathcal{U} \cup \{X - F\}$ is an open cover of K. Since K is compact, $\mathcal{U} \cup \{X - F\}$ must admit a finite subcover of K. This finite subcover of K is of the form $\mathcal{U}' \cup \{X - F\}$, where $\mathcal{U}'$ is a finite subcover of $\mathcal{U}$ of F. Thus, F is compact. □

Problem A.1.19 established the fact that two distinct points p_1 and p_2 in a metric space possess, respectively, open neighborhoods U_1 and U_2 such that $U_1 \cap U_2 = \emptyset$. This type of property is called a *separation* property of a topological space because it gives some qualification for how much we can distinguish points in the topological space. There exists a variety of separation axioms, but we only present the one that is relevant for differential geometry.

Definition A.2.55. A topological space (X, τ) is called *Hausdorff* if given any two points p_1 and p_2 in X, there exist open neighborhoods U_1 of p_1 and U_2 of p_2 such that $U_1 \cap U_2 = \emptyset$.

Proposition A.2.56. *If (X, τ) is a Hausdorff topological space, then every compact subset K of X is closed.*

Proof. Let K be compact. Since X is Hausdorff, for every $x \in X - K$ and $y \in K$, there exist open sets U_{xy} and V_{xy}, with $x \in U_{xy}$ and $y \in V_{xy}$, such that $U_{xy} \cap V_{xy} = \emptyset$. For each $x \in X - K$,

$$\{V_{xy} \mid y \in K\}$$

is an open cover of K, so it must possess a finite subcover that we index with a finite number of points $y_1, y_2, \dots, y_n$. But then for each x,

$$U_x = \bigcap_{i=1}^{n} U_{xy_i}$$

is open since it is a finite intersection of open sets. Since $K \subset \bigcup_{i=1}^{n} V_{xy_i}$, we conclude that $K \cap U_x = \emptyset$ for all $x \in X - K$. Thus, $X - K$ is a neighborhood of all of its points and hence it is open. Thus, K is closed. □

Theorem A.2.57. *Let A be any subset of $\mathbb{R}^n$ (equipped with the Euclidean topology). The set A is compact if and only if it is closed and bounded.*

Proof. (We only prove $\Longrightarrow$.)

Suppose that A is compact. Since by Problem A.1.19 any metric space is Hausdorff, Proposition A.2.56 allows us to conclude that A is closed. Since every open set in a metric space is the union of open balls, any open cover of A can be viewed as an open cover of open balls. If A is compact, it is contained in only a finite number of such open balls $\{B_{r_i}(p_i)\}_{i=1}^{m}$. There exists an open ball $B_r(p)$ that contains all the $B_{r_i}(p_i)$. The radius r will be less than $(m-1)\max\{d(p_i,p_j)\}+2\max\{r_i\}$. Then $K \subset B_r(P)$, and hence, K is bounded.

(The proof of the converse is more difficult and uses other techniques that we do not have the time to develop here.) $\square$

Theorem A.2.57 establishes that we might view closed and bounded subsets of $\mathbb{R}^n$ as the topological analog to $[a,b] \subset \mathbb{R}$ in Theorem A.2.49. We now complete the generalization to topological spaces.

Theorem A.2.58. *Let $f : X \to Y$ be a continuous function between topological spaces X and Y. If X is a compact space, then $f(X)$ is compact in Y.*

Proof. Let $\mathcal{U}$ be an open cover of $f(X)$. Since f is continuous, each $f^{-1}(U)$ is open and the collection $\{f^{-1}(U) \mid U \in \mathcal{U}\}$ is an open cover of X. Since X is compact, there exists a finite set $\{U_1, U_2, \ldots, U_n\} \subset \mathcal{U}$ such that

$$X = \bigcup_{i=1}^{n} f^{-1}(U_i).$$

Since for any functions $f(f^{-1}(A)) \subset A$ always and $f(\bigcup_\lambda A_\lambda) = \bigcup_\lambda f(A_\lambda)$, then

$$f(X) = f\Big(\bigcup_{i=1}^{n} f^{-1}(U_i)\Big) = \bigcup_{i=1}^{n} f(f^{-1}(U_i)) \subset \bigcup_{i=1}^{n} U_i\,.$$

Thus, $f(X)$ is compact. $\square$

Corollary A.2.59. *Let X be a compact topological space, and let $f : X \to \mathbb{R}$ be a real-valued function from X. Then f attains both a maximum and a minimum.*

Proof. By Theorem A.2.58, the image $f(X)$ is compact. By Theorem A.2.57, $f(X)$ is a closed and bounded subset of $\mathbb{R}$. Hence, lub $\{f(x) \mid x \in X\}$ and glb $\{f(x) \mid x \in X\}$ are both elements of $f(X)$ and hence are the maximum and minimum of f over X. $\square$

Corollary A.2.60. *Let (X,τ) and (Y,τ') be topological spaces, and let $f : X \to Y$ be a continuous function onto Y. If X is compact, then so is Y.*

Corollary A.2.61. *Let X be a compact topological space. If a space Y is homeomorphic to X, then Y is compact.*

8 Curvature I: The Riemann Curvature Tensor

8.1 Curvature: Preliminary Remarks

We now come to one of the most important concepts of General Relativity and Riemannian Geometry, that of curvature and how to describe it in tensorial terms. Among other things, this will finally allow us to decide unambiguously if a given metric is just the (flat) Minkowski metric in disguise or the metric of a genuinely curved space (but a proof of this statement is postponed to section 11). More importantly (for present purposes) it will allow us to construct tensors that depend on the 2nd derivatives of the metric and will thus allow us to construct tensorial (generally covariant) differential equations for the metric. In particular, this will then lead us fairly directly to the Einstein equations (section 19), i.e. to the field equations for the gravitational field.

Recall that the equations that describe the behaviour of particles and fields in a gravitational field involve the metric and the Christoffel symbols determined by the metric. Thus the equations for the gravitational field should be generally covariant (tensorial) differential equations for the metric.

At first, here we seem to face a dilemma. How can we write down covariant differential equations for the metric when the covariant derivative of the metric is identically zero? Having come to this point, Einstein himself reached an impasse and required the help of his mathematician friend Marcel Grossmann ("Grossmann, you have to help me, or else I'll go crazy!") whom he had asked to investigate if there were any tensors that could be built from the second derivatives of the metric.

Grossmann soon found that this problem had indeed been addressed and solved in the mathematics literature, in particular by Riemann (generalising work of Gauss on curved surfaces), Ricci-Curbastro and Levi-Civita. It was shown by them that there are indeed non-trivial tensors that can be constructed from (ordinary) derivatives of the metric. These can then be used to write down covariant differential equations for the metric.[18]

The most important among these are the Riemann curvature tensor and its various contractions. In fact, it is known that these are the only tensors that can be constructed from the metric and its first and second derivatives, and they will therefore play a central role in all that follows.

Technically the most straightforward way of introducing the Riemann curvature tensor is via the commutator of covariant derivatives. In this section we will adopt this pragmatic (and relatively streamlined) approach, as it is sufficient to

---

[18] Of course, the story is not as simple and straightforward as that. For an account of Marcel Grossmann's (often overlooked) contributions to tensor calculus and the development of general relativity, see T. Sauer, *Marcel Grossmann and his contribution to the general theory of relativity*, `arXiv:1312.4068 [physics.hist-ph]`.

- determine the most important algebraic and differential properties of the curvature tensor (symmetries and Bianchi identities)
- assess its physical significance (gravitational tidal forces) via the influence of the curvature tensor on the motion of (families of) freely falling particles
- and to thus provide us with all the information and ingredients we need to then discuss the Einstein equations (section 19) and their formulation in terms of an action principle (section 20).

However, this is not geometrically the most intuitive way to introduce the concept of curvature, and it downplays the extent to which the curvature tensor reflects and encodes the geometric properties of space-time and, more generally, does not do justice to the fundamental differential geometric notion and significance of curvature. Some of these aspects are discussed in Part B of these notes, in particular in sections 11, 12, 13 and 14.

8.2 RIEMANN TENSOR FROM THE COMMUTATOR OF COVARIANT DERIVATIVES

As mentioned before, second covariant derivatives do not commute on (p,q)-tensors unless $p=q=0$. However, the fact that they *do* commute on scalars has the pleasant consequence that e.g. the commutator of covariant derivatives acting on a vector field V^μ does not involve any derivatives of V^μ. In fact, I will first show, without actually calculating the commutator, that

$$[\nabla_\mu, \nabla_\nu](\phi V^\lambda) = \phi[\nabla_\mu, \nabla_\nu]V^\lambda \tag{8.1}$$

for any scalar field ϕ. This implies that $[\nabla_\mu, \nabla_\nu]V^\lambda$ cannot depend on derivatives of V because if it did it would also have to depend on derivatives of ϕ.

Hence, the commutator can be expressed purely algebraically in terms of V. As the dependence on V is clearly linear, the commutator of covariant derivatives must then act like a linear transformation. There must therefore be an object $R^\lambda_{\ \sigma\mu\nu}$ such that

$$[\nabla_\mu, \nabla_\nu]V^\lambda = R^\lambda_{\ \sigma\mu\nu}V^\sigma \quad . \tag{8.2}$$

This can of course also be verified by a direct calculation, and we will come back to this below. For now let us just note that, since the left hand side of this equation is clearly a tensor for any V, the quotient theorem implies that the quantities $R^\lambda_{\ \sigma\mu\nu}$ are the components of a tensor.

Let us first verify (8.1). We have

$$\nabla_\mu\nabla_\nu\phi V^\lambda = (\nabla_\mu\nabla_\nu\phi)V^\lambda + (\nabla_\nu\phi)(\nabla_\mu V^\lambda) + (\nabla_\mu\phi)(\nabla_\nu V^\lambda) + \phi\nabla_\mu\nabla_\nu V^\lambda \quad . \tag{8.3}$$

Thus, upon taking the commutator the 2nd and 3rd terms drop out (because the 3rd is the symmetrisation of the 2nd), and we are left with

$$\begin{aligned}[\nabla_\mu, \nabla_\nu]\phi V^\lambda &= ([\nabla_\mu, \nabla_\nu]\phi)V^\lambda + \phi[\nabla_\mu, \nabla_\nu]V^\lambda \\ &= \phi[\nabla_\mu, \nabla_\nu]V^\lambda \ , \end{aligned} \tag{8.4}$$

where the last line follows from the fact that 2nd covariant derivatives do commute on scalars. Thus we have established (8.1).

By explicitly calculating the commutator, one can confirm the structure displayed in (8.2). This explicit calculation shows that the *Riemann-Christoffel Curvature Tensor* (or Riemann tensor for short) is given by

$$\boxed{R^\lambda_{\ \sigma\mu\nu} = \partial_\mu \Gamma^\lambda_{\ \sigma\nu} - \partial_\nu \Gamma^\lambda_{\ \sigma\mu} + \Gamma^\lambda_{\ \mu\rho}\Gamma^\rho_{\ \nu\sigma} - \Gamma^\lambda_{\ \nu\rho}\Gamma^\rho_{\ \mu\sigma}} \tag{8.5}$$

REMARKS:

1. Note how useful the quotient theorem is in this case. It would be quite unpleasant to have to verify the tensorial nature of this expression by explicitly checking its behaviour under coordinate transformations.
2. Note also that this tensor is clearly zero for the Minkowski metric written in Cartesian coordinates. Hence it is also zero for the Minkowski metric written in any other coordinate system. We will prove the converse, that vanishing of the Riemann curvature tensor implies that the metric is (locally) equivalent to the Minkowski metric, in section 11.2.
3. In the above we have defined the Riemann tensor by the relation (8.2) and then deduced the explicit expression (8.5). While this is, pragmatically speaking, a useful way of proceeding, it may be more logical to initially define the Riemann tensor in a different way, e.g. directly by (8.5) (for instance because by painful calculations one has discovered that this particular combination of non-tensorial objects miraculously happens to transform as a tensor). In that case, (8.2) is a result rather than a definition, known as the *Ricci identity.*

It is straightforward to extend the above to an action of the commutator $[\nabla_\mu, \nabla_\nu]$ on arbitrary tensors. For covectors we have, since we can raise and lower the indices with the metric with impunity,

$$\begin{aligned}[\nabla_\mu, \nabla_\nu]V_\rho &= g_{\rho\lambda}[\nabla_\mu, \nabla_\nu]V^\lambda \\ &= g_{\rho\lambda}R^\lambda_{\ \sigma\mu\nu}V^\sigma \\ &= R_{\rho\sigma\mu\nu}V^\sigma \\ &= R_\rho^{\ \sigma}{}_{\mu\nu}V_\sigma \ . \end{aligned} \tag{8.6}$$

We will see later that the Riemann tensor is anti-symmetric in its first two indices. Hence we can also write

$$[\nabla_\mu, \nabla_\nu] V_\rho = -R^\sigma_{\ \rho\mu\nu} V_\sigma \quad . \tag{8.7}$$

The extension to arbitrary (p, q)-tensors now follows the usual pattern, with one Riemann curvature tensor, contracted as for vectors, appearing for each of the p upper indices, and one Riemann curvature tensor, contracted as for covectors, for each of the q lower indices. Thus, e.g. for a $(2, 0)$-tensor $T^{\alpha\beta}$ one has

$$[\nabla_\mu, \nabla_\nu] T^{\alpha\beta} = R^\alpha_{\ \gamma\mu\nu} T^{\gamma\beta} + R^\beta_{\ \gamma\mu\nu} T^{\alpha\gamma} \tag{8.8}$$

and for a (1,1)-tensor $A^\lambda_{\ \rho}$ one has

$$[\nabla_\mu, \nabla_\nu] A^\lambda_{\ \rho} = R^\lambda_{\ \sigma\mu\nu} A^\sigma_{\ \rho} - R^\sigma_{\ \rho\mu\nu} A^\lambda_{\ \sigma} \quad . \tag{8.9}$$

I will give two other versions of the fundamental formula (8.2) which are occasionally useful and used.

1. Instead of looking at the commutator $[\nabla_\mu, \nabla_\nu]$ of two derivatives in the coordinate directions x^μ and x^ν, we can look at the commutator $[\nabla_X, \nabla_Y]$ of two directional covariant derivatives. Evidently, in calculating this commutator one will pick up new terms involving $\nabla_X Y^\mu - \nabla_Y X^\mu$. Denoting this vector field by $[X, Y[^\mu$ (the rationale for this notation will be explained in section 9.3), we can also write the formula for the curvature tensor as

$$([\nabla_X, \nabla_Y] - \nabla_{[X,Y]}) V^\lambda = R^\lambda_{\ \sigma\mu\nu} X^\mu Y^\nu V^\sigma \quad . \tag{8.10}$$

2. Secondly, one can consider a net of curves $x^\mu(s_1, s_2)$ parametrising, say, a two-dimensional surface, and look at the commutators of the covariant derivatives along the s_1- and s_2-curves. The formula one obtains in this case (it can be obtained from (8.10) by noting that X and Y commute in this case) is

$$(D_{s_1} D_{s_2} - D_{s_2} D_{s_1}) V^\lambda = R^\lambda_{\ \sigma\mu\nu} \frac{dx^\mu}{ds_1} \frac{dx^\nu}{ds_2} V^\sigma \quad , \tag{8.11}$$

where D_{s_k} denotes the covariant derivative along the curve parametrised by s_k, i.e. (section 5.7)

$$D_{s_k} = \frac{\partial x^\mu(s_1, s_2)}{\partial s_k} \nabla_\mu \quad . \tag{8.12}$$

8.3 SYMMETRIES AND ALGEBRAIC PROPERTIES OF THE RIEMANN TENSOR

A priori, the Riemann tensor has $256 = 4^4$ components in 4 dimensions. However, because of a large number of symmetries, the actual number of independent components is much smaller.

In general, to read off all the symmetries from the formula (8.5) is difficult. One way to simplify things is to look at the Riemann curvature tensor at the origin x_0 of a Riemann normal coordinate system (or some other inertial coordinate system). In that case, all the first derivatives of the metric disappear and only the first two terms of (8.5) contribute. One finds

$$\begin{aligned} R_{\alpha\beta\gamma\delta}(x_0) &= g_{\alpha\lambda}(\partial_\gamma \Gamma^\lambda_{\beta\delta} - \partial_\delta \Gamma^\lambda_{\beta\gamma})(x_0) \\ &= (\partial_\gamma \Gamma_{\alpha\beta\delta} - \partial_\delta \Gamma_{\alpha\beta\gamma})(x_0) \\ &= \tfrac{1}{2}(g_{\alpha\delta,\beta\gamma} + g_{\beta\gamma,\alpha\delta} - g_{\alpha\gamma,\beta\delta} - g_{\beta\delta,\alpha\gamma})(x_0) \ . \end{aligned} \tag{8.13}$$

In principle, this expression is sufficiently simple to allow one to read off all the symmetries of the Riemann tensor. However, it is more insightful to derive these symmetries in a different way, one which will also make clear *why* the Riemann tensor has these symmetries.

1. Anti-symmetry in the second pair of indices:

   $$R_{\alpha\beta\gamma\delta} = -R_{\alpha\beta\delta\gamma} \tag{8.14}$$

   This is obviously true from the definition or by construction.

2. Anti-symmetry in the first pair of indices:

   $$R_{\alpha\beta\gamma\delta} = -R_{\beta\alpha\gamma\delta} \tag{8.15}$$

   This is a consequence of the fact that the metric is covariantly constant. In fact, we can calculate

   $$\begin{aligned} 0 &= [\nabla_\gamma, \nabla_\delta] g_{\alpha\beta} \\ &= R_\alpha{}^\lambda{}_{\gamma\delta} g_{\lambda\beta} + R_\beta{}^\lambda{}_{\gamma\delta} g_{\alpha\lambda} \\ &= (R_{\alpha\beta\gamma\delta} + R_{\beta\alpha\gamma\delta}) \ . \end{aligned} \tag{8.16}$$

   As mentioned before, this implies that we can write the commutator of covariant derivatives on a covector as

   $$[\nabla_\mu, \nabla_\nu] V_\rho = R_\rho{}^\sigma{}_{\mu\nu} V_\sigma = -R^\sigma{}_{\rho\mu\nu} V_\sigma \ . \tag{8.17}$$

3. Cyclic permutation symmetry (or first Bianchi identity)

   $$R_{\alpha[\beta\gamma\delta]} = 0 \quad \Leftrightarrow \quad R_{\alpha\beta\gamma\delta} + R_{\alpha\delta\beta\gamma} + R_{\alpha\gamma\delta\beta} = 0 \tag{8.18}$$

   This Bianchi identity is a consequence of the fact that there is no torsion. In fact, applying $[\nabla_\gamma, \nabla_\delta]$ to the covector $\nabla_\beta \phi$, ϕ a scalar, one has

   $$\nabla_{[\gamma} \nabla_\delta \nabla_{\beta]} \phi = 0 \quad \Rightarrow \quad R^\lambda{}_{[\beta\gamma\delta]} \nabla_\lambda \phi = 0 \ . \tag{8.19}$$

As this has to be true for all scalars ϕ, this implies $R_{\alpha[\beta\gamma\delta]} = 0$ (to see this you could e.g. choose the (locally defined) coordinate functions $\phi(x) = x^\mu$ with $\nabla_\lambda \phi = \delta^\mu_{\ \lambda}$).

In turn this identity now implies that for any covector (not necessarily a gradient) one has the identity (also called Bianchi identity)

$$\nabla_{[\gamma}\nabla_\delta V_{\beta]} = -R^\alpha_{\ [\beta\gamma\delta]} V_\alpha = 0 \ . \tag{8.20}$$

4. Symmetry under exchange of the two pairs of indices

$$R_{\alpha\beta\gamma\delta} = R_{\gamma\delta\alpha\beta} \tag{8.21}$$

This identity, stating that the Riemann tensor is symmetric in its two pairs of indices, is not an independent symmetry but can be deduced from the three other symmetries by some not particularly interesting algebraic manipulations. One (quite possibly not optimal or minimal) possibility is

$$\begin{aligned} R_{\gamma\delta\alpha\beta} &\overset{(3)}{=} -R_{\gamma\alpha\beta\delta} - R_{\gamma\beta\delta\alpha} \\ &\overset{(2)}{=} R_{\alpha\gamma\beta\delta} + R_{\beta\gamma\delta\alpha} \\ &\overset{(3)}{=} -R_{\alpha\delta\gamma\beta} - R_{\alpha\beta\delta\gamma} - R_{\beta\alpha\gamma\delta} - R_{\beta\delta\alpha\gamma} \\ &\overset{(1,2)}{=} 2R_{\alpha\beta\gamma\delta} + R_{\delta\alpha\gamma\beta} R_{\delta\beta\alpha\gamma} \\ &\overset{(3)}{=} 2R_{\alpha\beta\gamma\delta} - R_{\delta\gamma\beta\alpha} \\ &\overset{(1,2)}{=} 2R_{\alpha\beta\gamma\delta} - R_{\gamma\delta\alpha\beta} \ , \end{aligned} \tag{8.22}$$

from which the claim follows.

Slightly more elegant (but equally obtuse) is the following argument.[19] Consider the matrix

$$\mathcal{R} = \begin{pmatrix} R_{\alpha\beta\gamma\delta} & R_{\alpha\delta\beta\gamma} & R_{\alpha\gamma\delta\beta} \\ R_{\delta\alpha\beta\gamma} & R_{\delta\gamma\alpha\beta} & R_{\delta\beta\gamma\alpha} \\ \vdots & \dots & \dots \end{pmatrix} \tag{8.23}$$

where the first column consists of the 4 cyclic permutations of all 4 indices of the Riemann tensor, while each row consists of the 3 cyclic permutations of the last 3 indices. Thus the sum σ_k of the entries of the k'th row is zero for all k (by symmetry (3)),

$$\sigma_k = \sum_{l=1}^{3} \mathcal{R}_{kl} \overset{(3)}{=} 0 \ , \tag{8.24}$$

while

$$\sigma_1 + \sigma_2 - \sigma_3 - \sigma_4 \overset{(1,2)}{=} 2R_{\alpha\beta\gamma\delta} - 2R_{\gamma\delta\alpha\beta} \ . \tag{8.25}$$

---

[19] See e.g. D. Bleecker, *Gauge Theory and Variational Principles.*

We can now count how many independent components the Riemann tensor really has. (1) implies that the second pair of indices can only take $N = (4 \times 3)/2 = 6$ independent values. (2) implies the same for the first pair of indices. (4) thus says that the Riemann curvature tensor behaves like a symmetric (6×6) matrix and therefore has $(6 \times 7)/2 = 21$ components. We now come to the remaining condition (3): if two of the indices in (3) are equal, (3) is equivalent to (4) and (4) we have already taken into account. With all indices unequal, (3) then provides one and only one more additional constraint. We conclude that the total number of independent components is 20.

Remarks:

1. Note that this agrees precisely with our previous counting in section 3.6 of how many of the second derivatives of the metric cannot be set to zero by a coordinate transformation: the second derivative of the metric has 100 independent components, to be compared with the $4 \times (4 \times 5 \times 6)/(2 \times 3) = 80$ components of the third derivatives of the coordinates. This also leaves 20 components. We thus see very explicitly that the Riemann curvature tensor contains all the coordinate independent information about the geometry up to second derivatives of the metric. In fact, it can be shown that in a Riemann normal coordinate system one has

$$g_{\mu\nu}(x) = \eta_{\mu\nu} + 0 + \tfrac{1}{3} R_{\mu\lambda\sigma\nu}(x_0)(x - x_0)^\lambda (x - x_0)^\sigma + \mathcal{O}((x - x_0)^3) \ . \qquad (8.26)$$

2. Just for the record, I note here that in general dimension $D = d + 1$ the Riemann tensor has $D^2(D^2 - 1)/12$ independent components. This number arises as

$$\begin{aligned} \frac{D^2(D^2-1)}{12} &= \frac{N(N+1)}{2} - \binom{D}{4} \\ N &= \frac{D(D-1)}{2} \end{aligned} \qquad (8.27)$$

and describes (as above) the number of independent components of a symmetric $(N \times N)$-matrix, now subject to $\binom{D}{4}$ conditions which arise from all the possibilities of choosing 4 out of D possible distinct values for the indices in (3). Just as for $D = 4$, this number of components of the Riemann tensor coincides with the number of second derivatives of the metric minus the number of independent components of the third derivatives of the coordinates determined in (3.176),

$$\frac{D(D+1)}{2} \times \frac{D(D+1)}{2} - D \times \frac{D(D+1)(D+2)}{2 \times 3} = \frac{D^2(D^2-1)}{12} \ . \qquad (8.28)$$

For $D = 2$ this formula predicts one independent component, and this is as it should be. Rather obviously the only independent non-vanishing component of the Riemann tensor in this case is R_{1212}. We will discuss curvature in 2 dimensions in more detail in sections 8.6 and 11.3 below.

Finally, a word of warning: there are a large number of sign conventions involved in the definition of the Riemann tensor (and its contractions we will discuss below), so whenever reading a book or article, in particular when you want to use results or equations presented there, make sure what conventions are being used and either adopt those or translate the results into some other convention. As a check: the conventions used here are such that $R_{\phi\theta\phi\theta}$ as well as the curvature scalar (to be introduced below) are *positive* for the standard metric on the two-sphere.

8.4 TIDAL FORCES: INFLUENCE OF CURVATURE ON PARTICLE TRAJECTORIES

In a certain sense the main effect of curvature (or gravity) is that initially parallel trajectories of freely falling non-interacting particles (dust, pebbles,…) do not remain parallel, i.e. that gravity is an attractive force that has the tendency to focus matter. This statement find its mathematically precise formulation in equations describing the influence of space-time curvature on the behaviour of (families of) geodesics.

Let us, as we will need this later anyway, recall first the situation in the Newtonian theory. One particle moving under the influence of a gravitational field is governed by the equation

$$\tfrac{d^2}{dt^2}x^i = -\partial^i\phi(x) \ , \tag{8.29}$$

where ϕ is the potential. Now consider a family of particles, or just two nearby particles, one at $x^i(t)$ and the other at $x^i(t)+\delta x^i(t)$. The other particle will of course obey the equation

$$\tfrac{d^2}{dt^2}(x^i+\delta x^i) = -\partial^i\phi(x+\delta x) \ . \tag{8.30}$$

From these two equations one can deduce an equation for δx itself, namely

$$\tfrac{d^2}{dt^2}\delta x^i = -\partial^i\partial_j\phi(x)\delta x^j \ . \tag{8.31}$$

It describes the effect of *gravitational tidal forces* (the gradient of the gravitational force) on a family of particles moving in a gravitational field.

In particular, when there is no gravitational force, and the trajectories are straight lines, one has

$$\tfrac{d^2}{dt^2}\delta x^i = 0 \quad \Rightarrow \quad \delta x^i = (\delta x^i)_0 + (\delta v^i)t \ . \tag{8.32}$$

Thus one recovers Euclid's parallel axiom, that two straight lines intersect at most once (for suitable choices of $\delta v^i \neq 0$) and that they never intersect when they are initially parallel ($\delta v^i = 0$). Any departure from this equation or its Minkowskian counterpart

$$\tfrac{d^2}{d\tau^2}\delta\xi^a = 0 \ , \tag{8.33}$$

will therefore indicate a departure from Euclidean geometry!

It is the counterpart of (8.31) that we will be seeking in the context of General Relativity. One derivation of this can be modelled on the Newtonian derivation above. It is elementary but looks non-covariant (and therefore somewhat messy) at intermediate stages of the calculation (see section 12.1 for a manifestly covariant derivation).

The starting point is of course the geodesic equation for x^μ and for its nearby partner $x^\mu + \delta x^\mu$,

$$\tfrac{d^2}{d\tau^2}x^\mu + \Gamma^\mu_{\ \nu\lambda}(x)\tfrac{d}{d\tau}x^\nu\tfrac{d}{d\tau}x^\lambda = 0 \ , \tag{8.34}$$

and

$$\tfrac{d^2}{d\tau^2}(x^\mu + \delta x^\mu) + \Gamma^\mu_{\ \nu\lambda}(x+\delta x)\tfrac{d}{d\tau}(x^\nu + \delta x^\nu)\tfrac{d}{d\tau}(x^\lambda + \delta x^\lambda) = 0 \ . \tag{8.35}$$

As above, from these one can deduce an equation for δx, namely

$$\tfrac{d^2}{d\tau^2}\delta x^\mu + 2\Gamma^\mu_{\ \nu\lambda}(x)\tfrac{d}{d\tau}x^\nu\tfrac{d}{d\tau}\delta x^\lambda + \partial_\rho\Gamma^\mu_{\ \nu\lambda}(x)\delta x^\rho\tfrac{d}{d\tau}x^\nu\tfrac{d}{d\tau}x^\lambda = 0 \ . \tag{8.36}$$

Now this does not look particularly covariant. Thus instead of in terms of $d/d\tau$ we would like to rewrite this in terms of the covariant operator D_τ, with

$$D_\tau \delta x^\mu = \frac{d}{d\tau}\delta x^\mu + \Gamma^\mu_{\ \nu\lambda}\frac{dx^\nu}{d\tau}\delta x^\lambda \ . \tag{8.37}$$

Calculating $(D_\tau)^2\delta x^\mu$, replacing $\ddot{x}^\mu$ appearing in that expression by $-\Gamma^\mu_{\ \nu\lambda}\dot{x}^\nu\dot{x}^\lambda$ (because x^μ satisfies the geodesic equation) and using (8.36), one eventually finds the nice covariant *geodesic deviation equation*

$$(D_\tau)^2\delta x^\mu = R^\mu_{\ \nu\lambda\rho}\dot{x}^\nu\dot{x}^\lambda\delta x^\rho \tag{8.38}$$

REMARKS:

1. This shows very clearly that curvature, as captured by the Riemann curvature tensor, leads to non-Euclidean geometry in which e.g. the parallel axiom is not necessarily satisifed.

2. In general, solutions to the geodesic deviation equation are called *Jacobi fields*. They describe the difference between the given geodesic and a (hypothetical) infinitely close neighbouring geodesic.

3. Clearly the present derivation of this result leaves something to be desired. It is also possible to give a manifestly covariant, and thus perhaps slightly more satisfactory, derivation of the above geodesic deviation equation, and we will return to this in section 12.1.

The Riemann tensor, as we have seen, is a four-index tensor. For many purposes this is not the most useful object, but we can create new tensors by contractions of the Riemann tensor. Due to the symmetries of the Riemann tensor, there is essentially only one possibility, namely the *Ricci tensor*

$$R_{\mu\nu} := R^{\lambda}_{\ \mu\lambda\nu} = g^{\lambda\sigma} R_{\sigma\mu\lambda\nu} \quad . \tag{8.39}$$

It arises naturally from the definition (8.2) of the Riemann tensor in terms of commutators of covariant derivatives, when one considers a contracted commutator,

$$[\nabla_\mu, \nabla_\nu] V^\lambda = R^{\lambda}_{\ \sigma\mu\nu} V^\sigma \quad \Rightarrow \quad [\nabla_\mu, \nabla_\nu] V^\mu = R^{\mu}_{\ \sigma\mu\nu} V^\sigma \equiv R_{\sigma\nu} V^\sigma \quad . \tag{8.40}$$

In particular, this identity explains why the Maxwell equations in the covariant Lorenz gauge (6.45) take the non-minimally coupled form (6.46).

It follows from the symmetries of the Riemann tensor that $R_{\mu\nu}$ is symmetric. Indeed

$$R_{\nu\mu} = g^{\lambda\sigma} R_{\sigma\nu\lambda\mu} = g^{\lambda\sigma} R_{\lambda\mu\sigma\nu} = R^{\sigma}_{\ \mu\sigma\nu} = R_{\mu\nu} \quad . \tag{8.41}$$

Thus, for $D = 4$, the Ricci tensor has 10 independent components, for $D = 3$ it has 6, while for $D = 2$ there is only 1 because there is only one independent component of the Riemann curvature tensor to start off with.

There is one more contraction of the Riemann tensor we can perform, namely on the Ricci tensor itself, to obtain what is called the *Ricci scalar* or *curvature scalar*

$$R := g^{\mu\nu} R_{\mu\nu} \quad . \tag{8.42}$$

REMARKS:

1. One might have thought that at least in four dimensions there is another way of constructing a (pseudo-)scalar, by contracting the Riemann tensor with the Levi-Civita tensor, but
$$\epsilon^{\mu\nu\rho\sigma} R_{\mu\nu\rho\sigma} = 0 \tag{8.43}$$
because of the Bianchi identity (cyclic symmetry of the Riemann tensor).

2. Note that for $D = 2$ the Riemann curvature tensor has as many independent components as the Ricci scalar, namely one, and that for $D = 3$ the Ricci tensor has as many components as the Riemann tensor, namely 6. Thus in $D = 2$ one can express the entire Riemann tensor in terms of the Ricci scalar (and the metric) alone, and one has
$$D = 2: \quad R_{\alpha\beta\gamma\delta} = \tfrac{1}{2}(g_{\alpha\gamma} g_{\beta\delta} - g_{\alpha\delta} g_{\beta\gamma}) R \tag{8.44}$$

(we will establish this relation in section 11.3, see (11.29)), while in $D = 3$ one has

$$D = 3: \quad \begin{aligned} R_{\alpha\beta\gamma\delta} = &(g_{\alpha\gamma}R_{\beta\delta} + R_{\alpha\gamma}g_{\beta\delta} - g_{\alpha\delta}R_{\beta\gamma} - R_{\alpha\delta}g_{\beta\gamma}) \\ &+ \tfrac{1}{2}(g_{\alpha\delta}g_{\beta\gamma} - g_{\alpha\gamma}g_{\beta\delta})R \end{aligned} \tag{8.45}$$

(and we will prove this in section 11.4).

3. It is thus only in four (and more) dimensions that there are strictly less components of the Ricci tensor than of the Riemann tensor. This has profound implications for the dynamics of gravity in these dimensions. In fact, we will see that it is only in dimensions $D > 3$ that gravity becomes truly dynamical, where empty space can be curved, where gravitational waves can exist etc.

4. Contracting (8.8), one consequence of the symmetry of the Ricci tensor is the useful general result

$$[\nabla_\mu, \nabla_\nu]T^{\mu\nu} = R_{\mu\nu}(T^{\mu\nu} - T^{\nu\mu}) = 0 \tag{8.46}$$

for any tensor $T^{\mu\nu}$. If $T^{\mu\nu} = F^{\mu\nu}$ is anti-symmetric, $F^{\mu\nu} = -F^{\nu\mu}$, it is not necessary to take the commutator, so one also has

$$F^{\mu\nu} = -F^{\nu\mu} \quad \Rightarrow \quad \nabla_\mu(\nabla_\nu F^{\mu\nu}) = \tfrac{1}{2}[\nabla_\mu, \nabla_\nu]F^{\mu\nu} = 0 \ . \tag{8.47}$$

Note that this can also be deduced (without knowing anything about curvature in general or the Ricci tensor in particular) from the general expression (5.64) for the divergence of an anti-symmetric tensor,

$$\nabla_\mu F^{\mu\nu} = g^{-1/2}\partial_\mu(g^{1/2}F^{\mu\nu}) \quad \Rightarrow \quad \nabla_\nu\nabla_\mu F^{\mu\nu} = g^{-1/2}\partial_\nu\partial_\mu(g^{1/2}F^{\mu\nu}) = 0 \ . \tag{8.48}$$

This is how we had shown in section 6.6 that the Maxwell equations imply covariant current conservation,

$$\nabla_\mu F^{\mu\nu} = -J^\nu \quad \Rightarrow \quad \nabla_\nu J^\nu = 0 \ . \tag{8.49}$$

Now we see that we can alternatively directly use the identity (8.47) to arrive at this result.

5. There are other scalars that can be built from the curvature tensor, but these are necessarily of higher order in the curvature tensor, such as (trivially) R^2 or (somewhat less trivially) $R_{\mu\nu}R^{\mu\nu}$ or the square of the Riemann tensor, the so-called *Kretschmann scalar*

$$K = R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} \ . \tag{8.50}$$

Analogously, scalars can be built from higher powers of the Riemann tensor and or from powers of covariant derivatives of the Riemann tensor ($\Box R$ being the simplest example).

6. Such scalars are useful in analysing a given metric because, since they are scalars they are invariant under coordinate transformations. Thus they directly provide coordinate-invariant information about a metric. For instance if K is singular at some point in some coordinate system then it will be singular at that point in all coordinate systems, and thus such a singularity is not an artefact of a bad choice of coordinate system but a property of the space(-time) itself described by that metric. A prominent example is the singularity at the origin $r = 0$ of the Schwarzschild metric, unambiguously unveiled by the singularity of its Kretschmann scalar (27.163).

7. Contracting (8.40) with V^ν, one finds

$$V^\nu \nabla_\mu \nabla_\nu V^\mu - V^\nu \nabla_\nu \nabla_\mu V^\mu = R_{\mu\nu} V^\mu V^\nu \quad . \tag{8.51}$$

   Rewriting the first term as

$$V^\nu \nabla_\mu \nabla_\nu V^\mu = \nabla_\mu (V^\nu \nabla_\nu V^\mu) - (\nabla_\mu V^\nu)(\nabla_\nu V^\mu) \tag{8.52}$$

   this identity can be written as

$$V^\nu \nabla_\nu (\nabla_\mu V^\mu) + (\nabla_\mu V_\nu)(\nabla^\nu V^\mu) - \nabla_\mu (V^\nu \nabla_\nu V^\mu) + R_{\mu\nu} V^\mu V^\nu = 0 \quad . \tag{8.53}$$

   This is a very useful and versatile "master equation" which provides valuable information about the relation between vector fields and curvature when specialised e.g. to geodesic vector fields, $V^\nu \nabla_\nu V^\mu = 0$, or Killing vector fields, $\nabla_\mu V_\mu = -\nabla_\nu V_\mu$ and $\nabla_\mu V^\mu = 0$. Various specialisations of this equation will therefore appear later on in these notes, and even though we will then usually rederive them from scratch in the case at hand, it is good to keep in mind that e.g. (12.22) (our starting point for the discussion of the Raychaudhuri equation in section 12.2) and (13.12) (a useful identity relating Killing vectors and curvature) are special cases of (8.53).

8. As an a(far)side, and as an illustration of what one can do with (8.53), assume that V is such that its curl $\nabla_\mu V_\nu - \nabla_\nu V_\mu = 0$ and its divergence $\nabla_\mu V^\mu = 0$ are zero. Locally, the first condition has the solution $V_\mu = \partial_\mu f$, and then the second condition says that $\Box f = 0$, i.e. that f is *harmonic*. Therefore let us call a V^μ *harmonic* if it satisfies the above two conditions (to the mathematically more sophisticated: yes, I know that this is backwards, but we will specialise to the compact Riemannian case below . . .).

   For V harmonic in this sense, (8.53) reduces to

$$(\nabla_\mu V_\nu)(\nabla^\mu V^\nu) + R_{\mu\nu} V^\mu V^\nu = \nabla_\mu (V^\nu \nabla_\nu V^\mu) \quad . \tag{8.54}$$

   The simplest (albeit perhaps not of most direct relevance for physics) situation where one can deduce something of substance from this equation is when one has a Riemannian (i.e. positive-definite) metric and the space one is dealing with is compact, without boundary. Then (a) the first term is non-negative, and (b) upon integration over the space the total derivative term on the right-hand side gives zero upon use of the Gauss theorem (5.62) (discussed in some more detail in section 16.3).

This implies that for a harmonic V to exist on such a space, the integral of $R_{\mu\nu}V^\mu V^\nu$ must be non-positive. In particular,

- if the Ricci tensor is positive (as a quadratic form), there are no harmonic vector fields at all,
- and if $R_{\mu\nu}V^\mu V^\nu = 0$, then a harmonic vector field is necessarily covariantly constant, $\nabla_\mu V_\nu = 0$.

In more mathematical terms this means that the first Betti number of a compact manifold admitting a metric with positive Ricci curvature is equal to zero. A variant of this kind of argument for Killing vectors will be given in section 13.3.[20]

8.6 Example: Curvature Tensor of the 2-Sphere

To see how calculations of the curvature tensor can be done in practice, let us work out the example of the two-sphere of unit radius, i.e. with line element

$$ds^2 = d\theta^2 + \sin^2\theta d\phi^2 \equiv g_{ab}dx^a dx^b \quad . \tag{8.55}$$

We already know that the non-zero Christoffel symbols necessarily have two ϕ-indices and one θ-index (from $g_{\phi\phi} = \sin^2\theta$), and are given by

$$\Gamma^\phi{}_{\phi\theta} = \cot\theta \quad , \qquad \Gamma^\theta{}_{\phi\phi} = -\sin\theta\cos\theta \quad . \tag{8.56}$$

We also know that the Riemann curvature tensor has only one independent component. Let us therefore work out $R^\theta{}_{\phi\theta\phi}$. From the definition we find

$$R^\theta{}_{\phi\theta\phi} = \partial_\theta \Gamma^\theta{}_{\phi\phi} - \partial_\phi \Gamma^\theta{}_{\theta\phi} + \Gamma^\theta{}_{\theta c}\Gamma^c{}_{\phi\phi} - \Gamma^\theta{}_{\phi c}\Gamma^c{}_{\theta\phi} \quad . \tag{8.57}$$

The second and third terms are manifestly zero, and we are left with

$$R^\theta{}_{\phi\theta\phi} = \partial_\theta(-\sin\theta\cos\theta) + \sin\theta\cos\theta\cot\theta = \sin^2\theta \quad . \tag{8.58}$$

Thus we have

$$\begin{aligned} R^\theta{}_{\phi\theta\phi} &= R_{\theta\phi\theta\phi} = \sin^2\theta \\ R^\phi{}_{\theta\phi\theta} &= 1 \quad . \end{aligned} \tag{8.59}$$

---

[20] Theorems of this kind, and proved with the help of these kinds of techniques, were pioneered by S. Bochner and K. Yano in the 1930s - 1950s. See e.g. S. Bochner, K. Yano, *Curvature and Betti Numbers* or W. Poor, *Differential Geometric Structures* for more details, rigour and applications.

Therefore the Ricci tensor R_{ab} has the components

$$\begin{aligned} R_{\theta\theta} &= 1 \\ R_{\theta\phi} &= 0 \\ R_{\phi\phi} &= \sin^2\theta \ . \end{aligned} \tag{8.60}$$

These equations can succinctly be written as

$$R_{ab} = g_{ab} \ , \tag{8.61}$$

showing that the standard metric on the two-sphere is what we will later call an *Einstein metric.* The Ricci scalar R is

$$R = g^{\theta\theta}R_{\theta\theta} + g^{\phi\phi}R_{\phi\phi} = 1 + \frac{1}{\sin^2\theta}\sin^2\theta = 2 \ . \tag{8.62}$$

In particular, we have here our first concrete example of a space with non-trivial, in fact positive, curvature.

The result for the Riemann tensor can be written succinctly as

$$R^a{}_{bcd} = \delta^a{}_c g_{bd} - \delta^a{}_d g_{bc} \ , \tag{8.63}$$

which also immediately implies (8.61),

$$R_{bd} = R^a{}_{bad} = g_{bd} \ . \tag{8.64}$$

We will see later on, in section 14, that this form of the curvature tensor, or its equivalent,

$$R_{abcd} = g_{ac}g_{bd} - g_{ad}g_{bc} \ , \tag{8.65}$$

is characteristic of the curvature tensor of the sphere in any dimension.

8.7 More Examples: Curvature Tensor and Polar/Spherical Coordinates

We now turn to some variations of the above theme (and some other generalisations are discussed in section 11.3 below).

1. First of all, let us address the question what is the curvature (scalar) of a sphere of radius L, i.e. of the space with line element

   $$ds^2 = L^2(d\theta^2 + \sin^2\theta d\phi^2) \ . \tag{8.66}$$

   There are at least 3 ways to answer this question:

   - The first is to simply and blindly redo the above calculations in this case and to see what one gets.

- Alternatively, and somewhat more insightfully, rather than redoing the calculation in that case one can argue as follows. Let us observe first of all that the Christoffel symbols are invariant under constant rescalings of the metric because they are schematically of the form $g^{-1}\partial g$. Therefore the Riemann curvature tensor, which only involves derivatives and products of Christoffel symbols, is also invariant. Hence the Ricci tensor, which is just a contraction of the Riemann tensor, is also invariant:

  $$g_{ab} \to L^2 g_{ab} \quad \Rightarrow \quad \Gamma^a_{\ bc} \to \Gamma^a_{\ bc} \quad \Rightarrow \quad R^a_{\ bcd} \to R^a_{\ bcd} \quad \Rightarrow \quad R_{bd} \to R_{bd} \ . \tag{8.67}$$

  However, to construct the Ricci scalar, one needs the inverse metric. This introduces an explicit L-dependence and the result is that the curvature scalar of a sphere of radius L is $R = 2/L^2$,

  $$R(L^2 g_{ab}) = L^{-2} R(g_{ab}) = 2/L^2 \ . \tag{8.68}$$

  In particular, the curvature scalar of a large sphere is smaller than that of a small sphere, something which makes intuitve sense, a very large sphere locally "looking flatter" than a small sphere. However, one should use this intuition with care since, as we have seen, e.g. the Ricci tensor is independent of the size of the sphere.

- Finally, this result could also have been obtained on purely dimensional grounds. The curvature scalar is constructed from second derivatives of the metric. Hence it has length-dimension (-2). Therefore for a sphere of radius L, R has to be proportional to $1/L^2$. Comparing with the known result for $L = 1$ determines $R = 2/L^2$, as before.

2. Now let us consider, instead of the unit 2-sphere, the unit hyperboloid H^2 with metric (2.31)

   $$ds^2(H^2) = d\sigma^2 + \sinh^2\sigma \, d\phi^2 \ . \tag{8.69}$$

   It is clear that, apart from a few sign changes here and there, the calculation of the Riemann curvature tensor is identical to that for S^2. These sign changes ultimately lead to the conclusion that the curvature scalar of H^2 is (-2). While the sphere is the prototypical example of a space with positive curvature, the hyperboloid is the prototypical example of a space with negative curvature.

   Instead of just doing the calculation for this specific example, it is slightly more instructive to do it for the class of metrics

   $$ds^2 = dx^2 + f(x)^2 d\phi^2 \ , \tag{8.70}$$

   for some (for the time being unspecified) function $f = f(x)$. Denoting the derivative with respect to x by a prime, $f'(x) = df/dx$, one finds (this is a simple but ionstructive exercise) that the Ricci tensor and Ricci scalar are

$$R_{ab} = -(f''/f)g_{ab} \quad , \quad R(x) = -2f''(x)/f(x) \ . \tag{8.71}$$

In particular, for the Euclidean metric and the standard metrics on the sphere and the hyperboloid one finds

$$f(x) = \begin{cases} x & (R^2) \\ \sin x & (S^2) \\ \sinh x & (H^2) \end{cases} \quad \Rightarrow \quad R = \begin{cases} 0 \\ +2 \\ -2 \end{cases} \tag{8.72}$$

In 2 dimensions, R is related to the *Gauss Curvature* K of a surface by $K = R/2$ so that $K = 0, \pm 1$ in these examples. See section 11.3 for some more information.

3. Now let us promote the constant radius L of S^2 to a new radial coordinate r and ask the question what is the curvature tensor of the 3-dimensional space with coordinates $(r, x^a) = (r, \theta, \phi)$ and line element

$$ds^2 = dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2) \ . \tag{8.73}$$

On the one hand, because one seems to have just added a trivial r-direction to the 2-sphere, one might be tempted to suspect that also this 3-dimensional space has non-trivial curvature. On the other hand, we recognise the above metric as the Euclidean metric on $\mathbb{R}^3$, written in spherical coordinates, and as such we expect its curvature (in fact, all components of the Riemann tensor) to be zero.

The latter expectation is of course borne out, but it is instructive to see explicitly how this cancellation occurs. In fact, it will be even more instructive to consider an apparently harmless and innocuous modification of the above metric which consists in replacing dr^2 by some constant multiple of dr^2,

$$ds^2 = p\, dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2) \ . \tag{8.74}$$

Equivalently, up to a truly harmless overall constant factor, we can think of this as the Euclidean metric, but with the metric on the unit-sphere replaced by that of a sphere of radius $1/\sqrt{p} \neq 1$),

$$ds^2 = p\ \left(dr^2 + (r^2/p)(d\theta^2 + \sin^2\theta d\phi^2)\right) \ . \tag{8.75}$$

Proceeding in a pedestrian way, we thus have a metric $g_{\alpha\beta}$ with components

$$g_{rr} = p \quad , \quad g_{ar} = 0 \quad , \quad g_{ab} = r^2\gamma_{ab} \ , \tag{8.76}$$

with γ_{ab} in this example denoting the components of the metric on the unit sphere (and with $\gamma^a_{\ bc}$ and $r^a_{\ bcd}$ its associated Christoffel symbols and components of the Riemann curvature tensor determined in the previous section). From these we can deduce that for $r > 0$ the non-trivial Christoffel symbols are

$$\Gamma^r_{\ ab} = -p^{-1}r\gamma_{ab} \quad , \quad \Gamma^a_{\ br} = r^{-1}\delta^a_b \quad , \quad \Gamma^a_{\ bc} = \gamma^a_{\ bc} \ . \tag{8.77}$$

From this, in turn, one finds that all the components of the Riemann tensor involving at least one r-index are zero, whereas for the purely angular components one finds

$$R^a{}_{bcd} = r^a{}_{bcd} + \Gamma^a{}_{cr}\Gamma^r{}_{bd} - \Gamma^a{}_{dr}\Gamma^r{}_{bc} \quad . \tag{8.78}$$

Using (8.63) and (8.77), one sees that

$$R^a{}_{bcd} = (1-p^{-1})r^a{}_{bcd} = (1-p^{-1})(\delta^a{}_c\gamma_{bd} - \delta^a{}_d\gamma_{bc}) \quad . \tag{8.79}$$

Therefore precisely for $p=1$ the two contributions to the curvature tensor indeed cancel and the curvature tensor is identically zero, as expected.

Equally interesting is the fact that for $p \neq 1$ the curvature is non-zero even away from $r=0$ (in addition, there is a conical deficit angle singularity at $r=0$, as in the next example below, but this shall not be our concern here). In particular it follows from the above result that the only non-vanishing components of the Ricci tensor of this 3-dimensional space are

$$R^a{}_{bcd} = (1-p^{-1})r^a{}_{bcd} \quad \Rightarrow \quad R_{bd} = (1-p^{-1})r_{bd} = (1-p^{-1})\gamma_{bd} \quad . \tag{8.80}$$

Therefore also its Ricci scalar is non-zero,

$$R = g^{\alpha\beta}R_{\alpha\beta} = g^{ab}R_{ab} = 2(1-p^{-1})r^{-2} \quad . \tag{8.81}$$

We also see from this that this space actually has a curvature singularity as $r \to 0$. Since the Ricci scalar is a scalar (under coordinate transformations), this divergence cannot be an artefact of a bad choice of coordinates, and indicates that there is a genuine geometric singularity for $r \to 0$.

Extended to a four-dimensional space-time metric via

$$ds^2 = -dt^2 + p\,dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2) \quad , \tag{8.82}$$

this describes the gravitational field outside a "monopole".[21]

4. As a final variation of this theme, we consider the above example in one dimension less, i.e. we look at the metric one obtains if one replaces the Euclidean metric on $\mathbb{R}^2$ written in polar coordinates by

   $$dr^2 + r^2 d\phi^2 \to p\,dr^2 + r^2 d\phi^2 \quad , \tag{8.83}$$

   where the angle ϕ has period 2π.

   In this case there is an interesting twist (pun intended) and the situation is somewhat different. Pulling out the factor of p, one sees that (up to this irrelevant overall constant factor) the metric can be written as

   $$ds^2 = dr^2 + r^2 d(\phi/\sqrt{p})^2 \equiv dr^2 + C^2 r^2 d\phi^2 \quad . \tag{8.84}$$

---

[21] M. Barriola, A. Vilenkin, *Gravitational Field of a Global Monopole*, Phys. Rev. Lett. 63 (1989) 341-343.

This would be the standard Euclidean metric on $\mathbb{R}^2$ either for $p = 1$ or if the angle ϕ had periodicity $2\pi\sqrt{p}$, but since ϕ has period 2π, this results in a misidentification of the points in a plane, like when one rolls up a flat piece of paper into a cone. Away from $r = 0$, this space is intrinsically flat (all the components of the Riemann curvature tensor are zero, as one can easily calculate - see section 11.1 for an explanation of this use of the word "intrinsic"). There is, however, a conical singularity at the tip of the cone $r = 0$, which can be thought of as a δ-function contribution to the curvature localised at $r = 0$. Extended to a four-dimensional space-time metric,

$$ds^2 = -dt^2 + dz^2 + dr^2 + C^2r^2d\phi^2 \ , \qquad (8.85)$$

it can be interpreted as the space-time metric of an idealised cosmic string extended in the z-direction.[22]

8.8 BIANCHI IDENTITIES AND THE EINSTEIN TENSOR

So far, we have discussed algebraic properties of the Riemann tensor. The Riemann tensor also satisfies some differential identities which, in particular in their contracted form, will be of fundamental importance in the following.

The first identity is easy to derive. As a (differential) operator the covariant derivative clearly satisfies the Jacobi identity

$$[\nabla_{[\mu}, [\nabla_\nu, \nabla_{\lambda]}]] = 0 \qquad (8.86)$$

(total anti-symmetrisation over all 3 indices). Since the commutator $[\nabla_\nu, \nabla_\lambda]$ is already anti-symmetric in the indices ν, λ, this anti-symmetrisation is equivalent to cyclic permutation of the 3 indices,

$$[\nabla_{[\mu}, [\nabla_\nu, \nabla_{\lambda]}]] = 0 \quad \Leftrightarrow \quad [\nabla_\mu, [\nabla_\nu, \nabla_\lambda]] + \circlearrowleft (\mu, \nu, \lambda) = 0 \ . \qquad (8.87)$$

If you do not believe this identity (valid for any 3 associative linear operators), you can just write out the twelve relevant terms explicitly to see that there is indeed a complete cancellation:

---

[22] It is far from straightforward, however, to find a formalism which allows one to calculate and derive the distributional Riemann tensor of this space-time - see R. Geroch, J. Traschen, *Strings and other distributional sources in general relativity*, Phys. Rev. D36 (1987) 1017-1031 for a general analysis of the problem and issues arising in this and related contexts, C. Clarke, J. Vickers, J. Wilson, *Generalized functions and distributional curvature of cosmic strings*, Class. Quantum Grav. 13 (1996) 2485-2498 for one approach (based on the Colombeau algebra of distributions), and D. Garfinkle, *Metrics with distributional curvature*, `arXiv:gr-qc/9906053` for a different approach. We will (mostly) stay away from distributional curvatures in these notes.

$$\begin{aligned}
[\nabla_{[\mu},[\nabla_\nu,\nabla_{\lambda]}]] &\sim \nabla_\mu\nabla_\nu\nabla_\lambda-\nabla_\mu\nabla_\lambda\nabla_\nu-\nabla_\nu\nabla_\lambda\nabla_\mu+\nabla_\lambda\nabla_\nu\nabla_\mu\\
&+\nabla_\lambda\nabla_\mu\nabla_\nu-\nabla_\lambda\nabla_\nu\nabla_\mu+\nabla_\nu\nabla_\mu\nabla_\lambda-\nabla_\mu\nabla_\nu\nabla_\lambda\\
&+\nabla_\nu\nabla_\lambda\nabla_\mu-\nabla_\nu\nabla_\mu\nabla_\lambda-\nabla_\lambda\nabla_\mu\nabla_\nu+\nabla_\mu\nabla_\lambda\nabla_\nu\\
&= 0\ . \qquad (8.88)
\end{aligned}$$

To determine the implications of this identity for the Riemann tensor, we apply it to a vector field V, say. The first term in (8.87) is

$$\begin{aligned}
[\nabla_\mu,[\nabla_\nu,\nabla_\lambda]]V^\rho &= \nabla_\mu(R^\rho_{\ \sigma\nu\lambda}V^\sigma)-[\nabla_\nu,\nabla_\lambda](\nabla_\mu V^\rho)\\
&=(\nabla_\mu R^\rho_{\ \sigma\nu\lambda})V^\sigma+R^\rho_{\ \sigma\nu\lambda}\nabla_\mu V^\sigma-R^\rho_{\ \sigma\nu\lambda}\nabla_\mu V^\sigma+R^\sigma_{\ \mu\nu\lambda}\nabla_\sigma V^\rho \qquad (8.89)\\
&=(\nabla_\mu R^\rho_{\ \sigma\nu\lambda})V^\sigma+R^\sigma_{\ \mu\nu\lambda}\nabla_\sigma V^\rho\ .
\end{aligned}$$

Upon taking the cyclic permutations, the sum of the 2nd terms vanishes by the cyclic symmetry of the Riemann tensor, and therefore one finds

$$(\nabla_\mu R^\rho_{\ \sigma\nu\lambda})V^\sigma+\circlearrowleft(\mu,\nu,\lambda)=0\ . \qquad (8.90)$$

Since this holds for any V, one deduces the *Bianchi identity*

$$\nabla_\mu R^\rho_{\ \sigma\nu\lambda}+\circlearrowleft(\mu,\nu,\lambda)=0 \quad\Leftrightarrow\quad \nabla_{[\mu}R^\rho_{\ |\sigma|\nu\lambda]}=0 \qquad (8.91)$$

(where $|\sigma|$ indicates that this index is to be excluded from the anti-symmetrisation). Using the symmetry (IV) of the Riemann tensor, this can equivalently be written as

$$\nabla_{[\mu}R_{\nu\lambda]\rho\sigma}=0\ . \qquad (8.92)$$

We will mainly be interested in a (double) contraction of this identity. To that end we write out (8.91) explicitly as

$$\nabla_\lambda R_{\alpha\beta\mu\nu}+\nabla_\nu R_{\alpha\beta\lambda\mu}+\nabla_\mu R_{\alpha\beta\nu\lambda}=0\ . \qquad (8.93)$$

By contracting this with $g^{\alpha\mu}$ we obtain

$$\nabla_\lambda R_{\beta\nu}-\nabla_\nu R_{\beta\lambda}+\nabla_\mu R^\mu_{\ \beta\nu\lambda}=0\ . \qquad (8.94)$$

This is not yet particularly useful. To also turn the last term into a Ricci tensor we contract once more, with $g^{\beta\lambda}$ to obtain the contracted Bianchi identity

$$\nabla_\lambda R^\lambda_\nu-\nabla_\nu R+\nabla_\mu R^\mu_\nu=0\ , \qquad (8.95)$$

or

$$\nabla^\mu(R_{\mu\nu}-\tfrac{1}{2}g_{\mu\nu}R)=0\ . \qquad (8.96)$$

The tensor appearing in this equation is the so-called *Einstein tensor* $G_{\mu\nu}$,

$$G_{\mu\nu}=R_{\mu\nu}-\tfrac{1}{2}g_{\mu\nu}R\ . \qquad (8.97)$$

It is the unique divergence-free tensor that can be built from the metric and its first and second derivatives (apart from $g_{\mu\nu}$ itself, of course),

$$\nabla^\mu G_{\mu\nu} = 0 \ , \tag{8.98}$$

and this is why it will play *the* central role in the Einstein equations for the gravitational field.

A minor *caveat* regarding the above statement about the uniqueness of the Einstein tensor is that, as it stands, it is only true in $D = 4$ space-time dimensions. In $D > 4$, there are other tensors with this property, but they are non-linear in 2nd derivatives of the metric. The uniqueness statement continues to be true for $D > 4$ if one adds the requirement that the tensor is linear in 2nd derivatives of the metric. I will briefly come back to this in the discussion of the action principle for general relativity in section 20.1.

8.9 RIEMANN NORMAL COORDINATES REVISITED

In section 3.6 we had introduced Riemann normal coordinates as a special class of inertial coordinate systems, based on geodesics. The main idea was to introduce new coordinates $x^\alpha \to \xi^a$ in such a way that the coordinate lines of the new coordinates ξ^a are geodesics passing through the point p at which one wants to erect this coordinate system.

In particular,

1. we considered the Taylor expansion (3.167)

   $$x^\alpha(\tau) = x_0^\alpha + \tau u_0^\alpha - \tfrac{1}{2}\tau^2 \Gamma^\alpha_{\beta\gamma}(x_0) u_0^\beta u_0^\gamma + \dots \ , \tag{8.99}$$

   of a solution to the geodesic equation;

2. this led us to consider the coordinate transformation (3.169)

   $$x^\alpha(\xi) = x_0^\alpha + (\xi - \xi_0)^a e_a^\alpha - \tfrac{1}{2}(\xi - \xi_0)^b (\xi - \xi_0)^c \Gamma^\alpha_{\beta\gamma}(x_0) e_b^\beta e_c^\gamma + \dots \tag{8.100}$$

   which has the property that the lines

   $$\xi^a(\tau) = \xi_0^a + \tau\lambda^a \tag{8.101}$$

   are geodesics for any constant λ^a;

3. for these geodesics the geodesic equation reduces to

   $$\ddot{\xi}^a + \Gamma^a_{bc}\dot{\xi}^b\dot{\xi}^c = 0 \quad \Rightarrow \quad \Gamma^a_{bc}(\xi_0^a + \tau\lambda^a)\lambda^b\lambda^c = 0 \ , \tag{8.102}$$

   implying at $\tau = 0$

   $$\Gamma^a_{bc}(\xi_0)\lambda^b\lambda^c = 0 \quad \forall\lambda^a \quad \Rightarrow \Gamma^a_{bc}(\xi_0) = 0 \tag{8.103}$$

   (and we will look at the implications of the next term in the Taylor expansion of (8.102) below).

Therefore the Taylor expansion of the metric around $\xi = \xi_0$ has the form

$$g_{ab}(\xi) = \eta_{ab} + \tfrac{1}{2}(\xi-\xi_0)^c(\xi-\xi_0)^d g_{ab,\,cd}(\xi_0) + \dots \quad , \tag{8.104}$$

and we will now determine the quadratic term in this expansion (and be able to express it in terms of the components of the Riemann tensor $R_{abcd}(\xi_0)$ at the point p in these coordinates). To that end we look at the next term in the Taylor expansion of (8.102). Thus we differentiate (8.102) along the geodesic, i.e. with respect to τ, and evaluate the results at $\tau = 0$ to deduce

$$\partial_d \Gamma^a_{\ bc}(\xi_0)\lambda^d\lambda^b\lambda^c = 0 \quad \forall \ \lambda^b \tag{8.105}$$

or, equivalently

$$\partial_{(d}\Gamma^a_{\ bc)}(\xi_0) = 0 \quad \Leftrightarrow \quad \partial_d\Gamma^a_{\ bc}(\xi_0) + \partial_b\Gamma^a_{\ cd}(\xi_0) + \partial_c\Gamma^a_{\ db}(\xi_0) = 0 \ . \tag{8.106}$$

This condition, and the analogous conditions

$$\partial_{(d\ldots e}\Gamma^a_{\ bc)}(\xi_0) = 0 \tag{8.107}$$

arising from the higher-order terms in the Taylor expansion of (8.102) impose constraints on the Christoffel symbols and their derivatives that are satisfied in Riemann normal coordinates (but not in general inertial coordinate systems).

A useful way of reexpressing the condition (8.106) is the following (a certain amount of hindsight or trial-and-error is required for this): because $\Gamma^a_{\ bc}(\xi_0) = 0$, from the definition of the Riemann tensor we have

$$\begin{aligned} R^a_{\ bcd}(\xi_0) + R^a_{\ cbd}(\xi_0) &= \partial_c\Gamma^a_{\ bd}(\xi_0) - \partial_d\Gamma^a_{\ bc}(\xi_0) + \partial_b\Gamma^a_{\ cd}(\xi_0) - \partial_d\Gamma^a_{\ cb}(\xi_0) \\ &= \partial_c\Gamma^a_{\ bd}(\xi_0) + \partial_b\Gamma^a_{\ cd}(\xi_0) - 2\partial_d\Gamma^a_{\ bc}(\xi_0) \quad , \end{aligned} \tag{8.108}$$

and using (8.106) this can be written as

$$\partial_d\Gamma^a_{\ bc}(\xi_0) = -\tfrac{1}{3}(R^a_{\ bcd}(\xi_0) + R^a_{\ cbd}(\xi_0)) \ . \tag{8.109}$$

On the other hand, from

$$g_{ab,\,c}(\xi) = \Gamma_{abc}(\xi) + \Gamma_{bac}(\xi) \tag{8.110}$$

we have

$$g_{ab,\,cd}(\xi) = \partial_d\Gamma_{abc}(\xi) + \partial_d\Gamma_{bac}(\xi) \tag{8.111}$$

and at ξ_0 we can use (8.109) and the symmetries of the Riemann tensor to deduce

$$\begin{aligned} g_{ab,\,cd}(\xi_0) &= -\tfrac{1}{3}(R_{abcd} + R_{acbd} + R_{bacd} + R_{bcad})(\xi_0) \\ &= -\tfrac{1}{3}(R_{acbd} + R_{bcad})(\xi_0) = -\tfrac{1}{3}(R_{acbd} + R_{adbc})(\xi_0) \ . \end{aligned} \tag{8.112}$$

We have thus found that, to quadratic order in a Taylor expansion of the metric around the origin of a Riemann normal coordinate system, the metric can be written as

$$\begin{aligned} g_{ab}(\xi) &= \eta_{ab} - \tfrac{1}{6}(R_{acbd}(\xi_0) + R_{adbc}(\xi_0))(\xi-\xi_0)^c(\xi-\xi_0)^d + \mathcal{O}(\xi^3) \\ &= \eta_{ab} - \tfrac{1}{3}R_{acbd}(\xi_0)(\xi-\xi_0)^c(\xi-\xi_0)^d + \mathcal{O}(\xi^3) \ . \end{aligned} \tag{8.113}$$

If required, higher order terms can be determined analogously with the help of the higher order terms in the Taylor expansion of (8.102), and (with a steady hand) can be expressed in terms of the covariant derivatives of the Riemann tensor at ξ_0.

8.10 PRINCIPLE OF MINIMAL COUPLING REVISITED

In sections 4.1 and 6.1 on the principles of general covariance and minimal coupling respectively, I mentioned that these do not necessarily fix the equations uniquely. In other words, there could be more than one generally covariant equation which reduces to a given equation in Minkowski space. Having the curvature tensor at our disposal now, we can construct examples of this kind.

Given some tensorial equation, obtained by the minimal coupling prescription, say, one can always contemplate the possiblity to add additional terms to it involving the curvature tensor. Since such terms take the form of higher derivative corrections to the original equation, multiplied by appropriate dimensionful constants, one can usually get away with ignoring such terms when dealing with weak fields and other low-energy phenomena, and under such conditions the minimal coupling rule can usually be trusted. However, such terms are not negligible under extreme conditions involving e.g. very strong or strongly fluctuating gravitational fields.

An example which shows very clearly that the minimal coupling prescription, at least the way we have formulated it, is itself ambiguous is, as already briefly pointed out in section 6.6, provided by Maxwell theory. In that case, we saw that in the covariant Lorenz gauge one has (6.45)

$$\nabla_\mu A^\mu = 0 \quad \Rightarrow \quad \nabla_\mu F^{\mu\nu} = \nabla_\mu(\nabla^\mu A^\nu - \nabla^\nu A^\mu) = \Box A^\nu - [\nabla_\mu, \nabla^\nu]A^\mu \quad , \tag{8.114}$$

where $\Box A^\nu = \nabla^\mu \nabla_\mu A^\nu$. It thus follows from (8.40) that the Maxwell equations in the covariant Lorenz gauge can be written as (6.46)

$$\nabla_\mu A^\mu = 0 \quad \Rightarrow \quad \nabla_\mu F^{\mu\nu} = -J^\nu \quad \rightarrow \quad \Box A^\nu - R^\nu_{\ \mu} A^\mu = -J^\nu \quad . \tag{8.115}$$

What this shows is that "minimal coupling" all by itself is not a unique prescription, as we would have obtained (8.115) without the curvature terms by applying the minimal coupling prescription to the special relativity Maxwell equation in the Lorenz gauge, namely just $\Box A_\nu = -J_\nu$.

In the present situation, (6.46) is superior to the equation without the curvature term because

- it follows from a variational principle (involving the minimally coupled counterpart of the Maxwell action)

- and (related to this) because (8.115) implies that the current is covariantly conserved (as we had verified in section 6.6 in an arbitrary gauge), while for the equation without the curvature term covariant current conservation would then be violated by a curvature term (as can easily be verified).

Thus occasionally some such additional criteria can be used to eliminate (or reduce) the ambiguity in the minimal coupling prescription, but this need not always be the case.

As another example, consider the wave equation for a (massless, say) scalar field Φ. In Minkowski space, this is the Klein-Gordon equation which has the obvious curved space analogue (5.56)

$$\Box\Phi = 0 \tag{8.116}$$

obtained by the minimal coupling description. However, one could equally well postulate the equation

$$(\Box + \xi R)\Phi = 0 \ \ , \tag{8.117}$$

where ξ is a (dimensionless) constant and R is the scalar curvature. This equation is generally covariant, and reduces to the ordinary Klein-Gordon equation in Minkowski space, so this is an acceptable curved-space extension of the wave equation for a scalar field. This equation of motion arises (in D sapce-time dimensions) from the action

$$S_\xi[\phi, g_{\alpha\beta}] = -\tfrac{1}{2}\int \sqrt{g} d^D x \ \left(g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi + \xi R\phi^2\right) \ \ , \tag{8.118}$$

exhibiting the non-minimal (yet generally covariant) coupling of the scalar field to gravity via the term $\xi R\phi^2$ (which acts as an x-dependent mass term for the scalar field).

Moreover, ξ is dimensionless, so one cannot argue that on dimensional grounds this ambiguity is irrelevant for weak fields. Indeed, one frequently postulates a specific non-zero value for ξ which makes the wave equation *conformally invariant* (invariant under position-dependent Weyl rescalings of the metric) for massless fields, and this criterion can be imposed to select a particular non-zero value for ξ (e.g. for a 4-dimensional space-time this turns out to be the value $\xi = 1/6$). This will be discussed and explained in section 22.3.

Thus in general such ambiguities are present and are something one has to live with.

11 CURVATURE II: GEOMETRY AND CURVATURE

In this section, we will first discuss two properties of the Riemann curvature tensor that illustrate its geometric significance and thus, *a posteriori*, justify equating the commutator of covariant derivatives with the intuitive concept of curvature. These properties are

- the *path-dependence of parallel transport* in the presence of curvature,
- the fact that the space-time metric is equivalent to the (in an obvious sense flat) Minkowski metric if and only if the Riemann curvature tensor vanishes.

We then briefly discuss some other general aspects of the relation between geometry and curvature (while the interplay between geodesics and curvature and Killing vectors and curvature will be discussed in sections 12 and 13 respectively).

11.1 INTRINSIC GEOMETRY, CURVATURE AND PARALLEL TRANSPORT

The Riemann curvature tensor and its relatives, introduced above, measure the *intrinsic geometry* and curvature of a space or space-time. This means that they can be calculated by making experiments and measurements in the space itself. Such experiments might involve things like checking if the interior angles of a triangle add up to π or not.

This intrinsic geometry and curvature described above should be contrasted with the *extrinsic geometry* which depends on how the space may be embedded in some larger space. As we have no intention of embedding space-time into something higher dimensional, we will mainly be concerned with intrinsic geometry in the following. However, if you would for example be interested in the properties of spacelike hypersurfaces in space-time, then aspects of both intrinsic and extrinsic geometry of that hypersurface would be relevant. See section 18 for some further comments on this.

Let us return to intrinsic geometry. An even better method, the subject of this section, to determine the curvature is to check the properties of parallel transport. The tell-tale sign (or smoking gun) of the presence of curvature is the fact that parallel transport is path dependent, i.e. that parallel transporting a vector V from a point A to a point B along two different paths will in general produce two different vectors at B. Another way of saying this is that parallel transporting a vector around a closed loop at A will in general produce a new vector at A which differs from the initial vector.

This is easy to see in the case of the two-sphere, for which we also worked out explicitly the parallel transport in section 5.9 (see Figure 8). Since all the great circles on a two-sphere are geodesics, in particular the segments N-C, N-E, and E-C in the figure, we know that in order to parallel transport a vector along such a line we just need to

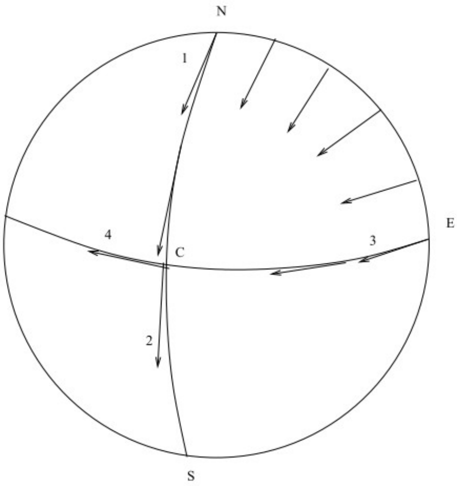

Figure 8: Figure illustrating the path dependence of parallel transport on a curved space: Vector 1 at N can be parallel transported along the geodesic N-S to C, giving rise to Vector 2. Alternatively, it can first be transported along the geodesic N-E (Vector 3) and then along E-C to give the Vector 4. Clearly these two are different. The angle between them reflects the curvature of the two-sphere.

make sure that its length and the angle between the vector and the geodesic line are constant. Thus imagine a vector 1 at the north pole N, pointing downwards along the line N-C-S. First parallel transport this along N-C to the point C. There we will obtain the vector 2, pointing downwards along C-S. Alternatively imagine parallel transporting the vector 1 first to the point E. Since the vector has to remain at a constant (right) angle to the line N-E, at the point E parallel transport will produce the vector 3 pointing westwards along E-C. Now parallel transporting this vector along E-C to C will produce the vector 4 at C. This vector clearly differs from the vector 2 that was obtained by parallel transporting along N-C instead of N-E-C.

To illustrate the claim about closed loops above, imagine parallel transporting vector 1 along the closed loop N-E-C-N from N to N. In order to complete this loop, we still have to parallel transport vector 4 back up to N. Clearly this will give a vector, not indicated in the figure, different from (and pointing roughly at a right angle to) the vector 1 we started off with.

The precise statement regarding the relation between the path dependence of parallel transport and the presence of curvature is the following. If one parallel transports a covector V_μ (I use a covector instead of a vector only to save myself a few minus signs here and there) along a closed infinitesimal loop $x^\mu(\tau)$ with, say, $x(\tau_0) = x(\tau_1) = x_0$, then one has

$$V_\mu(\tau_1) - V_\mu(\tau_0) = \tfrac{1}{2}(\oint x^\rho dx^\nu) R^\sigma{}_{\mu\rho\nu}(x_0) V_\sigma(\tau_0) \quad . \tag{11.1}$$

Thus an arbitrary vector V^μ will not change under parallel transport around an arbitrary small loop at x_0 only if the curvature tensor at x_0 is zero. This can of course be extended to finite loops, but the important point is that in order to detect curvature at a given point one only requires parallel transport along infinitesimal loops.

Before turning to a proof of this result, I just want to note that intuitively it can be understood directly from the definition of the curvature tensor (8.2). Imagine that the infinitesimal loop is actually a tiny parallelogram made up of the coordinate lines x^1 and x^2. Parallel transport along x^1 is governed by the equation $\nabla_1 V^\mu = 0$, that along x^2 by $\nabla_2 V^\mu = 0$. The fact that parallel transporting first along x^1 and then along x^2 can be different from doing it the other way around is precisely the statement that ∇_1 and ∇_2 do not commute, i.e. that some of the components $R_{\mu\nu 12}$ of the curvature tensor are non-zero.

To establish (11.1) we first reformulate the condition of parallel transport,

$$D_\tau V_\mu = 0 \quad \Leftrightarrow \quad \frac{d}{d\tau} V_\mu = \Gamma^\lambda_{\mu\nu} \dot{x}^\nu V_\lambda \tag{11.2}$$

with the initial condition at $\tau = \tau_0$ as the integral equation

$$V_\mu(\tau) = V_\mu(\tau_0) + \int_{\tau_0}^{\tau} d\tau' \, \Gamma^\lambda_{\mu\nu}(x(\tau')) \dot{x}^\nu(\tau') V_\lambda(\tau') \quad . \tag{11.3}$$

As usual, such an equation can be 'solved' by iteration (leading to a time-ordered exponential). Keeping only the first two non-trivial terms in the iteration, one has

$$\begin{aligned} V_\mu(\tau) \; = \; & V_\mu(\tau_0) + \int_{\tau_0}^{\tau} d\tau' \, \Gamma^\lambda_{\mu\nu}(x(\tau')) \dot{x}^\nu(\tau') V_\lambda(\tau_0) \\ & + \int_{\tau_0}^{\tau} d\tau' \int_{\tau_0}^{\tau'} d\tau'' \, \Gamma^\lambda_{\mu\nu}(x(\tau')) \dot{x}^\nu(\tau') \Gamma^\sigma_{\lambda\rho}(x(\tau'')) \dot{x}^\rho(\tau'') V_\sigma(\tau_0) \\ & + \ldots \end{aligned} \tag{11.4}$$

For sufficiently small (infinitesimal) loops, we can expand the Christoffel symbols as

$$\Gamma^\lambda_{\mu\nu}(x(\tau)) = \Gamma^\lambda_{\mu\nu}(x_0) + (x(\tau) - x_0)^\rho (\partial_\rho \Gamma^\lambda_{\mu\nu})(x_0) + \ldots \tag{11.5}$$

The linear term in the expansion of $V_\mu(\tau)$ arises from the zero'th order contribution $\Gamma^\lambda_{\mu\nu}(x_0)$ in the first order (single integral) term in (11.4),

$$[V_\mu(\tau_1) - V_\mu(\tau_0)]^{(1)} = \Gamma^\lambda_{\mu\nu}(x_0) V_\lambda(\tau_0) (\int_{\tau_0}^{\tau_1} d\tau' \, \dot{x}^\nu(\tau')) \quad . \tag{11.6}$$

Now the important observation is that, for a closed loop, the integral in brackets is zero,

$$\int_{\tau_0}^{\tau_1} d\tau' \dot{x}^\nu(\tau') = x^\nu(\tau_1) - x^\nu(\tau_0) = 0 \quad . \tag{11.7}$$

Thus the change in $V_\mu(\tau)$, when transported along a small loop, is at least of second order. Such second order terms arise in two different ways, from the first order term in the expansion of $\Gamma^\lambda_{\mu\nu}(x)$ in the first order term in (11.4), and from the zero'th order terms $\Gamma^\lambda_{\mu\nu}(x_0)$ in the quadratic (double integral) term in (11.4),

$$\begin{aligned}[V_\mu(\tau_1) - V_\mu(\tau_0)]^{(2)} &= (\partial_\rho \Gamma^\lambda_{\mu\nu})(x_0) V_\lambda(\tau_0) (\int_{\tau_0}^{\tau_1} d\tau' \; (x(\tau') - x_0)^\rho \dot{x}^\nu(\tau')) \\ &+ (\Gamma^\lambda_{\mu\nu}\Gamma^\sigma_{\lambda\rho})(x_0) V_\sigma(\tau_0) \int_{\tau_0}^{\tau_1} d\tau' \int_{\tau_0}^{\tau'} d\tau'' \; \dot{x}^\nu(\tau')\dot{x}^\rho(\tau'') \quad (11.8)\end{aligned}$$

The τ''-integral can be performed explicitly,

$$\int_{\tau_0}^{\tau_1} d\tau' \int_{\tau_0}^{\tau'} d\tau'' \; \dot{x}^\nu(\tau')\dot{x}^\rho(\tau'') = \int_{\tau_0}^{\tau_1} d\tau' \; \dot{x}^\nu(\tau')(x(\tau') - x_0)^\rho = \int_{\tau_0}^{\tau_1} d\tau' \; \dot{x}^\nu(\tau') x^\rho(\tau') \tag{11.9}$$

and therefore we find

$$V_\mu(\tau_1) - V_\mu(\tau_0) \approx (\partial_\rho \Gamma^\sigma_{\mu\nu} + \Gamma^\lambda_{\mu\nu}\Gamma^\sigma_{\lambda\rho})(x_0) V_\sigma(\tau_0) (\int_{\tau_0}^{\tau_1} d\tau' \; \dot{x}^\nu(\tau') x^\rho(\tau')) \tag{11.10}$$

The final observation we need is that the remaining integral is anti-symmetric in the indices ν, ρ, which follows immediately from

$$\int_{\tau_0}^{\tau_1} d\tau' \; (\dot{x}^\nu(\tau') x^\rho(\tau') + x^\nu(\tau')\dot{x}^\rho(\tau') = \int_{\tau_0}^{\tau_1} d\tau' \; \frac{d}{d\tau'}(x^\nu(\tau') x^\rho(\tau')) = 0 \;\; . \tag{11.11}$$

It now follows from (11.10) and the definition of the Riemann tensor that

$$V_\mu(\tau_1) - V_\mu(\tau_0) = \tfrac{1}{2}(\oint x^\rho dx^\nu) R^\sigma_{\;\mu\rho\nu}(x_0) V_\sigma(\tau_0) \;\; . \tag{11.12}$$

Simply by raising and lowering of the indices, and using the symmetry properties of the Riemann tensor, we can deduce that the corresponding equation for the parallel tansport of vectors is

$$V^\mu(\tau_1) - V^\mu(\tau_0) = -\tfrac{1}{2}(\oint x^\rho dx^\nu) R^\mu_{\;\sigma\rho\nu}(x_0) V^\sigma(\tau_0) \;\; . \tag{11.13}$$

As an example, recall that in section 8.6 we already determined explicitly the parallel transport of vectors on the 2-sphere along the circles with fixed $\theta = \theta_0$. Choosing θ_0 infinitesimal corresponds to an infinitesimal loop around the north pole. Expanding the result (5.116) for small θ_0, in particular using

$$\sin(2\pi\cos\theta_0) \approx \sin(2\pi(1 - \theta_0^2/2)) \approx -\tfrac{1}{2}(2\pi)\theta_0^2 \;\; , \tag{11.14}$$

one finds complete agreement between (11.13) and the components of the Riemann tensor of the 2-sphere, determined in (8.59),

$$r^\theta_{\;\phi\theta\phi} = \sin^2\theta \quad , \quad r^\phi_{\;\theta\phi\theta} = 1 \;\; , \tag{11.15}$$

evaluated for $\theta_0 \to 0$. In verifying this, some care should be taken with the fact that $\theta = 0$ is a coordinate singularity so that one should never strictly set $\theta_0 = 0$. Alternatively, and to be on the safe side, one can rewrite (11.13) as an equation for orthonormal frame components and use the result (5.121) for the parallel transport of the frame components (which is not sensitive to coordinate singularities).

11.2 VANISHING RIEMANN TENSOR AND EXISTENCE OF FLAT COORDINATES

We are now finally in a position to prove the converse to the statement that the Minkowski metric has vanishing Riemann tensor. Namely, we will see that when the Riemann tensor of a metric vanishes, locally there are coordinates in which the metric is the standard Minkowski metric. Since the opposite of curved is flat, this then allows one to unambiguously refer to the Minkowski metric as *the* flat metric (locally at least), and to Minkowski space as *flat space(-time)*.

So let us assume that we are given a metric with vanishing Riemann tensor. Then, by the above, parallel transport is path independent and we can, in particular, extend a vector $V^\mu(x_0)$ to a vector field everywhere in space-time: to define $V^\mu(x_1)$ we choose any path from x_0 to x_1 and use parallel transport along that path. In particular, the vector field V^μ, defined in this way, will be covariantly constant or *parallel*, $\nabla_\mu V^\nu = 0$. We can also do this for four linearly independent vectors V_a^μ at x_0 and obtain four covariantly constant (parallel) vector fields which are linearly independent at every point.

An alternative way of saying or seeing this is the following: The integrability condition for the equation $\nabla_\mu V^\lambda = 0$ is

$$\nabla_\mu V^\lambda = 0 \;\;\Rightarrow\;\; [\nabla_\mu, \nabla_\nu] V^\lambda = R^\lambda_{\;\sigma\mu\nu} V^\sigma = 0 \;\; . \tag{11.16}$$

This means that the (4×4) matrices $M(\mu, \nu)$ with coefficients $M(\mu,\nu)^\lambda_{\;\sigma} = R^\lambda_{\;\sigma\mu\nu}$ have a zero eigenvalue. If this integrability condition is satisfied, a solution to $\nabla_\mu V^\lambda$ can be found. If one wants four linearly independent parallel vector fields, then the matrices $M(\mu, \nu)$ must have four zero eigenvalues, i.e. they are zero and therefore $R^\lambda_{\;\sigma\mu\nu} = 0$. If this condition is satisfied, all the integrability conditions are satisfied and there will be four linearly independent covariantly constant vector fields - the same conclusion as above.

We will now use this result in the proof, but for covectors instead of vectors. Clearly this makes no difference: if V^μ is a parallel vector field, then $g_{\mu\nu}V^\nu$ is a parallel covector field.

Fix some point x_0. At x_0, there will be an invertible matrix e^a_μ such that

$$g^{\mu\nu}(x_0) e^a_\mu e^b_\nu = \eta^{ab} \;\; . \tag{11.17}$$

Now we solve the equations

$$\nabla_\nu E^a_\mu = 0 \Leftrightarrow \partial_\nu E^a_\mu = \Gamma^\lambda{}_{\mu\nu} E^a_\lambda \tag{11.18}$$

with the initial condition $E^a_\mu(x_0) = e^a_\mu$. This gives rise to four linearly independent parallel covectors E^a_μ.

Now it follows from (11.18) that

$$\partial_\mu E^a_\nu = \partial_\nu E^a_\mu \quad . \tag{11.19}$$

Therefore locally there are four scalars ξ^a such that

$$E^a_\mu = \frac{\partial \xi^a}{\partial x^\mu} \quad . \tag{11.20}$$

These are already the flat coordinates we have been looking for. To see this, consider the expression $g^{\mu\nu} E^a_\mu E^b_\nu$. This is clearly constant because the metric and the E^a_μ are covariantly constant,

$$\partial_\lambda (g^{\mu\nu} E^a_\mu E^b_\nu) = \nabla_\lambda (g^{\mu\nu} E^a_\mu E^b_\nu) = 0 \quad . \tag{11.21}$$

At x_0, this is just the flat metric and thus

$$(g^{\mu\nu} E^a_\mu E^b_\nu)(x) = (g^{\mu\nu} E^a_\mu E^b_\nu)(x_0) = \eta^{ab} \quad . \tag{11.22}$$

Summing this up, we have seen that, starting from the assumption that the Riemann curvature tensor of a metric $g_{\mu\nu}$ is zero, we have proven the existence of coordinates ξ^a in which the metric takes the Minkowski form,

$$g_{\mu\nu} = \frac{\partial \xi^a}{\partial x^\mu} \frac{\partial \xi^b}{\partial x^\nu} \eta_{ab} \quad . \tag{11.23}$$

The argument given above is local in the sense that the existence of these coordinates ξ^a is only guaranteed locally, i.e. in the neighbourhood of some point. Whether or not these coordinates can be used to cover the space-time globally depends on gobal (topological) properties of the space-time which are not captured by the intrinsic local and locally determined Riemann tensor.

For example, imagine starting with Minkowski space $\mathbb{R}^{1,3}$ with inertial coordinates ξ^a, and then making a periodic identification of ξ^1, say,

$$\xi^1 \sim \xi^1 + 2\pi L_1 \quad \Rightarrow \quad \mathbb{R}^{1,3} \to \mathbb{R}^{1,2} \times S^1 \quad . \tag{11.24}$$

Since the Minkowksi metric is translation-invariant, it gives rise to a well-defined metric on the periodically identified space-time, and the metric of this space-time still has zero curvature tensor. Nevertheless, in this case

- in the new space-time the coordinate ξ^1, which is now an angular variable, is not globally well defined,
- and the space-time looks like Minkowski space only locally, not globally.

11.3 CURVATURE OF SURFACES: EULER, GAUSS(-BONNET) AND LIOUVILLE

We can generalise the example of the curvature of the 2-sphere, discussed in section 8.6, somewhat, in this way connecting our considerations with the classical realm of the differential geometry of surfaces, in particular with the *Gauss Curvature*, the *Euler characteristic*, the *Gauss-Bonnet* theorem and the *Liouville Equation*.

For any 2-dimensional metric g_{ab} it is a simple exercise to derive the relation between the one independent component, say R_{1212}, of the Riemann tensor, and the scalar curvature. First of all, the Ricci tensor is

$$R_{ab} = R^c{}_{acb} = R^1{}_{a1b} + R^2{}_{a2b} \tag{11.25}$$

so that the scalar curvature is

$$R(g_{ab}) = g^{ab}R_{ab} = g^{11}R^2{}_{121} + g^{12}R^1{}_{112} + g^{21}R^2{}_{221} + g^{22}R^1{}_{212} \ . \tag{11.26}$$

Using the fact that in 2 dimensions the components of the inverse metric are explicitly given by

$$\left(g^{ab}\right) = \frac{1}{g_{11}g_{22} - g_{12}g_{21}} \begin{pmatrix} g_{22} & -g_{12} \\ -g_{21} & g_{11} \end{pmatrix} \tag{11.27}$$

and the (anti-)symmetry properties (1) and (2) of the Riemann tensor, one finds

$$R(g_{ab}) = \frac{2}{g_{11}g_{22} - g_{12}g_{21}} R_{1212} \ . \tag{11.28}$$

This is precisely the relation (8.44) between the Riemann tensor and Ricci scalar. The factor of 2 in this equation is a consequence of our (and the conventional) definition of the Riemann curvature tensor, and is responsible for the fact that the scalar curvature of the unit 2-sphere is $R = +2$. We can also write this result as

$$R_{abcd} = \tfrac{1}{2}(g_{ac}g_{bd} - g_{ad}g_{bc})R \quad \Leftrightarrow \quad R^a{}_{bcd} = \tfrac{1}{2}(\delta^a{}_c g_{bd} - \delta^a{}_d g_{bc})R \ . \tag{11.29}$$

In two dimensions, it is often convenient and natural to absorb this ubiquitous factor of 2 into the definition of the (scalar) curvature, and what one then gets is the classical Gauss Curvature

$$K := \frac{1}{2}R(g_{ab}) \tag{11.30}$$

of a two-dimensional surface.

It follows from (11.29) that the Ricci tensor is related to the Ricci scalar by

$$R_{ab} = (R/2)g_{ab} = K g_{ab} \ . \tag{11.31}$$

This generalises the result for the standard metric on the 2-sphere found by explicit calculation in section 8.6. It shows that in complete generality the Ricci tensor of a two-dimensional space or space-time, thought of as the linear map

$$R^a_{\ b} = K\delta^a_{\ b} : \quad v^a \mapsto R^a_{\ b}\, v^b \ , \tag{11.32}$$

has only one (double) eigenvalue, namely the Gauss curvature K. It can also be interpreted as saying that in 2 dimensions the Einstein tensor (8.97) is identically zero,

$$G_{ab} = R_{ab} - \tfrac{1}{2} g_{ab} R = 0 \ . \tag{11.33}$$

We will now briefly look at two important and interesting consequences of the above formulae, one related to the Euler characteristic of a surface and its integral representation (the Gauss-Bonnet theorem), and the other to the Liouville equation describing metrics with constant Gauss curvauter $K = k = \pm 1$.

1. Euler Characteristic and the Gauss-Bonnet Theorem

   Let us consider a compact closed surface S, i.e. topologically something like a sphere, or a torus (a sphere with one handle), or a sphere with several handles. A surface S_h with h handles is called a surface of *genus h*.

   Given a metric on S_h, we can associate to S_h its area with respect to the metric,

   $$A(S_h) := \int_{S_h} \sqrt{g} d^2x \ . \tag{11.34}$$

   Clearly, this areas depends on a choice of metric, and under a variation δ_g of the metric it transforms as

   $$\delta_g A(S_h) = \int_{S_h} \delta_g \sqrt{g} d^2x = \tfrac{1}{2} \int_{S_h} \sqrt{g} d^2x \ g^{ab} \delta g_{ab} \ . \tag{11.35}$$

   Given a metric on S_g, we can also naturally associate to it the real number

   $$\chi(S_h) = \frac{1}{2\pi} \int \sqrt{g} d^2x \ K = \frac{1}{4\pi} \int \sqrt{g} d^2x \ R \ . \tag{11.36}$$

   Remarkably, this number turns out to be independent of the metric, in particular *$\chi(S_h)$ is invariant under variations of the metric g_{ab}*,

   $$\delta_g \chi(S_h) = 0 \ . \tag{11.37}$$

   Here are two rather explicit ways of establishing this remarkable result:

   (a) The variation of the integrand is

   $$\delta_g(\sqrt{g} R) = \delta_g(\sqrt{g} g^{ab} R_{ab}) \ . \tag{11.38}$$

   Since $R = g^{ab} R_{ab}$, it is convenient to express variations of the metric in terms of variations of the inverse metric, with (5.85)

   $$\delta \sqrt{g} = \tfrac{1}{2} g^{ab} \delta g_{ab} = -\tfrac{1}{2} g_{ab} \delta g^{ab} \ . \tag{11.39}$$

Then one finds

$$\begin{aligned}\delta_g(\sqrt{g}R) &= (\delta_g\sqrt{g})g^{ab}R_{ab} + \sqrt{g}(\delta g^{ab})R_{ab}) + \sqrt{g}g^{ab}\delta_g R_{ab} \\ &= \sqrt{g}(-\tfrac{1}{2}Rg_{ab} + R_{ab})\delta g^{ab} + \sqrt{g}g^{ab}\delta_g R_{ab} \\ &= \sqrt{g}G_{ab}\delta g^{ab} + \sqrt{g}g^{ab}\delta_g R_{ab} \quad .\end{aligned} \tag{11.40}$$

Now, as shown above, in 2 dimensions the Einstein tensor is identically zero, $G_{ab} = 0$. Moreover, in section 20.2 we will show that in any dimension the 2nd term is a total derivative (20.18),

$$g^{ab}\delta_g R_{ab} = \nabla_a B^a \tag{11.41}$$

for some well-defined B^a built from the covariant derivatives of the variations of the metric, as in (20.19). Taken together, these two facts imply that for a closed surface S_h (without boundary) one has

$$\delta_g\chi(S_h) = \frac{1}{4\pi}\int \sqrt{g}d^2x(G_{ab}\delta g^{ab} + \nabla_a B^a) = 0 \ \ , \tag{11.42}$$

as was to be shown.

(b) Alternatively, somewhat less covariantly but very explicitly, one can show that the integrand $\sqrt{g}K$ or $\sqrt{g}R$ can itself locally be written as a total derivative. Indeed, using (11.29) to write

$$R^1{}_{212} = \tfrac{1}{2}g_{11}R \quad \Leftrightarrow \quad K = \frac{1}{g_{11}}R^2{}_{121} \tag{11.43}$$

and simply writing out explicitly this Riemann curvature tensor component in terms of the Christoffel symbols,

$$R^2{}_{121} = \partial_2\Gamma^2{}_{11} - \partial_1\Gamma^2{}_{12} + \Gamma^2{}_{2a}\Gamma^a{}_{11} - \Gamma^2{}_{1a}\Gamma^a{}_{12} \ \ , \tag{11.44}$$

one finds that $\sqrt{g}K$ can be written as

$$\sqrt{g}K = \in^{ab}\partial_a\beta_b \tag{11.45}$$

with $\in^{12} = -\in^{21} = 1$ the Levi-Civita symbol, and

$$\beta_b = -\frac{\sqrt{g}}{g_{11}}\,\Gamma^2{}_{1b} \ \ . \tag{11.46}$$

The fact that the integrand is locally a total derivative does not mean that the integral is zero (because of the non-tensorial nature of β_a, which will typically exhibit coordinate singularities). It does mean however, that the integral of the metric variation of this expression is zero (because that is tensorial and well-defined on S_h),

$$\sqrt{g}K = \varepsilon^{ab}\partial_a\beta_b \quad \Rightarrow \quad \delta_g\chi(S_h) = \frac{1}{2\pi}\int d^2x\delta_g(\sqrt{g}K) = 0 \ \ . \tag{11.47}$$

Either way we have seen that the real number $\chi(S_h)$ is independent of the metric one uses to calculate it. For example, for $h = 0$ and for the standard metric on the sphere S^2 one finds

$$\chi(S_{h=0}) = \chi(S^2) = \frac{1}{4\pi}\int \sqrt{g}R = \frac{1}{2\pi}\int \sqrt{g} = 2 \ , \tag{11.48}$$

and this will therefore be the result for any metric on S^2. Likewise, for $h = 1$, i.e. a torus, by choosing the flat metric on T^2 (see e.g. the discussion and construction in section 18.1), one finds

$$\chi(S_{h=1}) = \chi(T^2) = 0 \ , \tag{11.49}$$

and this will therefore be the result for any metric on T^2 (and it is instructive to check this explicitly for the non-trivial, non-flat metric on T^2 induced by its embedding into $\mathbb{R}^3$ constructed in section 18.1). I am not aware of an equally elementary calculation to determine $\chi(S_h)$ for $h > 1$ in this way but fact of the matter is that

$$\chi(S_h) = 2 - 2h \tag{11.50}$$

is the *Euler characteristic* of S_h, which can also be defined purely combinatorially as the number

$$\chi(S) = n_F - n_E + n_V \tag{11.51}$$

of faces minus vertices plus edges of any cubist rendition of a surface S (and $\chi(S)$ is independent of such a cubist realisation or *triangulation*). The remarkable fact that this *topological invariant* of a surface S can be calculated in terms of differential geometric quantities, namely as the integral of the curvature scalar, is known as the *Gauss-Bonnet theorem.*

2. Constant Curvature and the Liouville Equation

   When we specialise the above to the class of *conformally flat* metrics with line element

$$ds^2 = \mathrm{e}^{2h(x,y)}(dx^2 + dy^2) \quad \Leftrightarrow \quad g_{ab} = \exp 2h(x,y)\delta_{ab} \tag{11.52}$$

   the calculation of the Riemann tensor is particularly simple and one finds the (easy to memorise) results

$$R^x{}_{yxy} = -\Delta h \tag{11.53}$$

   and

$$K = -\mathrm{e}^{-2h}\Delta h \tag{11.54}$$

   where $\Delta = \partial_x^2 + \partial_y^2$ is the 2-dimensional Laplacian with respect to the flat Euclidean metric $dx^2 + dy^2$. Thus a surface with *constant curvature* $K = k$ is given by a solution to the non-linear differential equation

$$\Delta h + k\mathrm{e}^{2h} = 0 \ . \tag{11.55}$$

This is the (in-)famous *Liouville equation*, which plays a fundamental role in many branches of mathematics (and mathematical physics).

In terms of the intrinsic Laplacian Δ_g associated to the metric g_{ab}, the Gaussian cuvature and the Liouville equation can also simply be written as

$$K = -\Delta_g h \qquad , \qquad \Delta_g h + k = 0 \ , \tag{11.56}$$

since, due to the peculiarities of 2 dimensions, $\sqrt{g}g^{ab}$ in independent of h, i.e. is conformally invariant (as we already observed in a different context in section 7.7, cf. (7.120)),

$$\begin{aligned} &\sqrt{g}g^{ab} = \mathrm{e}^{2h}\mathrm{e}^{-2h}\delta^{ab} = \delta^{ab} \\ \Rightarrow \quad &\Delta_g = \frac{1}{\sqrt{g}}\partial_a(\sqrt{g}g^{ab}\partial_b) = \frac{1}{\sqrt{g}}\partial_a(\delta^{ab}\partial_b) = \mathrm{e}^{-2h}\Delta \ . \end{aligned} \tag{11.57}$$

I will not attempt to say anything about the general (local) solution of this equation (which roughly speaking depends on an arbitrary meromorphic function of the complex coordinate $z = x + iy$), but close this section with some special (and particularly prominent) solutions of this equation.

(a) It is easy to see that

$$\mathrm{e}^{2h(x,y)} = y^{-2} \quad \Leftrightarrow \quad h(x,y) = -\ln y \tag{11.58}$$

solves the Liouville equation with $k = -1$. The corresponding space of constant negative curvature is the *Poincaré upper-half plane* model of the hyperbolic geometry,

$$ds^2 = \frac{dx^2 + dy^2}{y^2} \qquad (\ (x,y) \in \mathbb{R}^2,\ y > 0\ ) \ . \tag{11.59}$$

By the coordinate transformation $y = e^z$ this is mapped to the equivalent metric

$$ds^2 = dz^2 + \mathrm{e}^{-2z}dx^2 \tag{11.60}$$

on the entire (x, z)-plane.

(b) Another solution (for any k) is the rotationally invariant function

$$\mathrm{e}^{2h(x,y)} = 4(1 + k(x^2 + y^2))^{-2} \quad \Leftrightarrow \quad h = -\ln(1 + k(x^2 + y^2)) + \text{const.} \tag{11.61}$$

i. For $k = 0$ one finds the flat (zero curvature) Euclidean metric on $\mathbb{R}^2$.

ii. For $k = +1$, one obtains the metric

$$ds^2 = 4\frac{dx^2 + dy^2}{(1 + x^2 + y^2)^2} \ . \tag{11.62}$$

This is the constant positive curvature metric on the *Riemann sphere* one gets by stereographic projection of the standard metric on the two-sphere S^2 to the (x,y)-plane.

In terms of polar coordinates (r,ϕ) on the Euclidean plane, this metric takes the form

$$ds^2 = 4\frac{dr^2 + r^2 d\phi^2}{(1+r^2)^2} \quad , \tag{11.63}$$

and the further change of variables $r = \tan\theta/2$ shows that this is indeed the standard line element $d\Omega^2$ on the 2-sphere,

$$r = \tan\theta/2 \quad \Rightarrow \quad ds^2 = d\theta^2 + \sin^2\theta d\phi^2 = d\Omega^2 \quad . \tag{11.64}$$

Read backwards, this can also be read as the statement that via the above change of variables the Euclidean metric on $\mathbb{R}^2$ can be written as

$$dr^2 + r^2 d\phi^2 = \frac{(1+r(\theta)^2)^2}{4}(d\theta^2 + \sin^2\theta d\phi^2) = \frac{1}{4\cos^4\theta/2}d\Omega^2 \quad . \tag{11.65}$$

In this process the points "at infinity" in $\mathbb{R}^2$ (where $r \to \infty$) are mapped to the south pole $\theta = \pi$ of the sphere (where the conformal factor in front of the line element of the sphere diverges accordingly). This exhibits S^2 as the *conformal compactification* of $\mathbb{R}^2$.

iii. For $k = -1$, one finds

$$ds^2 = 4\frac{dx^2 + dy^2}{(1-(x^2+y^2))^2} \qquad (\ \{x,y\} \in \mathbb{R}^2, x^2+y^2 < 1\ ) \quad . \tag{11.66}$$

This is the *Poincaré disc* model of the hyperbolic geometry, defined in the interior of the unit disc in $\mathbb{R}^2$. In terms of polar coordinates, it can also be written as

$$ds^2 = 4\frac{dr^2 + r^2 d\phi^2}{(1-r^2)^2} \qquad (\ 0 \leq r < 1\ ) \tag{11.67}$$

The two metrics (11.59) and (11.66) are isometric, i.e. related by a (albeit not completely evident) coordinate transformation.

(c) As our final example, one other solution (given here only for $k = -1$) is

$$\mathrm{e}^{2h(x,y)} = \mathrm{e}^{2h(x)} = 4\frac{\mathrm{e}^{2x}}{(1-\mathrm{e}^{2x})^2} \quad . \tag{11.68}$$

This leads to the form (2.31) of the unit metric on H^2,

$$ds^2 = d\sigma^2 + \sinh^2\sigma\ d\phi^2 \quad . \tag{11.69}$$

Indeed, we can write this in conformally flat form as

$$ds^2 = \sinh^2\sigma(x)(dx^2 + d\phi^2) \tag{11.70}$$

where

$$x = \log\tanh(\sigma/2) \quad \Rightarrow \quad dx = d\sigma/\sinh\sigma \ . \tag{11.71}$$

Performing the exponential / hyperbolic gymnastics required to write the conformal factor $\sinh^2\sigma$ as a function of x, one finds

$$\sinh^2\sigma(x) = 4\frac{\mathrm{e}^{2x}}{(1-\mathrm{e}^{2x})^2} \ , \tag{11.72}$$

giving rise to the solution given in (11.68).

It is worth remarking that the Poincaré upper-half plane model of a space with constant negative curvature readily generalises to arbitrary dimensions and signature. Thus

$$ds^2 = \frac{d\vec{x}^2 + dy^2}{y^2} \quad , \quad d\vec{x}^2 = \delta_{ab}dx^a dx^b \quad \text{or} \quad d\vec{x}^2 = \eta_{ab}dx^a dx^b \tag{11.73}$$

is the metric of a $D = (d+1)$-dimensional space(-time) with constant negative curvature.

The Lorentzian metric will reappear later as a solution to the Einstein equations with a negative cosmological constant, and is in this context known as the *anti-de Sitter metric* (in Poincaré coordinates, which cover only a part of the complete space-time), and we will discuss this solution in some detail in section 39.

11.4 THE WEYL TENSOR AND ITS USES

In section 8 from the Riemann tensor we have extracted its traces, the Ricci tensor and the Ricci scalar, as well as a particular linear combination of them, the Einstein tensor. We can therefore also explicitly decompose the Riemann tensor into these trace parts and the remaining traceless part.

We noted in section 8.5 that for $D = 2$ and $D = 3$ the Riemann tensor would be "pure trace", i.e. could be written entirely in terms of the Ricci tensor and Ricci scalar. For $D = 2$ we have already established this explicitly by proving the relation (11.29),

$$D = 2: \quad R_{\alpha\beta\gamma\delta} = \tfrac{1}{2}(g_{\alpha\gamma}g_{\beta\delta} - g_{\alpha\delta}g_{\beta\gamma})R \tag{11.74}$$

in section 11.3.

We now look at this issue for $D \geq 3$. Simply by linear algebra one finds, for $D \geq 3$, the decomposition

$$\begin{aligned} R_{\mu\nu\rho\sigma} &= C_{\mu\nu\rho\sigma} \\ &+ \frac{1}{D-2}(g_{\mu\rho}R_{\nu\sigma} + R_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}R_{\mu\sigma} - R_{\nu\rho}g_{\mu\sigma}) \\ &- \frac{1}{(D-1)(D-2)}R(g_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}g_{\mu\sigma}) \ . \end{aligned} \tag{11.75}$$

This definition is such that $C_{\mu\nu\rho\sigma}$ has all the symmetries of the Riemann tensor (this is manifest) and such that all of its traces are zero, i.e.

$$C^{\mu}_{\ \nu\mu\sigma} = 0 \ , \tag{11.76}$$

as is easily verified. This traceless part $C_{\mu\nu\rho\sigma}$ of the Riemann tensor is called the *Weyl tensor*.

Occasionally it is more convenient and transparent to decompose the Riemann tensor not into the Weyl tensor, the Ricci tensor and the Ricci scalar, but to perform an orthogonal decomposition (with respect to the metric) into the Weyl tensor, the traceless part $S_{\mu\nu}$ of the Ricci tensor,

$$S_{\mu\nu} = R_{\mu\nu} - \frac{1}{D} g_{\mu\nu} R \ , \tag{11.77}$$

and the trace R. Then the decomposition becomes

$$\begin{aligned} R_{\mu\nu\rho\sigma} &= C_{\mu\nu\rho\sigma} \\ &\quad + \frac{1}{D-2}(g_{\mu\rho}S_{\nu\sigma} + S_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}S_{\mu\sigma} - S_{\nu\rho}g_{\mu\sigma}) \\ &\quad + \frac{1}{D(D-1)} R(g_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}g_{\mu\sigma}) \ . \end{aligned} \tag{11.78}$$

One other common and convenient decomposition is in terms of a tensor $P_{\mu\nu}$ such that (11.75) takes the form

$$R_{\mu\nu\rho\sigma} = C_{\mu\nu\rho\sigma} + (g_{\mu\rho}P_{\nu\sigma} + P_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}P_{\mu\sigma} - P_{\nu\rho}g_{\mu\sigma}) \ . \tag{11.79}$$

Comparison with (11.75) shows that this is accomplished by the choice

$$P_{\mu\nu} = \frac{1}{D-2}\left(R_{\mu\nu} - \frac{1}{2(D-1)} g_{\mu\nu} R\right) \ . \tag{11.80}$$

This tensor $P_{\mu\nu}$ is known as the *Schouten Tensor*.

Regardless of how we write the trace part of the Riemann tensor, it turns out that for $D = 3$ the Weyl tensor vanishes identically,

$$D = 3: \quad C_{\alpha\beta\gamma\delta} \equiv 0 \tag{11.81}$$

(I will give an elementary proof of this momentarily). Therefore, for $D = 3$ one has the decomposition

$$\begin{aligned} D = 3: \quad R_{\alpha\beta\gamma\delta} &= (g_{\alpha\gamma}R_{\beta\delta} + R_{\alpha\gamma}g_{\beta\delta} - g_{\alpha\delta}R_{\beta\gamma} - R_{\alpha\delta}g_{\beta\gamma}) \\ &\quad + \tfrac{1}{2}(g_{\alpha\delta}g_{\beta\gamma} - g_{\alpha\gamma}g_{\beta\delta})R \end{aligned} \tag{11.82}$$

This is precisely the result claimed previously in (8.45).

To establish (11.81), in order to trivialise the algebra let us fix a point x_0 and choose coordinates there such that $g_{\alpha\beta}(x_0) = \delta_{\alpha\beta}$ (or $\eta_{\alpha\beta}$, depending on the signature of the metric, but let us assume that we are in the case of Euclidean signature - the same argument works in the Lorentzian case). Now the proof consists of the following elementary steps:

- Since we are in $D = 3$, at least two of the indices in $C_{\alpha\beta\gamma\delta}$ must be equal. Since the Weyl tensor has all the symmetries of the Riemann tensor, if more than two indices are equal, the Weyl tensor component is zero. Thus we only need to consider the components where 2 indices are equal and we can without loss of generality choose these to be $C_{1\beta 1\delta}$, say, with $\beta, \delta \neq 1$.

- Because the Weyl tensor is traceless, one has the relation

  $$C_{1\beta 1\delta} = -C_{2\beta 2\delta} - C_{3\beta 3\delta} \quad . \tag{11.83}$$

  This implies that $C_{1213} = C_{1312} = 0$, so a non-zero component requires $\beta = \delta$.

- For $\beta = \delta$, one derives from this

  $$C_{1212} = -C_{3232} \quad \text{and} \quad C_{1313} = -C_{2323} \tag{11.84}$$

  and likewise for $\alpha = \gamma = 2$ and $\alpha = \gamma = 3$.

- Thus all in all the Weyl tensor can have only 3 independent non-zero components, namely $C_{1212} = C_{2121}, C_{1313} = C_{3131}, C_{2323} = C_{3232}$, and they are all required to be pairwise negatives of each other. This is impossible for non-trivial $C_{\alpha\beta\gamma\delta}$,

  $$C_{1212} = -C_{3232} = +C_{3131} = -C_{2121} = -C_{1212} \quad \Rightarrow \quad C_{1212} = 0 \ , \tag{11.85}$$

  and implies that all of the components of the Weyl tensor are identically zero in $D = 3$.

Thus the Weyl tensor is only non-trivial for $D \geq 4$. Using the Bianchi identies discussed in section 8.8, in particular also (8.94),

$$\nabla^\mu R_{\mu\nu\rho\sigma} = \nabla_\rho R_{\nu\sigma} - \nabla_\sigma R_{\nu\rho} \tag{11.86}$$

from (11.75) one finds a simple expression for the divergence, namely

$$\nabla^\mu C_{\mu\nu\rho\sigma} = (D-3)\left(\nabla_\rho P_{\nu\sigma} - \nabla_\sigma P_{\nu\rho}\right) \quad . \tag{11.87}$$

The tensor appearing on the right-hand side also has its own name. It is called the *Cotton Tensor* $C_{\nu\rho\sigma}$,

$$C_{\nu\rho\sigma} = \nabla_\rho P_{\nu\sigma} - \nabla_\sigma P_{\nu\rho} \quad . \tag{11.88}$$

The content of (11.87) is evidently trivial in $D = 3$, but the Cotton tensor itself is not (and I will briefly come back to this below).

The Weyl tensor plays an important role in many aspects of gravitational physics:

1. For example, the Weyl tensor has traditionally been one of the central objects of interest in the invariant algebraic classification of gravitational fields and in

the characterisation of what are known as algebraically special solutions to the Einstein equations (the so-called *Petrov classification* and related procedures). Originally, this was (of course) developed for $D = 4$, and this case has a number of special features. It is based on the classification of the properties of the eigenvalues λ of the Weyl tensor (at a point x_0), thought of as a map on the space of anti-symmetric $(2,0)$-tensors (*bivectors*),

$$\tfrac{1}{2}C^{\alpha\beta}{}_{\gamma\delta}X^{\gamma\delta} = \lambda X^{\alpha\beta} \tag{11.89}$$

or

$$C^A_B X^B = \lambda X^A \tag{11.90}$$

with $C_{\alpha\beta\gamma\delta} \equiv C_{AB}$ thought of as a symmetric (6×6) matrix.[26]

An equivalent (as it turns out) classification arises from determining the number and multiplicity of linearly independent null vectors ℓ satisfying the condition

$$\ell_{[\gamma}C_{\alpha]\mu\nu[\beta}\ell_{\delta]}\ell^\mu\ell^\nu = 0 \ . \tag{11.91}$$

Such ℓ^α are called the *principal null directions* of the Weyl tensor. More recently, this classification scheme (based on the latter approach) has been (partially) extended to higher dimensions.[27]

2. As we will see in section 19.6, the Einstein equations imply that the Weyl tensor describes the gravitational field in vacuum. Specifically, when (or where) the energy-momentum tensor is zero, the Riemann curvature tensor is equal to the Weyl tensor,

$$T_{\alpha\beta}(x) = 0 \quad \Rightarrow \quad R_{\alpha\beta\gamma\delta}(x) = C_{\alpha\beta\gamma\delta}(x) \ . \tag{11.92}$$

The Weyl tensor thus encodes the information about things like gravitational waves and the asymptotic behaviour of a gravitational field and has been studied extensively from this point of view.

3. In the presence of matter, on the other hand, (11.87), in conjunction with the Einstein equations, becomes an evolution equation for these vacuum components of the gravitational field in terms of the sources - see equations (19.57) and (19.58).

The Weyl tensor also plays an important role in geometry, as it is *conformally invariant*, i.e. $C^\mu_{\nu\rho\sigma}$ is invariant under conformal (Weyl) rescalings of the metric,

$$g_{\mu\nu}(x) \to \mathrm{e}^{2f(x)}g_{\mu\nu}(x) \quad \Rightarrow \quad C^\mu_{\ \nu\rho\sigma} \to C^\mu_{\ \nu\rho\sigma} \ , \tag{11.93}$$

equivalently

$$g_{\mu\nu}(x) \to \mathrm{e}^{2f(x)} g_{\mu\nu}(x) \quad \Rightarrow \quad C_{\mu\nu\rho\sigma} \to \mathrm{e}^{2f(x)} C_{\mu\nu\rho\sigma} \ . \tag{11.94}$$

In particular, the Weyl tensor is zero if the metric is *conformally flat*, i.e. related by a conformal transformation to the flat metric $\eta_{\mu\nu}$ (of any signature),

$$g_{\mu\nu}(x) = \mathrm{e}^{2f(x)} \eta_{\mu\nu}(x) \quad \Rightarrow \quad C^{\mu}_{\ \nu\rho\sigma} = 0 \ . \tag{11.95}$$

This can be established by brute force calculation and is not *per se* particularly enlightning.

Conversely for $D \geq 4$ vanishing of the Weyl tensor is also a sufficient condition for a metric to be (locally) conformal to the flat metric. This is a non-trivial result because at face value one seems to obtain a completely overdetermined system of equations for the single function f, of the form

$$P_{\mu\nu} = \{\text{1st and 2nd derivatives of } f\}_{\mu\nu} \ . \tag{11.96}$$

However, it turns out that the integrability conditions for this system of equations are equivalent to the vanishing of the Weyl tensor, and then a variant of the *Frobenius integrability theorem* (mentioned in a different context in section 15.5) can be used to establish the local existence of a solution f.

For $D = 3$, the situation is slightly (but not fundamentally) different. We see from (11.88) that for any $D \geq 4$ conformal flatness implies vanishing of the Cotton tensor. It turns out that for $D = 3$ the Cotton tensor takes over the role of the Weyl tensor (which, as proven above, is itself trivial for $D = 3$), i.e. one has the statement that for $D = 3$ a metric is (locally) conformally flat if and only if the Cotton tensor vanishes.

11.5 Generalisations: Torsion and Non-Metricity

In section 5.4 we had seen that the Levi-Civita connection (defined by the Christoffel symbols) is characterised by the fact that

1. the metric is covariantly constant, $\nabla_\mu g_{\nu\lambda} = 0$, and
2. the torsion is zero, i.e. the second covariant derivatives of a scalar commute.

It is of course possible to relax either of the conditions (1) or (2), or both of them and, in particular, connections with torsion (relaxation of condition 2) are popular in certain circles and/or arise naturally in certain generalised (gauge) theories of gravity and in string theory.

To discuss this a bit more systematically, we consider a general connection

$$\tilde{\Gamma}^{\mu}_{\ \nu\lambda} = \Gamma^{\mu}_{\ \nu\lambda} + C^{\mu}_{\ \nu\lambda} \tag{11.97}$$

with $\Gamma^{\mu}_{\ \nu\lambda}$ the canonical Levi-Civita connection, and $C^{\mu}_{\ \nu\lambda}$ a $(1,2)$-tensor. We will also use the corresponding $(0,3)$-tensor

$$C_{\mu\nu\lambda} = g_{\mu\rho} C^{\rho}_{\ \nu\lambda} \quad . \tag{11.98}$$

Associated with $\tilde{\Gamma}^{\mu}_{\ \nu\lambda}$ we have the covariant derivative $\tilde{\nabla}_{\mu}$. Since $\tilde{\Gamma}^{\mu}_{\ \nu\lambda}$ will in general not be symmetric in its lower indices, in this section we need to be particularly careful with (and choose a convention for) the ordering of the lower indices in the covariant derivative. We will choose the convention that the last index always refers to the direction along which one is differentiating, i.e.

$$\tilde{\nabla}_{\mu} V^{\nu} = \partial_{\mu} V^{\nu} + \tilde{\Gamma}^{\nu}_{\ \lambda\mu} V^{\lambda} \tag{11.99}$$

etc. The reason for this choice is that one should think of the collection of objects $\Gamma^{\nu}_{\ \lambda\mu}$ (and $\tilde{\Gamma}^{\nu}_{\ \lambda\mu}$) as the coefficients of a matrix-valued 1-form (cf. section 4.6) $\Gamma^{\nu}_{\ \lambda} = \Gamma^{\nu}_{\ \lambda\mu} dx^{\mu}$, the matrices acting by rotation on vectors (and more general tensors), as in (5.21).

We now define the *torsion tensor* $T^{\lambda}_{\mu\nu}$ by

$$[\tilde{\nabla}_{\mu}, \tilde{\nabla}_{\nu}]\phi = T^{\lambda}_{\mu\nu} \partial_{\lambda}\phi \quad , \quad T_{\lambda\mu\nu} = g_{\lambda\rho} T^{\rho}_{\ \mu\nu} \quad , \tag{11.100}$$

and the *non-metricity tensor* $Q_{\nu\lambda\mu}$ by

$$\tilde{\nabla}_{\mu} g_{\nu\lambda} = -Q_{\nu\lambda\mu} \quad . \tag{11.101}$$

In terms of the $C^{\mu}_{\ \nu\lambda}$ these tensors can be written as

$$\begin{aligned} T_{\lambda\mu\nu} &= C_{\lambda\mu\nu} - C_{\lambda\nu\mu} = 2C_{\lambda[\mu\nu]} \\ Q_{\nu\lambda\mu} &= C_{\nu\lambda\mu} + C_{\lambda\nu\mu} = 2C_{(\nu\lambda)\mu} \quad . \end{aligned} \tag{11.102}$$

Thus the torsion is zero iff $C^{\lambda}_{\mu\nu}$ (and hence $\tilde{\Gamma}^{\lambda}_{\mu\nu}$) is symmetric in its lower indices, and the connection is compatible with the metric iff $C_{\nu\lambda\mu}$ is anti-symmetric in its first two indices. In particular, if the torsion is zero and the connection is metric-compatible, one has

$$C_{\lambda\mu\nu} = C_{\lambda\nu\mu} \quad \text{and} \quad C_{\lambda\mu\nu} = -C_{\mu\lambda\nu} \quad \Rightarrow \quad C_{\lambda\mu\nu} = 0 \quad , \tag{11.103}$$

as one can see by the gymnastics

$$C_{\lambda\mu\nu} = C_{\lambda\nu\mu} = -C_{\nu\lambda\mu} = -C_{\nu\mu\lambda} = C_{\mu\nu\lambda} = C_{\mu\lambda\nu} = -C_{\lambda\mu\nu} \quad . \tag{11.104}$$

Conversely, since the absence of torsion and non-metricity characterises the Levi-Civita connection, it should be possible to express the deviation $C_{\lambda\mu\nu}$ from the Levi-Civita connection entirely in terms of torsion and non-metricity. This is indeed the case. By repeating the calculation (5.44) in this more general context, one finds

$$2C_{\lambda(\mu\nu)} = Q_{\nu\lambda\mu} + Q_{\mu\lambda\nu} - Q_{\mu\nu\lambda} - T_{\mu\lambda\nu} - T_{\nu\lambda\mu} \quad . \tag{11.105}$$

Combining this with $2C_{\lambda[\mu\nu]} = T_{\lambda\mu\nu}$, one obtains

$$\begin{aligned} C_{\lambda\mu\nu} &= \tfrac{1}{2}(T_{\lambda\mu\nu} - T_{\mu\lambda\nu} - T_{\nu\lambda\mu}) + \tfrac{1}{2}(Q_{\mu\lambda\nu} + Q_{\nu\lambda\mu} - Q_{\mu\nu\lambda}) \\ &\equiv \tilde{T}_{\lambda\mu\nu} + \tilde{Q}_{\lambda\mu\nu} \;\;, \end{aligned} \tag{11.106}$$

with

$$\tilde{T}_{\lambda\mu\nu} = \tfrac{1}{2}(T_{\lambda\mu\nu} - T_{\mu\lambda\nu} - T_{\nu\lambda\mu}) = -\tilde{T}_{\mu\lambda\nu} \tag{11.107}$$

and

$$\tilde{Q}_{\lambda\mu\nu} = \tfrac{1}{2}(Q_{\mu\lambda\nu} + Q_{\nu\lambda\mu} - Q_{\mu\nu\lambda}) = \tilde{Q}_{\lambda\nu\mu} \;\;. \tag{11.108}$$

Thus we can now split a general connection more informatively into the 3 pieces

$$\tilde{\Gamma}^{\lambda}_{\ \mu\nu} = \Gamma^{\lambda}_{\ \mu\nu} + \tilde{T}^{\lambda}_{\ \mu\nu} + \tilde{Q}^{\lambda}_{\ \mu\nu} \;\;. \tag{11.109}$$

REMARKS:

1. The tensor $\tilde{T}_{\lambda\mu\nu}$ is known as the *contorsion tensor* (frequently (mis-)spelled as "contortion" tensor). I am not aware of a commonly used name for $\tilde{Q}_{\lambda\mu\nu}$, and will not try to invent one. The contorsion tensor is the linear combination of components of the torsion tensor that appear as the connection coefficents of a general metric-compatible connection with torsion,

   $$Q_{\lambda\mu\nu} = 0 \quad \Rightarrow \quad \tilde{\Gamma}^{\lambda}_{\ \mu\nu} = \Gamma^{\lambda}_{\ \mu\nu} + \tilde{T}^{\lambda}_{\ \mu\nu} \;\;. \tag{11.110}$$

   In general it can have both symmetric and anti-symmetric components,

   $$\tilde{T}_{\lambda(\mu\nu)} = -\tfrac{1}{2}(T_{\mu\lambda\nu} + T_{\nu\lambda\mu}) = T_{(\mu\nu)\lambda} \quad , \quad \tilde{T}^{\lambda}_{\ [\mu\nu]} = \tfrac{1}{2}T^{\lambda}_{\ \mu\nu} \;\;, \tag{11.111}$$

   but it cannot be symmetric (if the contorsion were symmetric, the torsion, and hence the contorsion, would be zero). If its symmetric part vanishes, then $\tilde{T}_{\lambda\mu\nu}$ is completely anti-symmetric,

   $$\tilde{T}^{\lambda}_{\ (\mu\nu)} = 0 \quad \Rightarrow \quad \tilde{T}_{\lambda\mu\nu} = \tilde{T}_{[\lambda\mu\nu]} \;\;. \tag{11.112}$$

2. Since $\Gamma_{\lambda\mu\nu}$ contains a part that is antisymmetric in the first 2 indices,

   $$\Gamma_{\lambda\mu\nu} = \tfrac{1}{2}g_{\lambda\mu,\nu} + \tfrac{1}{2}(g_{\nu\lambda,\mu} - g_{\nu\mu,\lambda}) \;\;, \tag{11.113}$$

   one might be tempted to think that that part can be cancelled (or absorbed) by a metric-compatible $C_{\lambda\mu\nu} = C_{[\lambda\mu]\nu}$, so that a very simple metric-compatible connection would be

   $$\tilde{\Gamma}_{\lambda\mu\nu} \overset{?}{=} \tfrac{1}{2}g_{\lambda\mu,\nu} \quad , \quad \tilde{\Gamma}^{\lambda}_{\ \mu\nu} \overset{?}{=} \tfrac{1}{2}g^{\lambda\rho}g_{\rho\mu,\nu} \;\;. \tag{11.114}$$

   However, the term that one has cancelled (or absorbed) is *not* a tensor. Therefore, this candidate "connection" does not transform as (and therefore does not qualify as) a connection and cannot be used to define a covariant derivative.

3. In general, for a connection $\tilde{\nabla}$, the notions of autoparallels (section 5.8),

$$\tilde{\nabla}_\tau X^\mu = 0 \quad \Leftrightarrow \quad \ddot{x}^\mu + \tilde{\Gamma}^\mu_{\ \nu\lambda}\dot{x}^\nu \dot{x}^\lambda = 0 \ , \tag{11.115}$$

(i.e. curves characterised by the fact that their tangent vectors are parallel transported along the curve - this depends on a choice of connection) no longer coincides with the notion of geodesics (which are obtained by extremising proper time or distance, and which always lead to the Levi-Civita connection). However, this difference disappears if $C^\mu_{\ \nu\lambda}$ happens to be anti-symmetric in its lower indices (e.g. for a metric-compatible connection with totally anti-symmetric contorsion tensor), as one then has

$$\ddot{x}^\mu + \tilde{\Gamma}^\mu_{\ \nu\lambda}\dot{x}^\nu \dot{x}^\lambda = \ddot{x}^\mu + \Gamma^\mu_{\ \nu\lambda}\dot{x}^\nu \dot{x}^\lambda \ . \tag{11.116}$$

We have defined the Riemann tensor via the commutator of covariant derivatives (8.2)

$$[\nabla_\mu, \nabla_\nu]V^\lambda = R^\lambda_{\ \sigma\mu\nu}V^\sigma \tag{11.117}$$

associated to the Levi-Civita connection (Christoffel symbols), or, equivalently, by the relation (8.5) (now being careful with the positioning of the lower indices)

$$R^\lambda_{\ \sigma\mu\nu} = \partial_\mu \Gamma^\lambda_{\ \sigma\nu} - \partial_\nu \Gamma^\lambda_{\ \sigma\mu} + \Gamma^\lambda_{\ \rho\mu}\Gamma^\rho_{\ \sigma\nu} - \Gamma^\lambda_{\ \rho\nu}\Gamma^\rho_{\ \sigma\mu} \ . \tag{11.118}$$

In order to show explicitly (rather than by appealing to (11.117)) that this transforms as a tensor, all that one needs is the characteristic non-tensorial transformation behaviour of the Christoffel symbols $\Gamma^\lambda_{\ \mu\nu}$. As discussed in section 5.4 and above, an arbitrary connection $\tilde{\Gamma}^\lambda_{\ \mu\nu}$ that can be used to define a tensorial covariant derivative has the same non-tensorial transformation behaviour. Therefore

$$\tilde{R}^\lambda_{\ \sigma\mu\nu} \equiv R^\lambda_{\ \sigma\mu\nu}(\tilde{\Gamma}) = \partial_\mu \tilde{\Gamma}^\lambda_{\ \sigma\nu} - \partial_\nu \tilde{\Gamma}^\lambda_{\ \sigma\mu} + \tilde{\Gamma}^\lambda_{\ \rho\mu}\tilde{\Gamma}^\rho_{\ \sigma\nu} - \tilde{\Gamma}^\lambda_{\ \rho\mu}\tilde{\Gamma}^\rho_{\ \sigma\mu} \tag{11.119}$$

defines a tensor for any connection, namely the curvature tensor of the connection $\tilde{\Gamma}^\lambda_{\ \mu\nu}$. It is related to the commutator of covariant derivatives by

$$[\tilde{\nabla}_\mu, \tilde{\nabla}_\nu]V^\lambda = \tilde{R}^\lambda_{\ \sigma\mu\nu}V^\sigma + (\tilde{\Gamma}^\rho_{\ \mu\nu} - \tilde{\Gamma}^\rho_{\ \nu\mu})\nabla_\rho V^\lambda = \tilde{R}^\lambda_{\ \sigma\mu\nu}V^\sigma + T^\rho_{\mu\nu}\nabla_\rho V^\lambda \ , \tag{11.120}$$

where $T^\rho_{\mu\nu}$ is the torsion tensor. As before, one can also define the Ricci tensor and Ricci scalar by

$$\tilde{R}_{\mu\nu} \equiv R_{\mu\nu}(\tilde{\Gamma}) = \tilde{R}^\lambda_{\ \mu\lambda\nu} \quad , \quad \tilde{R} \equiv R(\tilde{\Gamma}) = g^{\mu\nu}\tilde{R}_{\mu\nu} \ . \tag{11.121}$$

However, it is crucial to keep in mind that the symmetry properties and Bianchi identities satisfied by these generalised curvature tensors will in general differ from those of the Riemann-Christoffel tensor. This should be clear from the way we derived the symmetries of the Riemann tensor in section 8.3, where we related the symmetries to the properties (metricity, no torsion) that characterise the canonical Levi-Civita connection (Christoffel symbols). For example, in general the Ricci tensor will not be symmetric, the Bianchi identity $R_{\alpha[\beta\gamma\delta]} = 0$ will be replaced by an identity relating $\tilde{R}_{\alpha[\beta\gamma\delta]}$ to the torsion (and its covariant derivative), etc.[28]

---

[28] For more on this and related topics, see e.g. section 1 of T. Ortin, *Gravity and Strings*.

12 CURVATURE III: CURVATURE AND GEODESIC CONGRUENCES

In section 8.4 we had already encountered the so-called *geodesic deviation equation* (8.38),

$$(D_\tau)^2 \delta x^\mu = R^\mu_{\ \nu\lambda\rho} \dot{x}^\nu \dot{x}^\lambda \delta x^\rho \quad , \tag{12.1}$$

describing the evolution of a separation (or deviation) vector along a given geodesic. In this section we will rederive this result in a more satisfactory and covariant manner and also use the same covariant framework to discuss the extension of these results to the so-called *Raychaudhuri equation*, which descibes the focussing properties of congruences of geodesics.

12.1 COVARIANT DERIVATION OF THE GEODESIC DEVIATION EQUATION

The starting point is a geodesic with tangent vector field u^α,

$$u^\beta \nabla_\beta u^\alpha = 0 \quad , \tag{12.2}$$

and a deviation vector field $\delta x^\alpha = \xi^\alpha$ characterised by the condition

$$[u, \xi]^\alpha = u^\beta \nabla_\beta \xi^\alpha - \xi^\beta \nabla_\beta u^\alpha = 0 \quad \Leftrightarrow \quad D_\tau \xi^\alpha = \xi^\beta \nabla_\beta u^\alpha \quad . \tag{12.3}$$

The rationale for this condition is that, if $x^\alpha(\tau, s)$ is a family of geodesics labelled by s, one has the identifications

$$u^\alpha = \frac{\partial}{\partial \tau} x^\alpha(\tau, s) \quad , \quad \xi^\alpha = \frac{\partial}{\partial s} x^\alpha(\tau, s) \quad . \tag{12.4}$$

Since second partial derivatives commute, this implies the relation

$$\frac{\partial}{\partial \tau} \xi^\alpha(\tau, s) = \frac{\partial}{\partial s} u^\alpha(\tau, s) \quad , \tag{12.5}$$

(implicit in the identification $\delta \dot{x} = (d/d\tau)\delta x$ employed in the derivation in section 8.4). Condition (12.3) is nothing other than the covariant way of writing (12.5).

Introducing the tensor

$$B_{\alpha\beta} = \nabla_\beta u_\alpha \tag{12.6}$$

we can write (12.3) as

$$D_\tau \xi^\alpha = B^\alpha_{\ \beta} \xi^\beta \quad , \tag{12.7}$$

so the matrix $B_{\alpha\beta}$ describes the evolution and deformation of the deviation vector ξ^α along the geodesic. Because u^α is affinely geodesic, it satisfies

$$B_{\alpha\beta} u^\beta = u^\beta \nabla_\beta u_\alpha = 0 \tag{12.8}$$

and

$$u^\alpha B_{\alpha\beta} = \tfrac{1}{2} \nabla_\beta (u^\alpha u_\alpha) = 0 \quad , \tag{12.9}$$

and is thus transverse to u^α. This is a crucial property we will come back to in the discussion of the Raychaudhuri equation below. As a consequence one has

$$u_\alpha D_\tau \xi^\alpha = 0 \tag{12.10}$$

(i.e. $D_\tau \xi^\alpha$ is transverse to u^α) and therefore

$$\frac{d}{d\tau}(u_\alpha \xi^\alpha) = D_\tau(u_\alpha \xi^\alpha) = u_\alpha D_\tau \xi^\alpha = 0 \ . \tag{12.11}$$

This means that the u-component of a geodesic deviation vector ξ in the sense of $u_\alpha \xi^\alpha$ is simply constant and contains no interesting information about the geodesic itself.

In the timelike case this means that a vector of the form $\xi^\alpha = \xi u^\alpha$ is a deviation vector only if ξ is constant, and then ξ^α is simply a translation along the geodesic and therefore not a deviation vector of interest (and certainly anyhow not a vector of the kind one has in mind when thinking about a deviation vector, which should point away from the geodesic). In the null case, the interpretation is slightly different (and we will return to this in section 12.4), but the fact that $u_\alpha \xi^\alpha$ is simply constant for a deviation vector remains, and we can without loss of information choose the deviation vector to satisfy the condition $\xi^\alpha u_\alpha = 0$.

Given this set-up, we now want to calculate

$$\begin{aligned}(D_\tau)^2 \xi^\alpha &= (D_\tau B^\alpha_{\ \beta})\xi^\beta + B^\alpha_{\ \beta} D_\tau \xi^\beta \\ &= (D_\tau B^\alpha_{\ \gamma} + B^\alpha_{\ \beta} B^\beta_{\ \gamma})\xi^\gamma \ .\end{aligned} \tag{12.12}$$

Note that, along with $D_\tau \xi^\alpha$, also $D_\tau^2 \xi^\alpha$ is automatically transverse to u^α, $u_\alpha D_\tau^2 \xi^\alpha = 0$, regardless of whether or not one imposes the condition $\xi^\alpha u_\alpha = 0$.

For the term in brackets we find, using the geodesic equation for u^α,

$$\begin{aligned}D_\tau B^\alpha_{\ \gamma} + B^\alpha_{\ \beta} B^\beta_{\ \gamma} &= u^\beta \nabla_\beta \nabla_\gamma u^\alpha + (\nabla_\gamma u^\beta)\nabla_\beta u^\alpha \\ &= u^\beta \nabla_\beta \nabla_\gamma u^\alpha + \nabla_\gamma(u^\beta \nabla_\beta u^\alpha) - u^\beta \nabla_\gamma \nabla_\beta u^\alpha \\ &= u^\beta(\nabla_\beta \nabla_\gamma - \nabla_\gamma \nabla_\beta)u^\alpha = R^\alpha_{\ \delta\beta\gamma} u^\beta u^\delta \ ,\end{aligned} \tag{12.13}$$

and plugging this back into (12.12), we obtain straightaway the covariant version (8.38) of the geodesic deviation equation in the form

$$(D_\tau)^2 \xi^\alpha = R^\alpha_{\ \delta\beta\gamma} u^\delta u^\beta \xi^\gamma \ . \tag{12.14}$$

Note that this result is automatically transverse to u^α,

$$u_\alpha (D_\tau)^2 \xi^\alpha = R_{\alpha\delta\beta\gamma} u^\alpha u^\delta u^\beta \xi^\gamma = 0 \ . \tag{12.15}$$

REMARKS:

1. I hope you agree that this derivation is somewhat more satisfactory than the one given in section 8.4.

2. The object we have called $B_{\alpha\beta}$ in (12.6) and its evolution equation (12.13) will play a central role in our derivation of the Raychaudhuri equation below.

3. When considering a null geodesic, the condition $\xi^\alpha u_\alpha = 0$ does not eliminate the component of ξ^α tangent to the geodesic. In that case it is convenient to introduce an auxiliarly linearly independent null vector field in order to be able to project the deviation vector ξ^α and its derivatives $D_\tau \xi^\alpha$ and $D_\tau^2 \xi^\alpha$ into some spatial codimension 2 plane transverse to these null directions. This *transverse null geodesic equation* will be derived and discussed in section 12.3.

4. If the curve is not a geodesic (but still parametrised by proper time, so that $u^\alpha u_\alpha = -1$), then the above derivation shows that in addition to the force exerted by the space-time curvature the deviation vector feels a force proportional to the change of the acceleration $a^\alpha = u^\beta \nabla_\beta u^\alpha$ along the curve,

   $$(D_\tau)^2 \xi^\alpha = R^\alpha_{\ \delta\beta\gamma} u^\delta u^\beta \xi^\gamma + D_\tau a^\alpha \quad . \tag{12.16}$$

   In flat space, only the last term is present and describes the (tidal) forces arising from the possible non-uniformity of the external force acting on the particle (or, better: on the extended object described by a family of worldlines) to produce the acceleration a^α. Thus, in precise analogy with the Newtonian situation, the gravitational (i.e. here now Riemann curvature tensor) contribution to the geodesic deviation equation should be interpreted as the *gravitational tidal force*.

12.2 RAYCHAUDHURI EQUATION FOR TIMELIKE GEODESIC CONGRUENCES

A *congruence of curves* is a (locally) space-time filling family of curves, i.e. it is such that locally for any space-time point there is a unique curve passing through that point. A (timelike) *geodesic congruence* is then a congruence of (timelike) geodesics.

Manipulations similar to those leading to (12.14) allow one to derive an equation for the rate of change of the divergence $\nabla_\alpha u^\alpha$ of a family of geodesics along the geodesics. This simple result, known as the *Raychaudhuri equation*, has important implications and ramifications in general relativity, in particular in the context of the so-called *singularity theorems* of Penrose, Hawking and others, none of which will, however, be explored here (see footnote 96 of section 29.3 for some references).

Thus u^α now denotes a tangent vector field to an affinely parametrised geodesic congruence, $u^\alpha \nabla_\alpha u^\beta = 0$ (and $u^\alpha u_\alpha = -1$ or $u^\alpha u_\alpha = 0$ everywhere for a timelike or null congruence). As in section 12.1, we introduce the tensor field (12.6)

$$B_{\alpha\beta} = \nabla_\beta u_\alpha \quad . \tag{12.17}$$

Recall from section 12.1 that $B_{\alpha\beta}$ satisfies (12.8), (12.9),

$$B_{\alpha\beta} u^\beta = u^\alpha B_{\alpha\beta} = 0 \tag{12.18}$$

and therefore only has components in the directions transverse to u^α. Its trace

$$\theta = B^\alpha_{\ \alpha} = g^{\alpha\beta} B_{\alpha\beta} = \nabla_\alpha u^\alpha \tag{12.19}$$

is the divergence of u^α and is known as the *expansion* of the (affinely parametrised) geodesic congruence.

The key equation governing the evolution of $B_{\alpha\beta}$ along the integral curves of the geodesic vector field is (12.13)

$$D_\tau B^\alpha_{\ \gamma} + B^\alpha_{\ \beta} B^\beta_{\ \gamma} = R^\alpha_{\ \delta\beta\gamma} u^\beta u^\delta \quad . \tag{12.20}$$

By taking the trace of this equation, we evidently obtain an evolution equation for the expansion θ, namely

$$\frac{d}{d\tau}\theta = -(\nabla_\alpha u_\beta)(\nabla^\beta u^\alpha) - R_{\alpha\beta} u^\alpha u^\beta \quad . \tag{12.21}$$

Note that this equation, written in the form

$$u^\beta \nabla_\beta (\nabla_\alpha u^\alpha) + (\nabla_\alpha u_\beta)(\nabla^\beta u^\alpha) + R_{\alpha\beta} u^\alpha u^\beta = 0 \quad . \tag{12.22}$$

is a special case of the "master equation" (8.53) for $V^\alpha \to u^\alpha$ with $u^\beta \nabla_\beta u^\alpha = 0$.

To gain some more insight into the geometric significance of this equation, we now consider the case that the geodesic congruence u^α is timelike and normalised in the standard way as $u^\alpha u_\alpha = -1$ (so that τ is proper time).

Given this timelike geodesic congruence, we can introduce the tensor

$$h_{\alpha\beta} = g_{\alpha\beta} + u_\alpha u_\beta \quad . \tag{12.23}$$

The properties of this tensor are closely related to those of the (induced metric) tensor $h_{\alpha\beta} = g_{\alpha\beta} - \epsilon N_\alpha N_\beta$ (16.1) studied in section 16.1 in the context of hypersurfaces. The main difference in the present context is that u_α is not necessarily hypersurface-orthogonal (section 15.5) and therefore, in particular, not necessarily a normal vector field to a familiy of spacelike hypersurfaces. Therefore $h_{\alpha\beta}$ does not necesarily have an interpretation as the induced metric on some hypersurface. Nevertheless, pointwise it can be interpreted as a metric on the space of vectors transverse to the geodesic and its purely algebraic properties are identical to those of the induced metric.

In particular,

- $h_{\alpha\beta}$ has the characteristic property that it is orthogonal to u^α,

$$u^\alpha h_{\alpha\beta} = h_{\alpha\beta} u^\beta = 0 \quad . \tag{12.24}$$

- It can therefore be interpreted as the spatial projection of the metric in the directions orthogonal to the timelike vector field u^α. This can be seen more explicitly in terms of the projectors

$$\begin{aligned} h^{\alpha}_{\ \beta} &= \delta^{\alpha}_{\ \beta} + u^{\alpha}u_{\beta} \\ h^{\alpha}_{\ \beta}h^{\beta}_{\ \gamma} &= h^{\alpha}_{\ \gamma} \ . \end{aligned} \tag{12.25}$$

On directions tangential to u^{α} they act as

$$h^{\alpha}_{\ \beta}u^{\beta} = 0 \ , \tag{12.26}$$

whereas on vectors ξ^{α} orthogonal to u^{α}, $u_{\alpha}\xi^{\alpha} = 0$ (spacelike vectors), one has

$$h^{\alpha}_{\ \beta}\xi^{\beta} = \xi^{\alpha} \ . \tag{12.27}$$

- Thus, acting on an arbitrary vector field V^{α}, $v^{\alpha} = h^{\alpha}_{\ \beta}V^{\beta}$ is the projection of this vector into the plane orthogonal to u^{α}. In the same way one can project an arbitrary tensor to a spatial or transverse tensor. E.g.

  $$t_{\alpha\ldots\beta} = T_{\gamma\ldots\delta}\, h^{\gamma}_{\ \alpha}\ldots h^{\delta}_{\ \beta} \tag{12.28}$$

  satisfies

  $$u^{\alpha}t_{\alpha\ldots\beta} = \ldots = u^{\beta}t_{\alpha\ldots\beta} = 0 \ . \tag{12.29}$$

- In particular, the projection of the metric is

  $$g_{\alpha\beta} \to g_{\gamma\delta}h^{\gamma}_{\ \alpha}h^{\delta}_{\ \beta} = g_{\alpha\beta} + u_{\alpha}u_{\beta} = h_{\alpha\beta} \ , \tag{12.30}$$

  as anticipated above. Whereas for the space-time metric one obviously has $g^{\alpha\beta}g_{\alpha\beta} = 4$, the trace of $h_{\alpha\beta}$ is (in the 4-dimensional case)

  $$g^{\alpha\beta}h_{\alpha\beta} = g^{\alpha\beta}g_{\alpha\beta} + g^{\alpha\beta}u_{\alpha}u_{\beta} = 4 - 1 = 3 = h^{\alpha\beta}h_{\alpha\beta} \ . \tag{12.31}$$

Thus for an affinely parametrised congruence the properties (12.8) and (12.9) show that $B_{\alpha\beta}$ is automatically a spatial or transverse tensor in the sense above,

$$b_{\alpha\beta} \equiv h_{\alpha}^{\gamma}h_{\beta}^{\delta}B_{\gamma\delta} = B_{\alpha\beta} \ . \tag{12.32}$$

Note that the affine parametrisation of the timelike geodesic congruence, expressed by the normalisation condition $u^{\alpha}u_{\alpha} = -1$, is crucial for this entire set-up, since the projection operator requires a unit vector field. This is to be contrasted with the situation for null geodesic congruences ℓ^{α}, to be discussed below, where the property $\ell^{\alpha}\ell_{\alpha} = 0$ is independent of the parametrisation and one can (and we will) also consider the case of non-affine parametrisations.

In the spirit of elasticity theory, we now decompose $b_{\alpha\beta}$ into its anti-symmetric, symmetric traceless and trace part,

$$b_{\alpha\beta} = \omega_{\alpha\beta} + \sigma_{\alpha\beta} + \tfrac{1}{3}\theta h_{\alpha\beta} \ , \tag{12.33}$$

with

$$\begin{aligned} \omega_{\alpha\beta} &= \tfrac{1}{2}(b_{\alpha\beta} - b_{\alpha\beta}) \\ \sigma_{\alpha\beta} &= \tfrac{1}{2}(b_{\alpha\beta} + b_{\alpha\beta}) - \tfrac{1}{3}\theta h_{\alpha\beta} \\ \theta &= h^{\alpha\beta} b_{\alpha\beta} = g^{\alpha\beta} B_{\alpha\beta} = \nabla_\alpha u^\alpha \quad . \end{aligned} \tag{12.34}$$

The quantities $\omega_{\alpha\beta}$, $\sigma_{\alpha\beta}$ and θ are known as the *rotation tensor*, *shear tensor*, and *expansion* of the congruence (family) of geodesics defined by u^α.

In terms of these quantities we can write the evolution equation (12.7) for deviation vectors as

$$D_\tau \xi^\alpha = \omega^\alpha_{\ \beta}\xi^\beta + \sigma^\alpha_{\ \beta}\xi^\beta + \tfrac{1}{3}\theta\xi^\alpha \quad , \tag{12.35}$$

and the evolution equation (12.21) for the expansion θ as

$$\frac{d}{d\tau}\theta = -\tfrac{1}{3}\theta^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} + \omega^{\alpha\beta}\omega_{\alpha\beta} - R_{\alpha\beta}u^\alpha u^\beta \quad . \tag{12.36}$$

This is the *Raychaudhuri equation* for timelike geodesic congruences.

REMARKS:

1. The expansion θ can be written as

   $$\begin{aligned} \theta &= h^{\alpha\beta} b_{\alpha\beta} = h^{\alpha\beta} B_{\alpha\beta} = h^{\alpha\beta}\nabla_\beta u_\alpha \\ &= \tfrac{1}{2}h^{\alpha\beta}(\nabla_\beta u_\alpha + \nabla_\alpha u_\beta) = \tfrac{1}{2}h^{\alpha\beta} L_u g_{\alpha\beta} \end{aligned} \tag{12.37}$$

   where L_u denotes the Lie derivative along the vector field u. Substituting $g_{\alpha\beta} = h_{\alpha\beta} - u_\alpha u_\beta$, one finds

   $$\theta = \tfrac{1}{2}h^{\alpha\beta} L_u(h_{\alpha\beta} - u_\alpha u_\beta) = \tfrac{1}{2}h^{\alpha\beta} L_u h_{\alpha\beta} \quad . \tag{12.38}$$

   Recalling the formula

   $$\delta\sqrt{g} = \sqrt{g} g^{\alpha\beta}\delta g_{\alpha\beta}/2 \tag{12.39}$$

   for the variation of a volume element induced by a variation of the metric, morally speaking the above equation says that θ measures the change of a transverse (cross-sectional) volume of the congruence with volume element $\sqrt{h}$ as one moves along the geodesics,

   $$\theta = \frac{1}{\sqrt{h}}\frac{d}{d\tau}\sqrt{h} \quad . \tag{12.40}$$

   The statement as such is correct and provides the correct intuition for the meaning of θ, but the definition of the cross-sectional volume and its volume element require a bit of care. When the congruence is hypersurface orthogonal, with the induced metric (16.6)

   $$h_{ab} = E^\alpha_a E^\beta_b h_{\alpha\beta} \quad , \tag{12.41}$$

then (12.40) with $h = \det(h_{ab})$ follows from (12.38), because

$$\begin{aligned} h^{ab} L_u h_{ab} &= h^{ab} L_u (E^\alpha_a E^\beta_b h_{\alpha\beta}) \\ &= h^{ab} E^\alpha_a E^\beta_b L_u h_{\alpha\beta} = h^{\alpha\beta} L_u h_{\alpha\beta} \ . \end{aligned} \tag{12.42}$$

Here we have made use of the fact that u and E_a have vanishing Lie bracket, because (introducing τ and y^a as coordinates, instead of the x^α)

$$u^\alpha = \frac{\partial x^\alpha}{\partial \tau} \quad , \quad E^\alpha_a = \frac{\partial x^\alpha}{\partial y^a} \tag{12.43}$$

and the Lie bracket gives the commutator of the second partical derivatives of x^α.

When the congruence is not hypersurface orthogonal, one can still construct a transverse cross-sectional volume, but one can only choose it to be orthogonal at a given geodesic. Introducing in a neighbourhood of a point on this geodesic coordinates y^a labelling the geodesics, as well as the parameter τ along the geodesic, the above calculation will then still go through.[29]

2. If required and desired, from (12.20) similar (but somewhat less transparent) equations can be derived for the evolution of the shear and rotation tensors along the geodesic congruence, i.e. for $(d/d\tau)\sigma_{\alpha\beta}$ and $(d/d\tau)\omega_{\alpha\beta}$.

3. Since $\omega_{\alpha\beta}$ and $\sigma_{\alpha\beta}$ are purely spatial tensors, their squares are non-negative,

$$\sigma^{\alpha\beta}\sigma_{\alpha\beta} \geq 0 \quad , \quad \omega^{\alpha\beta}\omega_{\alpha\beta} \geq 0 \ , \tag{12.44}$$

with $\sigma^{\alpha\beta}\sigma_{\alpha\beta} = 0$ only for $\sigma_{\alpha\beta} = 0$ (and likewise for the rotation). They thus enter the Raychaudhuri equation with opposite signs.

4. In the presence of both these terms it is difficult to say something general about the evolution of θ. Since the first term $(-\theta^2/3)$ is non-positive, an important special case of the Raychaudhuri equation arises when the rotation is zero, $\omega_{\alpha\beta} = 0$. This happens for example when $u_\alpha = \partial_\alpha S$ is the gradient co-vector of some function S. In this case u_α is orthogonal to the level-surfaces of S. In fact, more generally we have the statement that

$$\omega_{\alpha\beta} = 0 \quad \Leftrightarrow \quad u^\alpha \quad \text{hypersurface orthogonal} \ . \tag{12.45}$$

Indeed, assume that u_α is hypersurface orthogonal, i.e. (15.55)

$$u_{[\alpha}\nabla_\beta u_{\gamma]} = 0 \quad \Leftrightarrow \quad \omega_{\alpha\beta}u_\gamma + \omega_{\beta\gamma}u_\alpha + \omega_{\gamma\alpha}u_\beta = 0 \ . \tag{12.46}$$

Contracting this with u^γ and using $u^\gamma u_\gamma = -1$ and $u^\gamma \omega_{\gamma\beta} = 0$, only the first term survives and one finds on the nose that $\omega_{\alpha\beta} = 0$,

$$u_{[\alpha}\nabla_\beta u_{\gamma]} = 0 \quad \Rightarrow \quad \omega_{\alpha\beta} = 0 \ , \tag{12.47}$$

---

[29] For a more careful proof of this statement see the discussion in section 2.4.8 of E. Poisson, *A Relativist's Toolkit*.

and the Frobenius theorem provides one with the converse statement. Alternatively, $\omega_{\alpha\beta} = 0$ follows from assuming that u_α has the explicit hypersurface-orthogonal form $u_\alpha = f\partial_\alpha S$. Then one has (15.52)

$$\omega_{\beta\alpha} = \nabla_{[\alpha} u_{\beta]} = (\nabla_{[\alpha} \log f) u_{\beta]} \tag{12.48}$$

and by contraction with u^α one deduces

$$\partial_\alpha f = -(u^\beta \partial_\beta f) u_\alpha \sim u_\alpha \quad \Rightarrow \qquad \omega_{\alpha\beta} = 0 \ . \tag{12.49}$$

5. Either way, for a hypersurface orthogonal congruence of timelike geodesics one has

$$\frac{d}{d\tau}\theta = -\tfrac{1}{3}\theta^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} - R_{\alpha\beta}u^\alpha u^\beta \ . \tag{12.50}$$

The first two terms on the right hand side are manifestly non-positive (recall that $\sigma_{\alpha\beta}$ is a spatial tensor and hence $\sigma_{\alpha\beta}\sigma^{\alpha\beta} \geq 0$). Thus, if one assumes that the geometry is such that

$$R_{\alpha\beta}u^\alpha u^\beta \geq 0 \tag{12.51}$$

(by the Einstein equations to be discussed in the section 19, this translates into a positivity condition on the energy-momentum tensor known as the *strong energy condition*, cf. section 22.1), one finds

$$\frac{d}{d\tau}\theta = -\tfrac{1}{3}\theta^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} - R_{\alpha\beta}u^\alpha u^\beta \leq 0 \ . \tag{12.52}$$

This means that the divergence (convergence) of geodesics will decrease (increase) in time. The interpretation of this result is that gravity is an *attractive* force (for matter satisfying the strong energy condition) whose effect is to focus geodesics.

6. According to (12.52), $d\theta/d\tau$ is not only negative but actually bounded from above by

$$\frac{d}{d\tau}\theta \leq -\tfrac{1}{3}\theta^2 \ . \tag{12.53}$$

Rewriting this equation as

$$\frac{d}{d\tau}\frac{1}{\theta} \geq \frac{1}{3} \ , \tag{12.54}$$

one deduces immediately that

$$\frac{1}{\theta(\tau)} \geq \frac{1}{\theta(0)} + \frac{\tau}{3} \ . \tag{12.55}$$

This has the rather dramatic implication that, if $\theta(0) < 0$ (i.e. the geodesics are initially converging), then $\theta(\tau) \to -\infty$ within finite proper time $\tau \leq 3/|\theta(0)|$,

$$\theta(\tau) \to -\infty \quad \text{for} \quad \tau \leq 3/|\theta(0)| \tag{12.56}$$

provided that the geodesics can be extended that far.

7. If one thinks of the geodesics as trajectories of physical particles, this is obviously a rather catastrophic situation in which these particles will be infinitely squashed. In general, however, the divergence of θ only indicates that the family of geodesics develops what is known as a *caustic* where different geodesics meet.

8. Simple non-catastrophic examples of such caustics are e.g. the poles of a sphere where great circles meet, or even just the origin in Euclidean space $\mathbb{R}^n$ when considering the family of radial geodesics passing through the origin. E.g. in the latter case the tangent vector field is simply ∂_r, and its divergence is

$$\nabla_\alpha(\partial_r)^\alpha = \frac{1}{\sqrt{g}}\partial_\alpha(\sqrt{g}(\partial_r)^\alpha) \sim r^{-1} \quad , \tag{12.57}$$

   which diverges as $r \to 0$. This divergent behaviour is strictly related to the breakdown at the origin $r = 0$ of spherical coordinates adapted to this congruence (cf. also the related discussion in section 43.6).

9. Nevertheless, the above result plays a crucial role in establishing the occurrence of true singularities in general relativity if supplemented e.g. by conditions which ensure that such "harmless" caustics cannot appear, as this means that the geodesic cannot be extended to where one would find $\theta \to -\infty$. This kind of argument (leading to the conclusion of *geodesic incompleteness* of a space-time) is one of the typical ingredients of the singularity theorems of general relativity (see footnote 96 of section 29.3 for some references).

10. The adaptation of this formalism in general and the Raychaudhuri equation in particular to congruences of null geodesics requires some more care (and is ultimately expressed in terms of 2-dimensional rather than 3-dimensional spatial tensors), and we will discuss this in section 12.4 below.

12.3 TRANSVERSE NULL GEODESIC DEVIATION EQUATION

In section 12.4 we will derive the null counterpart of the Raychaudhuri equation for timelike geodesic congruences discussed in section 12.2 above. The set-up we will use is a suitable combination of that for timelike geodesics and the formalism of projectors adapted to null directions. As a preparation for this, and a useful by-product, in this section we will first derive a variant of the geodesic deviation equation for null geodesics, the *transverse null geodesic deviation equation*.

Thus we consider a null geodesic (or congruence of null geodesics), with tangent vector field ℓ^α, and we will initially choose these null geodesics to be affinely parametrised so that one has

$$\ell^\alpha \ell_\alpha = 0 \quad , \quad \ell^\alpha \nabla_\alpha \ell^\beta = 0 \ . \tag{12.58}$$

The affine parameter along the null geodesics of this congruence will (for lack of imagination) be called τ.

Now recall from the discussion of the geodesic deviation equation in section 12.1 that for any geodesic deviation vector ξ^α, i.e. a vector satisfying the condition

$$D_\tau \xi^\alpha = \xi^\beta \nabla_\beta u^\alpha \quad , \tag{12.59}$$

the quantity $\xi^\alpha u_\alpha$ is constant along the geodesic,

$$\frac{d}{d\tau}(\xi^\alpha u_\alpha) = (D_\tau \xi^\alpha) u_\alpha = \xi^\beta u^\alpha \nabla_\beta u^\alpha = 0 \tag{12.60}$$

because $u^\alpha u_\alpha = \epsilon$ is constant, regardless of whether u^α is timelike or null. However, the interpretation of this and its implications depend on whether one is dealing with a timelike geodesic (congruence) or a null geodesic (congruence):

1. In the timelike case the quantity $(-\xi^\alpha u_\alpha)$ is the uninteresting component of ξ along the geodesic u^α, and there was clearly no point in not setting it to zero. The transversality condition $\xi^\alpha u_\alpha = 0$ on the deviation vector could be consistently imposed and was sufficient to remove this component.

2. In the null case, however, the condition $\xi^\alpha \ell_\alpha = 0$ does not accomplish this, i.e. does not remove the component of ξ pointing in the direction of ℓ^α because it imposes no condition precisely on that component. Thus we expect the deviation vector ξ to have *two* uninteresting components in the null case, $\xi^\alpha \ell_\alpha$ and the component of ξ in the direction of ℓ^α:

   - Indeed, as recalled above, we already know in general that $\xi^\alpha \ell_\alpha$ is constant,

     $$\frac{d}{d\tau}(\xi^\alpha \ell_\alpha) = 0 \quad . \tag{12.61}$$

   - To verify this also for a component of ξ along ℓ^α, we impose the condition that ξ be a deviation vector on the vector

     $$\xi^\alpha = \xi \ell^\alpha \tag{12.62}$$

     (note once again that this ξ is completely unrelated to $\xi^\alpha \ell_\alpha$). Since ℓ_α is a geodesic, we have

     $$D_\tau \xi^\alpha = (\frac{d}{d\tau}\xi)\ell^\alpha \overset{!}{=} \xi^\beta \nabla_\beta \ell^\alpha = \xi \ell^\beta \nabla_\beta \ell^\alpha = 0 \quad . \tag{12.63}$$

     Thus $\xi^\alpha = \xi \ell^\alpha$ is a (boring non-) deviation vector iff ξ is constant, and one should impose the condition $\xi = 0$.

Therefore it is natural to project out both these components from ξ_α. In order to construct a suitable projection operator, one can proceed as in section 17.4 and introduce a complementary null vector (field) n^α with

$$n^\alpha n_\alpha = 0 \quad , \quad n^\alpha \ell_\alpha = -1 \ . \tag{12.64}$$

Then

$$\xi^\alpha = \xi \ell^\alpha + \ldots \quad \Rightarrow \quad \xi = -\xi^\alpha n_\alpha \tag{12.65}$$

and we can elininate both boring components by imposing the transversality conditions

$$\xi^\alpha \ell_\alpha = \xi^\alpha n_\alpha = 0 \tag{12.66}$$

on the deviation vector ξ^α, in addition to the deviation vector condition (12.3),

$$\ell^\alpha \nabla_\alpha \xi^\beta = \xi^\alpha \nabla_\alpha \ell^\beta \ . \tag{12.67}$$

As in (12.6) we introduce

$$B_{\alpha\beta} = \nabla_\beta \ell_\alpha \ , \tag{12.68}$$

so that the above condition that ξ^α is a deviation vector can be written as

$$D_\tau \xi^\alpha = B^\alpha_{\ \beta} \xi^\beta \ . \tag{12.69}$$

Because ℓ^α is null and (affinely) geodesic, one has

$$\ell^\alpha B_{\alpha\beta} = B_{\alpha\beta} \ell^\beta = 0 \ , \tag{12.70}$$

but $B_{\alpha\beta}$ is not automatically orthogonal to n^α (and we will come back to and recitify this below). Exactly the same calculation as (12.13) in section 12.1 now shows that

$$D_\tau B_{\alpha\beta} + B^\alpha_{\ \gamma} B^\gamma_{\ \beta} = R^\alpha_{\ \delta\gamma\beta} \ell^\gamma \ell^\delta \tag{12.71}$$

so that one also has the null counterpart of (12.14), namely

$$(D_\tau)^2 \xi^\alpha = R^\alpha_{\ \delta\gamma\beta} \ell^\gamma \ell^\delta \xi^\beta \ . \tag{12.72}$$

Again this equation is automatically transverse to ℓ, in the sense that

$$\ell_\alpha (D_\tau)^2 \xi^\alpha = R_{\alpha\delta\gamma\beta} \ell^\alpha \ell^\gamma \ell^\delta \xi^\beta = 0 \ , \tag{12.73}$$

but not transverse to n^α.

In order to pick up only the transverse components of $D_\tau \xi^\alpha$ in (12.69) (and in subsequent equations), we thus need to project $B_{\alpha\beta}$ onto its transverse components. The construction of this projector is identical to that in section 17.4:

- Associated with a choice of n^α we have a decomposition of the metric into a longitudinal and a transverse spatial part,

  $$g_{\alpha\beta} = s_{\alpha\beta} - (\ell_\alpha n_\beta + \ell_\beta n_\alpha) \ , \tag{12.74}$$

  with the properties

  $$s_{\alpha\beta}\ell^\beta = s_{\alpha\beta}n^\beta = 0 \tag{12.75}$$

  and

  $$g^{\alpha\beta}s_{\alpha\beta} = s^{\alpha\beta}s_{\alpha\beta} = s^\alpha_{\ \alpha} = 2 \ . \tag{12.76}$$

  (we are considering the case $D = 4$).

- We then also have the corresponding transverse (spatial) projectors

  $$\begin{aligned} s^\alpha_{\ \beta} = \delta^\alpha_{\ \beta} + (\ell^\alpha n_\beta + n^\alpha \ell_\beta): \quad & s^\alpha_{\ \gamma}s^\gamma_{\ \beta} = s^\alpha_{\ \beta} \\ & s^\alpha_{\ \beta}\ell^\beta = s^\alpha_{\ \beta}n^\beta = 0 \ , \end{aligned} \tag{12.77}$$

With the aid of these projectors, we can now write the fully projected version of (12.69) as

$$s^\alpha_{\ \beta}D_\tau(s^\beta_{\ \gamma}\xi^\gamma) = b^\alpha_{\ \beta}\xi^\beta \tag{12.78}$$

where $b_{\alpha\beta}$ is the projection of $B_{\alpha\beta}$,

$$b_{\alpha\beta} = s_\alpha^{\ \gamma}s_\beta^{\ \delta}B_{\gamma\delta} \ . \tag{12.79}$$

Likewise the purely transverse (to ℓ and n) variant of the null geodesic equation (12.72) can be written as

$$s^\alpha_{\ \beta}(D_\tau)^2(s^\beta_{\ \gamma}\xi^\gamma) = s^\alpha_{\ \beta}s^\gamma_{\ \delta}R^\beta_{\ \mu\nu\gamma}\ell^\mu\ell^\nu\xi^\delta \ . \tag{12.80}$$

While this is essentially the final result, it is not particularly transparent yet. We will put this equation into a somewhat more attractive form below, in which manifestly only the transverse components of the deviation vector and $R^\beta_{\ \mu\nu\gamma}\ell^\mu\ell^\nu$ appear.

First of all, note that the auxiliary normal vector n^α is not unique. For a fixed choice of ℓ^α, at a point on the geodesic, that is for a given value of τ, it is uniquely determined up to null rotations around ℓ^α,

$$\ell \to \ell \quad , \quad n \to n + \beta^a E_a + \tfrac{1}{2}\beta^2\ell \quad , \quad E_a \to E_a + \beta_a \ell \ , \tag{12.81}$$

where E_a are (necessarily spatial) vectors orthogonal to ℓ and n, and $\beta_a = \beta_a(\tau)$. This ambiguity does not affect any of the results in this section, so in principle one can make any choice of auxiliary n^α. In particular, one can choose n^α to be parallel-transported along ℓ^α,

$$\ell^\alpha\nabla_\alpha n^\beta = 0 \ . \tag{12.82}$$

Then the properties of parallel transport obtained in section 5.8 imply that the conditions (12.64) on n^α hold everywhere along the null geodesic (or congruence of null geodesics) if they are satisified initially. This reduces the ambiguity in (12.81) to τ-independent null rotations.

In fact, one can do even better than that and choose (see also the discussion at the end of section 17.4, in particular around (17.57)) an entire pseudo-orthonormal frame

$$\{E_A\} = \{E_+ = \ell, E_- = n, E_a\} : \quad g_{\alpha\beta} E^\alpha_A E^\beta_B = \eta_{AB} \tag{12.83}$$

where

$$\eta_{++} = \eta_{--} = 0 \quad , \quad \eta_{+-} = -1 \quad , \quad \eta_{a+} = \eta_{a-} = 0 \quad , \quad \eta_{ab} = \delta_{ab} \quad . \tag{12.84}$$

If one selects such a frame at one point along the geodesic and then parallel transports the frame along the geodesic, the orthogonality relations (12.83) will hold everywhere along the geodesic. Thus we can always choose a basis E_A such that

$$D_\tau E^\alpha_A = 0 \quad , \quad g_{\alpha\beta} E^\alpha_A E^\beta_B = \eta_{AB} \quad . \tag{12.85}$$

With this choice, a transverse geodesic deviation vector is simply one which has components only in the E_a-directions,

$$\xi^\alpha \ell_\alpha = \xi^\alpha n_\alpha = 0 \quad \Leftrightarrow \quad \xi^\alpha = \xi^a E^\alpha_a \quad , \tag{12.86}$$

or simply

$$\xi = \xi^a E_a \quad . \tag{12.87}$$

Since $D_\tau E_a$=0, one has

$$D_\tau E_a = 0 \quad \Rightarrow \quad D_\tau \xi^a = \frac{d}{d\tau}\xi^a \quad , \tag{12.88}$$

so that with respect to this basis covariant differentiation along the curve reduces to ordinary differentiation of the components. Then the null geodesic deviation equation (12.80) can simply be written as

$$\frac{d^2}{d\tau^2}\xi^a = R^a{}_{++b}\xi^b = -R^a{}_{+b+}\xi^b \quad , \tag{12.89}$$

where the R_{a+b+} are the frame components of the Riemann tensor,

$$R_{a+b+} = E^\alpha_a E^\mu_+ E^\beta_b E^\nu_+ R_{\alpha\mu\beta\nu} = E^\alpha_a E^\beta_b R_{\alpha\mu\beta\nu} \ell^\mu \ell^\nu \quad . \tag{12.90}$$

Thus the transverse null geodesic deviation equation has the form of a $(D-2)$-dimensional (transverse) harmonic oscillator equation,

$$\frac{d^2}{d\tau^2}\xi^a = -(\Omega^2)^a{}_b \xi^b \quad , \tag{12.91}$$

with the time-dependent symmetric frequency matrix

$$(\Omega^2)(\tau)^a{}_b = R^a{}_{+b+}(\tau) \quad . \tag{12.92}$$

The notation used here is perhaps suggestive but it is not meant to imply that Ω^2 is necessarily positive - the frequencies can be real or imaginary. Using the decomposition (11.75) of the Riemann tensor into its traceless and trace parts, we can (with $D = 4$, $\eta_{a+} = \eta_{++} = 0, \eta_{ab} = \delta_{ab}$) decompose R_{a+b+} as

$$R_{a+b+} = C_{a+b+} + \tfrac{1}{2}\delta_{ab}R_{++} \quad . \tag{12.93}$$

In particular, if the Ricci tensor is zero (as we will see this means that the metric solves the vacuum Einstein equations), the frequency matrix Ω^2 is symmetric traceless and thus necesarily has positive and negative eigenvalues (corresponding to real and imaginary frequencies).

12.4 RAYCHAUDHURI EQUATION FOR AFFINE NULL GEODESIC CONGRUENCES

We now consider a null geodesic congruence, with tangent vector field again denoted by ℓ^α, and we will initially choose these null geodesics to be affinely parametrised so that one has

$$\ell^\alpha \ell_\alpha = 0 \quad , \quad \ell^\alpha \nabla_\alpha \ell^\beta = 0 \quad . \tag{12.94}$$

We use the same framework as in the previous setion, with an auxiliary null vector field n^α with $\ell^\alpha n_\alpha = -1$, the associated projectors etc.

In (12.79) we introduced the transverse projection $b_{\alpha\beta}$ of the tensor $B_{\alpha\beta} = \nabla_\beta \ell_\alpha$,

$$b_{\alpha\beta} = s_\alpha^{\ \gamma} s_\beta^{\ \delta} B_{\gamma\delta} \quad . \tag{12.95}$$

Performing this projection explicitly, one sees that this spatial projection $b_{\alpha\beta}$ is equal to

$$b_{\alpha\beta} = s_\alpha^{\ \gamma} s_\beta^{\ \delta} B_{\gamma\delta} = B_{\alpha\beta} + \ell_\alpha n^\gamma B_{\gamma\beta} + \ell_\beta n^\delta B_{\alpha\delta} + \ell_\alpha \ell_\beta n^\gamma n^\delta B_{\gamma\delta} \quad . \tag{12.96}$$

This has two useful immediate consequences that we will make use of in the following, namely

- that the spatial trace of $b_{\alpha\beta}$ with respect to $s_{\alpha\beta}$ is equal to the space-time trace of $B_{\alpha\beta}$ (with respect to $g_{\alpha\beta}$),

$$g^{\alpha\beta} B_{\alpha\beta} = g^{\alpha\beta} b_{\alpha\beta} = s^{\alpha\beta} b_{\alpha\beta} \quad , \tag{12.97}$$

- and that the square of $b_{\alpha\beta}$ is identical to that of $B_{\alpha\beta}$,

$$B^{\alpha\beta} B_{\beta\alpha} = b^{\alpha\beta} b_{\beta\alpha} \quad . \tag{12.98}$$

We can now, as in the timelike case, decompose $b_{\alpha\beta}$ orthogonally into its irreducible (trace, symmetric traceless, anti-symmetric) parts,

$$\begin{aligned} b_{\alpha\beta} &= \tfrac{1}{2}\theta_\ell s_{\alpha\beta} + \tfrac{1}{2}(b_{\alpha\beta} + b_{\beta\alpha} - \theta_\ell s_{\alpha\beta}) + \tfrac{1}{2}(b_{\alpha\beta} - b_{\beta\alpha}) \\ &= \tfrac{1}{2}\theta_\ell s_{\alpha\beta} + \sigma_{\alpha\beta} + \omega_{\alpha\beta} \quad . \end{aligned} \tag{12.99}$$

Here θ_ℓ is the *expansion*

$$\theta_\ell = s^{\alpha\beta} b_{\alpha\beta} = s^{\alpha\beta}\nabla_\beta \ell_\alpha = g^{\alpha\beta}\nabla_\alpha \ell_\beta = \nabla^\alpha \ell_\alpha \ , \tag{12.100}$$

REMARKS:

1. As in the timelike case (12.38), the expansion θ_ℓ can be written as

   $$\theta_\ell = \tfrac{1}{2} s^{\alpha\beta} L_\ell s_{\alpha\beta} \ . \tag{12.101}$$

   and leads to an analogous interpretation of θ_ℓ as measuring the change in the cross-sectional area element $\sqrt{s}$ of the congruence (12.40),

   $$\theta_\ell = \frac{1}{\sqrt{s}} L_\ell \sqrt{s} \ . \tag{12.102}$$

2. The equivalence between the spatial and space-time traces of $\nabla_\alpha \ell_\beta$ in the above equation is due to the fact that we have chosen ℓ to be affinely parametrised. We will always define θ to be the spatial trace (divergence) of $\nabla_\alpha \ell_\beta$, even when ℓ is not affinely parametrised, but in that case θ and $\nabla_\alpha \ell^\alpha$ are no longer equal (see (12.126)). We will return to this issue below.

3. As regards the other terms, $\sigma_{\alpha\beta}$ and $\omega_{\alpha\beta}$ are again known as the *shear tensor* and *rotation tensor* respectively.

4. As in the timelike case, the rotation is zero if ℓ^α is hypersurface orthogonal. We will establish this result below.

5. Because the above decomposition is orthogonal, we have

   $$B^{\alpha\beta} B_{\beta\alpha} = b^{\alpha\beta} b_{\beta\alpha} = +\tfrac{1}{2}\theta_\ell^2 + \sigma^{\alpha\beta}\sigma_{\alpha\beta} - \omega^{\alpha\beta}\omega_{\alpha\beta} \ . \tag{12.103}$$

6. Because the tensors appearing on the right-hand side of this equation are spatial tensors, their squares are non-negative,

   $$\sigma^{\alpha\beta}\sigma_{\alpha\beta} \geq 0 \quad , \quad \omega^{\alpha\beta}\omega_{\alpha\beta} \geq 0 \ . \tag{12.104}$$

We now want to determine

$$\frac{d}{d\tau}\theta_\ell = \ell^\alpha \nabla_\alpha \theta_\ell \ . \tag{12.105}$$

We can do this either by again deriving an evolution equation for all of $b_{\alpha\beta}$, as in (12.71), or by calculating directly the derivative of θ_ℓ along ℓ. Adopting the latter procedure here, just following one's tensor calculus nose one finds

$$\begin{aligned}\frac{d}{d\tau}\theta_\ell &= \ell^\alpha \nabla_\alpha (\nabla_\beta \ell^\beta) \\ &= \ell^\alpha [\nabla_\alpha, \nabla_\beta] \ell^\beta + \ell^\alpha \nabla_\beta \nabla_\alpha \ell^\beta \\ &= -R_{\alpha\beta}\ell^\alpha \ell^\beta - (\nabla^\beta \ell^\alpha)\nabla_\alpha \ell_\beta + \nabla_\beta(\ell^\alpha \nabla_\alpha \ell^\beta) \ .\end{aligned} \tag{12.106}$$

The 2nd term is just $-B^{\alpha\beta}B_{\beta\alpha}$ and the 3rd term is zero because ℓ is geodesic. Thus one finds the *Raychaudhuri equation for null congruences*

$$\frac{d}{d\tau}\theta_\ell = -R_{\alpha\beta}\ell^\alpha\ell^\beta - \tfrac{1}{2}\theta_\ell^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} + \omega^{\alpha\beta}\omega_{\alpha\beta} \ . \tag{12.107}$$

Using (12.102) in the form

$$\frac{d}{d\tau}\sqrt{s} = \theta_\ell\sqrt{s} \ , \tag{12.108}$$

we can also write this as an equation for the change in the expansion rate of the cross-sectional area $\sqrt{s}$ of the congruence. This leads to an additional $+\theta_\ell^2$ in the evolution equation, and thus flips the sign of the 2nd term of (12.107), resulting in

$$\frac{d^2}{d\tau^2}\sqrt{s} = \left(-R_{\alpha\beta}\ell^\alpha\ell^\beta + \tfrac{1}{2}\theta_\ell^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} + \omega^{\alpha\beta}\omega_{\alpha\beta}\right)\sqrt{s} \ . \tag{12.109}$$

REMARKS:

1. If the geometry is such that

$$R_{\alpha\beta}\ell^\alpha\ell^\beta \geq 0 \tag{12.110}$$

(by the Einstein equations to be discussed in the section 19, this translates into a positivity condition on the energy-momentum tensor known as the *null energy condition*, cf. section 22.1), this gives a negative contribution to the right-hand side of the Raychaudhuri equation (indicating the focussing effect of gravity on lightrays).

2. If moreover the rotation $\omega_{\alpha\beta}$ is zero, for an affinely parametrised null congruence one has

$$\frac{d}{d\tau}\theta_\ell = -R_{\alpha\beta}\ell^\alpha\ell^\beta - \tfrac{1}{2}\theta_\ell^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} \tag{12.111}$$

and therefore, in particular,

$$\frac{d}{d\tau}\theta_\ell \leq -\tfrac{1}{2}\theta_\ell^2 \leq 0 \ . \tag{12.112}$$

In Minkowski space-time (with zero curvature) we would have an equality instead of the first inequality sign, so (12.112) is the (reasonable) statement that the expansion is smaller/slower than in Minkowski space, i.e. that (reasonable) matter has the tendency to focus lightrays.

3. Analogously to the timelike case, (12.112) has the consequence that if one has an initially converging null congruence, $\theta_\ell(\tau_0) < 0$, then because of

$$\frac{d}{d\tau}\theta_\ell \leq -\tfrac{1}{2}\theta_\ell^2 \quad \Rightarrow \quad \frac{1}{\theta_\ell(\tau)} \geq \frac{1}{\theta_\ell(\tau_0)} + \frac{\tau-\tau_0}{2} \tag{12.113}$$

$1/\theta(\tau) \to 0_-$ or $\theta(\tau) \to -\infty$ at the latest at

$$\theta_\ell(\tau) \to -\infty \quad \text{for} \quad \tau \leq \tau_0 + 2/|\theta_\ell(\tau_0)| \tag{12.114}$$

(if the geodesics can be extended that far). As in the timelike case, this usually indicates the formation of a (harmless) *caustic* where these null geodesics cross.

4. E.g. in Minkowski space radially outgoing lightrays $\ell = \partial_v$, $v = t + r$, have expansion

$$\theta_\ell = \nabla_\alpha(\partial_v)^\alpha = \frac{1}{r^2}\partial_\alpha(r^2(\partial_t + \partial_r)^\alpha) = +\frac{2}{r} > 0 \ , \tag{12.115}$$

while radially ingoing lightrays $n = \partial_u$, $u = t - r$, have expansion

$$\theta_n = \nabla_\alpha(\partial_u)^\alpha = \frac{1}{r^2}\partial_\alpha(r^2(\partial_t - \partial_r)^\alpha) = -\frac{2}{r} < 0 \ , \tag{12.116}$$

reflecting the fact that outgoing lightrays expand while ingoing lightrays contract. Both expansions diverge as $r \to 0$, but this evidently does not indicate a pathology of Minkowski space-time, but only of the chosen congruences at the origin (where all the lightrays of the congruence meet).

Note also that e.g. θ_ℓ satisfies the Raychaudhuri equation

$$\frac{d}{d\tau}\theta_\ell = \ell^\alpha\nabla_\alpha\theta_\ell = \partial_r(+2/r) = -2/r^2 = -\tfrac{1}{2}\theta_\ell^2 \ , \tag{12.117}$$

as it should (no curvature, no shear, no rotation). With cross-sectional area $\sqrt{s} \sim r^2$, one also has

$$\frac{1}{\sqrt{s}}\frac{d^2}{d\tau^2}\sqrt{s} = \frac{1}{r^2}(\partial_r)^2 r^2 = \frac{2}{r^2} = +\tfrac{1}{2}\theta_\ell^2 \ , \tag{12.118}$$

illustrating the variant (12.109) of the Raychaudhuri equation: while $\theta_\ell \sim r^{-1} \to 0$ as $r \to \infty$, indicating that the cross-sectional spheres become flatter and flatter for large r, the cross-sectional area grows like $\sqrt{s} \sim r^2$, leading to an acceleration of its growth.

5. An argument similar to that in the timelike case shows that the rotation vanishes if (and locally only if, by Frobenius) ℓ^α is hypersurface orthogonal

$$\omega_{\alpha\beta} = 0 \quad \Leftrightarrow \quad \ell^\alpha \quad \text{hypersurface-orthogonal} \ . \tag{12.119}$$

In order to establish this we begin with the condition

$$\ell_{[\alpha}\nabla_\beta\ell_{\gamma]} = 0 \quad \Leftrightarrow \quad B_{[\alpha\beta]}\ell_\gamma + B_{[\beta\gamma]}\ell_\alpha + B_{[\gamma\alpha]}\ell_\beta = 0 \ . \tag{12.120}$$

Contracting this with ℓ^γ, we would get $0 = 0$, which is true but unenlightning. To get something non-trivial and more useful, we contract with n^γ instead. Then we deduce

$$B_{[\alpha\beta]} - B_{[\beta\gamma]}n^\gamma\ell_\alpha - B_{[\gamma\alpha]}n^\gamma\ell_\beta = 0 \ . \tag{12.121}$$

Disentangling this, one sees that this is precisely the statement that the anti-symmetric part of $b_{\alpha\beta}$ is zero, i.e. that $\omega_{\alpha\beta} = 0$, so we have established the desired result

$$\ell_{[\alpha}\nabla_\beta\ell_{\gamma]} = 0 \quad \Rightarrow \quad \omega_{\alpha\beta} = 0 \ . \tag{12.122}$$

6. The expansion properties of families of null geodesics play a crucial role both in the singularity theorems of general relativity (where for example so-called *trapped surfaces* are characterised by negative expansions for both ingoing and "outgoing" families of lightrays), and in the study of black holes and the laws governing the evolution of their event horizons (where the interest is in the null geodesic congruences generating the horizon). In particular, in the latter case the Raychaudhuri equation is one crucial ingredient in the proof of the statement (Hawking's theorem) that under reasonable conditions the cross-sectional area of the event horizon of a black hole cannot decrease.

12.5 RAYCHAUDHURI EQUATION FOR NON-AFFINELY PARAMETRISED NULL GEODESICS

Let us now look at the case when the null geodesic congruence is not affinely parametrised, i.e. when, instead of (12.94), the starting point is a null vector field ℓ^α satisfying

$$\ell^\alpha \ell_\alpha = 0 \quad , \quad \ell^\alpha \nabla_\alpha \ell^\beta = \kappa_\ell \ell^\beta \quad , \tag{12.123}$$

with κ_ℓ the inaffinity. Then a couple of things change in the derivation, but the end result (12.129) turns out to differ from (12.107) by only one term (and I will give an alternative and much quicker derivation of the result below).

As before, we can choose an auxiliary null vector field n^α, construct the projectors $s^\alpha_{\ \beta}$ etc. Defining again $B_{\alpha\beta} = \nabla_\beta \ell_\alpha$, one still has $\ell^\alpha B_{\alpha\beta} = 0$ (because this is implied by $\ell^\alpha \ell_\alpha = 0$), but instead of $B_{\alpha\beta}\ell^\beta = 0$ one now has

$$B_{\alpha\beta}\ell^\beta = \kappa_\ell \ell_\alpha \quad . \tag{12.124}$$

While the projection (12.96) remains unchanged, i.e. the relation between $b_{\alpha\beta}$ and $B_{\alpha\beta}$ has the same form as in (12.96), the equations (12.97) and (12.98) for the trace and square of $B_{\alpha\beta}$ differ. Instead of (12.97) one has

$$\begin{aligned} s^{\alpha\beta} b_{\alpha\beta} &= (g^{\alpha\beta} + \ell^\alpha n^\beta + \ell^\beta n^\alpha) B_{\alpha\beta} \\ &= \nabla_\alpha \ell^\alpha + \kappa_\ell n^\alpha \ell_\alpha = \nabla_\alpha \ell^\alpha - \kappa_\ell \quad . \end{aligned} \tag{12.125}$$

Thus, if we define the expansion θ_ℓ as the spatial trace of $b_{\alpha\beta}$, instead of (12.100) we find

$$\nabla_\alpha \ell^\alpha = \theta_\ell + \kappa_\ell \quad . \tag{12.126}$$

Analogously, for the square of $B_{\alpha\beta}$ one finds, instead of (12.98),

$$B^{\alpha\beta} B_{\beta\alpha} = b^{\alpha\beta} b_{\beta\alpha} + \kappa_\ell^2 \quad . \tag{12.127}$$

Putting everything together and calculating $(d/d\tau)\nabla_\alpha \ell^\alpha$ as in (12.106), one then finds

$$\begin{aligned}\frac{d}{d\tau}(\theta_\ell + \kappa_\ell) &= -R_{\alpha\beta}\ell^\alpha\ell^\beta - (\nabla^\beta\ell^\alpha)\nabla_\alpha\ell_\beta + \nabla_\beta(\ell^\alpha\nabla_\alpha\ell^\beta)\\ &= -R_{\alpha\beta}\ell^\alpha\ell^\beta - B_{\alpha\beta}B^{\beta\alpha} + \nabla_\beta(\kappa_\ell\ell^\beta)\\ &= -R_{\alpha\beta}\ell^\alpha\ell^\beta - b_{\alpha\beta}b^{\beta\alpha} - \kappa_\ell^2 + \frac{d}{d\tau}\kappa_\ell + \kappa_\ell(\theta_\ell + \kappa_\ell)\\ &= -R_{\alpha\beta}\ell^\alpha\ell^\beta - b_{\alpha\beta}b^{\beta\alpha} + \frac{d}{d\tau}\kappa_\ell + \kappa_\ell\theta_\ell \ .\end{aligned} \tag{12.128}$$

Thus the net effect of dealing with a non-affinely parametrised null congruence is that one just picks up one additional term on the right-hand side of the Raychaudhuri equation,

$$\frac{d}{d\tau}\theta_\ell = \kappa_\ell\theta_\ell - R_{\alpha\beta}\ell^\alpha\ell^\beta - \tfrac{1}{2}\theta_\ell^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} + \omega^{\alpha\beta}\omega_{\alpha\beta} \ . \tag{12.129}$$

A quick(er) way to derive (12.129) is from the result (12.107) for affinely parametrised null geodesics, by determining how the quantities appearing in (12.107) change under a reparametrisation

$$\ell^\alpha \to \tilde{\ell}^\alpha = f\ell^\alpha \tag{12.130}$$

(with ℓ^α affinely parametrised, say).

- On the one hand, for the inaffinity one has

$$\tilde{\ell}^\alpha\nabla_\alpha\tilde{\ell}^\beta = \left(\frac{d}{d\tilde{\tau}}\log|f|\right)\tilde{\ell}^\beta \equiv \kappa_{\tilde{\ell}}\,\tilde{\ell}^\beta \ , \tag{12.131}$$

  where $\tilde{\tau}$ is the non-affine parameter along ℓ^α,

$$\frac{d}{d\tilde{\tau}}f = \tilde{\ell}^\alpha\nabla_\alpha f \tag{12.132}$$

- On the other hand for the expansion parameter etc one deduces from

$$\tilde{B}_{\alpha\beta} = \nabla_\beta\tilde{\ell}_\alpha = fB_{\alpha\beta} + \ell_\alpha\nabla_\beta f \tag{12.133}$$

  that the transverse projection is simply

$$\tilde{b}_{\alpha\beta} = fb_{\alpha\beta} \tag{12.134}$$

  which implies

$$\tilde{b}_{\alpha\beta} = fb_{\alpha\beta} \quad \Rightarrow \quad \left\{\begin{array}{ll}\theta_{\tilde{\ell}} & = f\theta_\ell\\ \tilde{\sigma}_{\alpha\beta} & = f\sigma_{\alpha\beta}\\ \tilde{\omega}_{\alpha\beta} & = f\omega_{\alpha\beta}\end{array}\right. \tag{12.135}$$

Plugging these results into (12.107) one obtains on the nose (12.129) (with $\tau \to \tilde{\tau}, \ell \to \tilde{\ell}$ etc.).

12.6 Expansions and Inaffinities of Radial Null Congruences

In this section, we look at some general properties of radial null congruences in a spherically symmetric space-time. All of the results of the previous sections 12.4 and 12.5 are of course also valid in this case, but the spherically symmetric case also has some special and simplifying features.

Thus we consider a spherically symmetric metric. Such a metric could always be written in the form

$$ds^2 = -A(t,r)dt^2 + B(t,r)dr^2 + r^2 d\Omega^2 \tag{12.136}$$

by a suitable choice of coordinates. However, we will not need to commit ourselves to this particular choice of coordinates. By making an arbitrary coordinate transformation

$$(t,r) \to z^a(t,r) \tag{12.137}$$

preserving the manifest spherical symmetry, this metric can be written in the form

$$ds^2 = g_{ab}(z)dz^a dz^b + r(z)^2 d\Omega^2 \tag{12.138}$$

for some 2-dimensional Lorentzian metric $g_{ab}(z)$, and with $r = r(z^a)$ now a function of the new coordinates.

We now consider two linearly independent radial and spherically symmetric null vector fields ℓ^α and n^α, which we choose to be cross normalised such that

$$\ell^\alpha \ell_\alpha = n^\alpha n_\alpha = 0 \quad , \quad \ell^\alpha n_\alpha = -1 \ . \tag{12.139}$$

Remarks:

1. Here "radial" means that it has components only in the ∂_{z^a}-directions transverse to the sphere, and "spherically symmetric" that the coefficients only depend on the z^a and not on the coordinates of the sphere (this can of course also, if desired, be phrased in a more coordinate-independent way, e.g. as the statement that the Lie derivatives of ℓ^α and n^α along the Killing vectors generating the rotational symmetry vanish, but for present purposes not much is gained by this).

2. In concrete applications we will choose n^α to be ingoing (in the sense that future directed null rays tangent to n^α will move towards smaller values of r) and ℓ^α to be (asymptotically) outgoing.

3. The minus sign in the cross normalisation is such that both vector fields are either future or past oriented (and we will of course choose the former).

4. Note that the individual normalisation of the ℓ^α and n^α is not fixed by the above conditions, i.e. one can still perform the boost

$$\ell^\beta \to \mathrm{e}^{+\alpha(x)}\ell^\beta \quad , \quad n^\beta \to \mathrm{e}^{-\alpha(x)}n^\beta \ . \tag{12.140}$$

> This can e.g. be used to select a preferred normalisation for one of them. If ℓ^α has been fixed, then, in spherical symmetry and with the assumption that n^α is also purely radial (longitudinal), n^α is uniquely determined by the 2 conditions $n^\alpha n_\alpha = 0$ and $n^\alpha \ell_\alpha = -1$. This should be contrasted with the situation without spherical symmetry where, as discussed in section 12.3, there is still the additional freedom to perform null rotations on n^α.

Spherical symmetry (and the choice of spherically symmetric null vector fields) also has other implications. For instance, it follows from spherical symmetry that $\ell^\alpha \nabla_\alpha \ell^\beta$ will be some linear combination of ℓ^β and n^β (i.e. no component tangent to the transverse sphere),

$$\ell^\alpha \nabla_\alpha \ell^\beta = A\ell^\beta + Bn^\beta \tag{12.141}$$

(and likewise for n^α). Taking the scalar product with ℓ_α and using

$$(\nabla_\alpha \ell^\beta)\ell_\beta = \tfrac{1}{2}\nabla_\alpha(\ell^\beta \ell_\beta) = 0 \ , \tag{12.142}$$

one finds that $B = 0$, so that automatically $\ell^\alpha \nabla_\alpha \ell^\beta \sim \ell^\beta$. Thus ℓ^α is automatically a geodesic null vector field, but perhaps not affinely parametrised. The proportionality constant A is then the *inaffinity* $A = \kappa_\ell$ (and likewise for n^α). Thus one has

$$\ell^\alpha \nabla_\alpha \ell^\beta = \kappa_\ell \ell^\beta \quad , \quad n^\alpha \nabla_\alpha n^\beta = \kappa_n n^\beta \ . \tag{12.143}$$

The boost freedom can then e.g. be used to choose either ℓ^α or n^α to be affinely parametrised (but usually not both of them simultaneously).

The same argument as above leads to the conclusion that necessarily $n^\alpha \nabla_\alpha \ell^\beta \sim \ell^\beta$ as well, and in this case the constant of proportionality is fixed by taking the scalar product with n_β (and likewise with $\ell \leftrightarrow n$), leading to the conclusions

$$\ell^\alpha \nabla_\alpha n^\beta = -\kappa_\ell n^\beta \quad , \quad n^\alpha \nabla_\alpha \ell^\beta = -\kappa_n \ell^\beta \ . \tag{12.144}$$

In particular, if $\kappa_\ell = 0$, say, this implies that n^α is parallel transported along ℓ, $\ell^\alpha \nabla_\alpha n^\beta = 0$.

It follows from either (12.143) or (12.144) that κ_ℓ and κ_n can be written as

$$\begin{aligned} \kappa_\ell &= -\ell^\alpha n^\beta \nabla_\alpha \ell_\beta = \ell^\alpha \ell^\beta \nabla_\alpha n_\beta \\ \kappa_n &= -n^\alpha \ell^\beta \nabla_\alpha n_\beta = n^\alpha n^\beta \nabla_\alpha \ell_\beta \ , \end{aligned} \tag{12.145}$$

or

$$\begin{aligned} \kappa_\ell &= \tfrac{1}{2}\ell^\alpha \ell^\beta (\nabla_\alpha n_\beta + \nabla_\beta n_\alpha) = \tfrac{1}{2}\ell^\alpha \ell^\beta L_n g_{\alpha\beta} \\ \kappa_n &= \tfrac{1}{2}n^\alpha n^\beta (\nabla_\alpha \ell_\beta + \nabla_\beta \ell_\alpha) = \tfrac{1}{2}n^\alpha n^\beta L_\ell g_{\alpha\beta} \end{aligned} \tag{12.146}$$

Here L_ℓ and L_n are the Lie derivatives. Thus the inaffinities encode the information about the longitudinal projections of the derivatives $\nabla_\alpha \ell_\beta$ and $\nabla_\alpha n_\beta$, or of the Lie derivatives $L_\ell g_{\alpha\beta}$ and $L_n g_{\alpha\beta}$.

Other useful information is contained in the transverse (i.e. parallel to the sphere) projections of these objects. To define them, note that, as in section 12.3, associated with a choice of ℓ^α and n^α we have the decomposition of the metric

$$g_{\alpha\beta} = s_{\alpha\beta} - (\ell_\alpha n_\beta + \ell_\beta n_\alpha) \tag{12.147}$$

with $s_{\alpha\beta}$ the transverse spatial metric (on the sphere),

$$s_{\alpha\beta} dx^\alpha dx^\beta = r(z)^2 d\Omega^2 \ \ , \tag{12.148}$$

but that in the current context this decomposition and the corresponding projectors $s^\alpha_{\ \beta}$ are now unique as the combination $\ell_\alpha n_\beta$ is boost-invariant.

The expansions of ℓ^α and n^α are defined as the transverse spatial projections of the divergence of ℓ^α respectively n^α, i.e.

$$\theta_\ell = s^{\alpha\beta}\nabla_\alpha \ell_\beta \quad , \quad \theta_n = s^{\alpha\beta}\nabla_\alpha n_\beta \ \ . \tag{12.149}$$

As in (12.101) and (12.102) of section 12.4, these can be written as

$$\begin{aligned} \theta_\ell &= \tfrac{1}{2} s^{\alpha\beta} L_\ell s_{\alpha\beta} = \frac{1}{\sqrt{s}} L_\ell \sqrt{s} \\ \theta_n &= \tfrac{1}{2} s^{\alpha\beta} L_n s_{\alpha\beta} = \frac{1}{\sqrt{s}} L_n \sqrt{s} \end{aligned} \tag{12.150}$$

With $\sqrt{s} = r(z)^2 \sin\theta$, one finds more explicitly

$$\theta_\ell = \frac{2}{r}\ell^\alpha \partial_\alpha r \quad , \quad \theta_n = \frac{2}{r} n^\alpha \partial_\alpha r \ \ . \tag{12.151}$$

If one works with r as one of the coordinates, then this can also succinctly be written as

$$\theta_\ell = \frac{2}{r}\ell^r \quad , \quad \theta_n = \frac{2}{r} n^r \ \ . \tag{12.152}$$

As in (12.126) of section 12.5, we also have the relations

$$\nabla^\alpha \ell_\alpha = \theta_\ell + \kappa_\ell \quad , \quad \nabla^\alpha n_\alpha = \theta_n + \kappa_n \ \ . \tag{12.153}$$

Turning now to the Raychaudhuri equation for a spherically symmetric radial null congruence ℓ, the general result (12.129) (for $\kappa_\ell \neq 0$), i.e.

$$\frac{d}{d\tau}\theta_\ell = \kappa_\ell \theta_\ell - R_{\alpha\beta}\ell^\alpha \ell^\beta - \tfrac{1}{2}\theta_\ell^2 - \sigma^{\alpha\beta}\sigma_{\alpha\beta} + \omega^{\alpha\beta}\omega_{\alpha\beta} \tag{12.154}$$

simplifies considerably. Spherical symmetry implies that the spatial shear and rotation tensors are zero (a spatial rotationally invariant 2-tensor is proportional to δ_{ik} which has neither a traceless nor an anti-symmetric part),

$$\sigma_{\alpha\beta} = \omega_{\alpha\beta} = 0 \ \ . \tag{12.155}$$

The vanishing of the rotation can also be deduced from the fact that ℓ is hypersurface orthogonal (specifically orthogonal to the family of null hypersurfaces generated by ℓ). Thus the Rauchaudhuri equation reduces to

$$\frac{d}{d\tau}\theta_\ell = \kappa_\ell \theta_\ell - R_{\alpha\beta}\ell^\alpha \ell^\beta - \tfrac{1}{2}\theta_\ell^2 \ \ . \tag{12.156}$$

13 CURVATURE IV: CURVATURE AND KILLING VECTORS

In (pseudo-)Riemannian geometry the rich interplay between symmetries and geometry is reflected in relations between the curvature tensor and Killing vectors of a metric. Here we will explore some of these relations and their consequences.

13.1 USEFUL IDENTITIES RELATING CURVATURE AND KILLING VECTORS

Using the defining relation of the Riemann curvature tensor,

$$(\nabla_\mu\nabla_\nu - \nabla_\nu\nabla_\mu)V_\lambda = -R^\rho{}_{\lambda\mu\nu}V_\rho \tag{13.1}$$

and its cyclic symmetry (8.18), it is possible to deduce that for a Killing vector K^μ,

$$\nabla_\mu K_\nu + \nabla_\nu K_\mu = 0 \ \ , \tag{13.2}$$

one has the following basic identity relating Killing vectors and the curvature tensor,

$$\nabla_\lambda\nabla_\mu K_\nu = R^\rho{}_{\lambda\mu\nu}\, K_\rho \ \ . \tag{13.3}$$

Indeed, proceeding as in the proof of the cyclic permutation identity (8.18), we deduce that

$$\nabla_{[\mu}\nabla_\nu K_{\lambda]} \sim R^\rho{}_{[\lambda\mu\nu]}K_\rho = 0 \ \ . \tag{13.4}$$

Since $\nabla_\nu K_\lambda$ is anti-symmetric, the total anti-symmetrisation is equivalent to cyclic permutation, and we therefore have

$$\nabla_\mu\nabla_\nu K_\lambda + \nabla_\nu\nabla_\lambda K_\mu + \nabla_\lambda\nabla_\mu K_\nu = 0 \ \ . \tag{13.5}$$

Using the Killing property in the second term, we can write this as

$$\nabla_\lambda\nabla_\mu K_\nu = -[\nabla_\mu, \nabla_\nu]K_\lambda = R^\rho{}_{\lambda\mu\nu}K_\rho \tag{13.6}$$

which is (13.3).

This identity can be interpreted as the statement (and can alternatively be derived from the fact) that the Lie derivative of the Christoffel symbols of a metric along a Killing vector of the metric is zero.

Indeed, first of all it is easy to see that under a general variation of the metric, the induced variation of the Christoffel symbol can be written as (20.14)

$$\delta\Gamma^\mu{}_{\nu\lambda} = \tfrac{1}{2}g^{\mu\rho}(\nabla_\nu\delta g_{\rho\lambda} + \nabla_\lambda\delta g_{\rho\nu} - \nabla_\rho\delta g_{\nu\lambda}) \ \ . \tag{13.7}$$

(this is easy to derive and also easy to remember as it takes exactly the same form as the definition of the Christoffel symbol, only with the metric replaced by the metric variation and the partial derivatives by covariant derivatives - see section 20.2 for a derivation and discussion of this identity). In particular, this exhibits the fact that the metric variation of the Christoffel symbols is a tensor (as could have been anticipated from the fact that the non-tensorial term in the transformation of the Christoffel symbols is independent of the metric), and additionally provides us with an explicit expression for this tensor.

Next, if the variation $\delta g_{\mu\nu} = L_\xi g_{\mu\nu}$ is the Lie derivative, i.e. the variation in the metric induced by an infinitesimal coordinate transformation $\delta x^\mu = \xi^\mu$, one can write this as

$$L_\xi \Gamma^\mu_{\ \nu\lambda} = \tfrac{1}{2} g^{\mu\rho}(\nabla_\nu L_\xi g_{\rho\lambda} + \nabla_\lambda L_\xi g_{\rho\nu} - \nabla_\rho L_\xi g_{\nu\lambda}) \ . \tag{13.8}$$

Note that in general the Lie derivative of a non-tensorial quantity is not well defined (or at least its definition requires a bit more thought). Here, however, it is natural to use the general formula (13.7) for the variation of the Christoffel symbols under metric variations to in particular define their Lie derivative (as the change in the Christoffel symbols induced by the Lie derivative of the metric).

Thus, adopting this definition and using $L_\xi g_{\mu\nu} = \nabla_\mu \xi_\nu + \nabla_\nu \xi_\nu$, the right-hand side can (upon using the definition and cyclic symmetry of the Riemann tensor) be written as

$$\begin{aligned} L_\xi \Gamma^\mu_{\ \nu\lambda} &= \nabla_\lambda \nabla_\nu \xi^\mu - R^\mu_{\ \nu\lambda\rho} \xi^\rho \\ &= \nabla_\nu \nabla_\lambda \xi^\mu + R^\mu_{\ \lambda\rho\nu} \xi^\rho \ . \end{aligned} \tag{13.9}$$

In particular, if $\xi^\mu = K^\mu$ is a Killing vector, one has

$$L_K g_{\mu\nu} = 0 \quad \Rightarrow \quad L_K \Gamma^\mu_{\ \nu\lambda} = 0 \quad \Leftrightarrow \quad \nabla_\lambda \nabla_\nu K_\mu = R_{\mu\nu\lambda\rho} K^\rho \ , \tag{13.10}$$

which is equivalent to (13.3).

Contracting (13.3) over λ and ν, one obtains the next useful and frequently used identity

$$\nabla^\nu \nabla_\mu K_\nu = K^\nu R_{\mu\nu} \ . \tag{13.11}$$

In turn, one immediate consequence of this identity is (contract with K^μ, "integrate by parts" and use the anti-symmetry of $\nabla_\mu K_\nu$)

$$R_{\mu\nu} K^\mu K^\nu = (\nabla^\mu K^\nu)(\nabla_\mu K_\nu) + \nabla_\nu (K^\mu \nabla_\mu K^\nu) \ . \tag{13.12}$$

Note that this can also be deduced directly from (8.53) for $V^\mu \to K^\mu$ a Killing vector.

We will now look at various consequences of the identities (13.3), (13.11) and (13.12) which are useful and interesting in their own right. The implications of these identities for *maximal symmetry* and *maximally symmetric spaces* will be discussed separately in section 14 below.

13.2 Killing Vectors form a Lie algebra

As the first application, we will explicitly prove the assertion (9.45) of section 9.5 that the Lie bracket of two Killing vectors is again a Killing vector. While this follows from the general property (9.34) of the Lie derivative, which itself can (with some work) be deduced from the general definition of the Lie derivative (as the generator of the action of coordinate transformations on tensors), it is instructive and reassuring to verify this by an explicit calculation, also because similar manipulations are required when extending the analysis from Killing vectors to Killing tensors or Killing-Yano tensors briefly mentioned in section 10.5.[30]

Thus consider two Killing vectors A^μ and B^μ, say, i.e. vector fields satisfying

$$\nabla_\mu A_\nu + \nabla_\nu A_\mu = \nabla_\mu B_\nu + \nabla_\nu B_\mu = 0 \tag{13.13}$$

or, equivalently,

$$\nabla_\mu A_\nu = \nabla_{[\mu} A_{\nu]} \quad , \quad \nabla_\mu B_\nu = \nabla_{[\mu} B_{\nu]} \ . \tag{13.14}$$

Explicitly, from (9.18) their Lie bracket is the vector field

$$C^\mu = [A,B]^\mu = A^\nu \nabla_\nu B^\mu - B^\nu \nabla_\nu A^\mu \ , \tag{13.15}$$

and the claim is that C^μ is also Killing, i.e. that $\nabla_\mu C_\nu$ is anti-symmetric,

$$C^\mu = [A,B]^\mu \quad \Rightarrow \quad \nabla_\mu C_\nu = \nabla_{[\mu} C_{\nu]} \ . \tag{13.16}$$

In calculating $\nabla_\mu C_\nu$ one encounters new first derivatives of A^μ and B^μ (which can be manipulated by the Killing equations), as well as second covariant derivatives, which can be reduced to zero-derivative terms by using the fundamental identity (13.3),

$$\begin{aligned}\nabla_\mu C_\nu &= (\nabla_\mu A_\lambda)\nabla^\lambda B_\nu - (\nabla_\mu B_\lambda)\nabla^\lambda A_\nu + A_\lambda \nabla_\mu \nabla^\lambda B_\nu - B_\lambda \nabla_\mu \nabla^\lambda A_\nu \\ &= -(\nabla_\lambda A_\mu)\nabla^\lambda B_\nu + (\nabla^\lambda B_\mu)\nabla_\lambda A_\nu + R_{\rho\mu\lambda\nu}(A^\lambda B^\rho - B^\lambda A^\rho) \ .\end{aligned} \tag{13.17}$$

The first two terms are already manifestly anti-symmetric (the second being the anti-symmetrisation of the first), and by the cyclic identity and other symmetries of the Riemann tensor, so is the last term,

$$R_{\rho\mu\lambda\nu} - R_{\lambda\mu\rho\nu} = R_{\mu\lambda\rho\nu} - R_{\mu\rho\lambda\nu} = R_{\mu\nu\lambda\rho} = -R_{\nu\mu\lambda\rho} \ . \tag{13.18}$$

Thus the Lie bracket of two Killing vectors is indeed again a Killing vector, as claimed.

---

[30] The interesting question if or when Killing-Yano tensors form a Lie algebra, extending and generalising the Lie algebra of the isometry group generated by the Killing vectors, is analysed in D. Kastor, S. Ray, J. Traschen, *Do Killing-Yano tensors form a Lie Algebra?*, `arXiv:0705.0535 [hep-th]`.

13.3 On the Isometry Algebra of a Compact Riemannian Space

In this section we will look at one immediate application of the identity (13.12),

$$R_{\mu\nu}K^\mu K^\nu = (\nabla^\mu K^\nu)(\nabla_\mu K_\nu) + \nabla_\nu(K^\mu \nabla_\mu K^\nu) \;\; , \tag{13.19}$$

namely an analogue of the Bochner-Yano type argument (given in remark 8 of section 8.5) for Killing vectors. Again, in order to be able to say something of substance we assume that the space we are dealing with is compact without boundary, and Riemannian, i.e. equipped with a positive-definite metric. In spite of this, the result we will derive is relevant also for physics, at least as long as one is willing to entertain the possibility that some higher-dimensional generalisations of general relativity (such as Kaluza-Klein theories discussed in section 44) plays a role in some more fundamental description of nature.

With the above assumptions, the first term on the right-hand side of (13.19) is non-negative and the second is a total derivative term that vanishes upon integration. Therefore for a Killing vector to exist on a compact Riemannian space, the integral of $R_{\mu\nu}V^\mu V^\nu$ must be non-negative as well.

This has two immediate implications:

1. If the Ricci tensor (regarded as a quadratic form) of a Riemannian metric on a compact space is negative, that metric can have no continuous isometries whatsoever.
2. If the metric on a compact Riemannian space has vanishing Ricci tensor, $R_{\mu\nu} = 0$, then any Killing vector is covariantly constant, $\nabla_\mu K_\nu = 0$.

Since the Lie bracket of two covariantly constant vector fields is zero,

$$\nabla_\mu V_\nu = \nabla_\mu W_\mu = 0 \quad \Rightarrow \quad [V,W]^\mu = V^\nu \nabla_\nu W^\mu - W^\nu \nabla_\nu V^\mu = 0 \;\; , \tag{13.20}$$

this means that continuous isometries of a space with vanishing Ricci tensor can at most be Abelian. An example is provided by the torus T^n equipped with the flat metric it inherits from regarding T^n as the periodic identification of $\mathbb{R}^n$. This metric has vanishing Ricci tensor (because evidently even the Riemann tensor is zero), but there are n linearly-independent (covariantly) constant translational Killing vectors (inherited from $\mathbb{R}^n$) that generate the Abelian isomtery group $U(1)^n$.

In Kaluza-Klein theory, one of the basic ideas is that gauge symmetries arise from isometries of the "internal" space living in the extra dimensions. This internal space is usually assumed to be compact (so as to be sufficiently small to have escaped our attention). Thus, if one wants to generate non-Abelian gauge theories in this way the above results provide one of the most basic constraints on the internal geometry, namely that the Ricci tensor should not be non-positive (but it does not have to be strictly positive everywhere).

13.4 Invariance of the Curvature along Killing Directions

It should be obvious and obviously true that for any Killing vector of a metric the scalar curvature of the metric inherits the corresponding symmetries of the metric, i.e. that it does not change along the orbits of that Killing vector,

$$\nabla_\mu K_\nu + \nabla_\nu K_\mu = 0 \quad \Rightarrow \quad K^\mu \nabla_\mu R = 0 \ , \tag{13.21}$$

or

$$L_K g_{\mu\nu} = 0 \quad \Rightarrow \quad L_K R = 0 \tag{13.22}$$

(with analogous statements for the Riemann and Ricci tensors).

While true, a covariant proof of this is a bit roundabout:

- One can start with the contracted Bianchi identity $\nabla^\mu G_{\mu\nu} = 0$, and contract it with K^ν to find

$$0 = (\nabla^\mu G_{\mu\nu}) K^\nu = (\nabla^\mu R_{\mu\nu}) K^\nu - \tfrac{1}{2} K^\nu \nabla_\nu R \ . \tag{13.23}$$

- Using the Killing equations, i.e. the anti-symmetry of $\nabla_\mu K_\nu$, and the symmetry of the Ricci tensor, one can write this as

$$K^\nu \nabla_\nu R = 2\nabla^\mu (K^\nu R_{\mu\nu}) \ . \tag{13.24}$$

- Using (13.11), one finally arrives at

$$K^\nu \nabla_\nu R = 2\nabla^\mu (\nabla^\nu \nabla_\mu K_\nu) = [\nabla^\mu, \nabla^\nu] \nabla_\mu K_\nu = 0 \tag{13.25}$$

  by (8.46).

Alternatively (and more quickly but somewhat less covariantly) one could have simply locally introduced an adapted coordinate system (9.59) in which $K = \partial_y$ and $\partial_y g_{\mu\nu} = 0$, to immediately deduce that then necessarily also $\partial_y R = 0$. However, on general grounds, and with an eye towards possible generalisations, it is always useful to have different arguments at one's disposal, in particular among them one which is covariant.

Analogously one can prove, either covariantly or non-covariantly (recommended in this case), that the Lie derivative of the Riemann tensor and the Ricci tensor along a Killing vector are zero,

$$L_K g_{\mu\nu} = 0 \quad \Rightarrow \quad L_K R_{\lambda\sigma\mu\nu} = 0 \quad , \quad L_K R_{\mu\nu} = 0 \ . \tag{13.26}$$

Since $\nabla_\mu K_\nu$ is anti-symmetric, one can write (13.11) more explicitly with the help of the formula (5.64) for the covariant divergence of an anti-symmetric tensor as

$$R^\mu_{\ \nu} K^\nu = \frac{1}{\sqrt{g}} \partial_\nu (\sqrt{g} \nabla^\mu K^\nu) \ . \tag{13.27}$$

This can be a quite efficient way to calculate certain components of the Ricci tensor of a metric, namely those which are of the form $R^\mu_{\ \nu} K^\nu$ for some Killing vector (the components referred to glibly as the "Killing components of the Ricci tensor" in the heading). In spite of this, this shortcut does not appear to be widely known or commonly used.

As an illustration of how this works, consider again the general static spherically symmetric metric (3.22),

$$ds^2 = -A(r)dt^2 + B(r)dr^2 + r^2 d\Omega^2 \ . \tag{13.28}$$

Among the Killing vectors of this metric is the vector field $\xi = \partial_t$ generating time-translations, and thus we can use (13.27) to determine the components $R^\mu_{\ t}$ of the Ricci tensor.

Since the only non-trivial component of ξ_μ is $\xi_t = -A(r)$, one has

$$\nabla_\mu \xi_\nu = \partial_\mu \xi_\nu - \Gamma^\lambda_{\ \mu\nu} \xi_\lambda = \partial_\mu \xi_\nu + A(r) \Gamma^t_{\ \mu\nu} \ , \tag{13.29}$$

and since according to (3.25) the only non-trivial component of $\Gamma^t_{\ \mu\nu}$ is

$$\Gamma^t_{\ rt} = \Gamma^t_{\ tr} = \frac{A'}{2A} \quad , \quad \Gamma^t_{\ \mu\nu} = 0 \quad \text{otherwise} \ , \tag{13.30}$$

the only non-trivial components of $\nabla_\mu \xi_\nu$ are

$$\nabla_t \xi_r = -\nabla_r \xi_t = A'/2 \quad , \quad \nabla_\mu \xi_\nu = 0 \quad \text{otherwise} \ . \tag{13.31}$$

Thus the only non-zero components of $\nabla^\mu \xi^\nu$ are

$$\nabla^r \xi^t = -\nabla^t \xi^r = A'/2AB \ . \tag{13.32}$$

With

$$\sqrt{g} = \sqrt{AB} r^2 \sin\theta \tag{13.33}$$

one then has

$$R^\mu_{\ t} = \frac{1}{\sqrt{AB} r^2} \partial_r (\sqrt{AB} r^2 \nabla^\mu \xi^r) \tag{13.34}$$

so that evidently

$$R^k_{\ t} = 0 \quad \text{with} \quad x^k = (r, \theta, \phi) \tag{13.35}$$

while

$$R^t{}_t = -\frac{1}{2\sqrt{AB}r^2}\partial_r(r^2A'/\sqrt{AB}) \quad . \tag{13.36}$$

Explicitly one can write this as

$$R_{tt} = -AR^t{}_t = \frac{A''}{2B} - \frac{A'}{4B}(\frac{A'}{A} + \frac{B'}{B}) + \frac{A'}{rB} \quad . \tag{13.37}$$

Remarks:

1. As you can check for yourself, this way of determining R_{tt} is much quicker than working it out from the general formula for the Ricci tensor involving the Christoffel symbols squared as well as their derivatives. In fact it is the quickest and slickest way to obtain R_{tt} by a calculation in coordinate components that I am aware of.
2. In the same way, one can also determine the angular components $R^\mu{}_\phi$, say, using the Killing vector $\eta = \partial_\phi$.
3. The only not obviously vanishing component of $R_{\mu\nu}$ (see the discussion in section 24.3) that cannot be obtained in this way is R_{rr}.

13.6 Killing Vectors as Solutions to the Maxwell Equations

A cute application of the identity (13.11) is the following. Recall that in the covariant Lorenz gauge

$$\nabla_\mu A^\mu = 0 \tag{13.38}$$

the vacuum Maxwell equations

$$\nabla^\mu F_{\mu\nu} = \nabla^\mu(\nabla_\mu A_\nu - \nabla_\nu A_\mu) = 0 \tag{13.39}$$

can be written as (8.115)

$$\nabla^\nu\nabla_\nu A^\mu = R^\mu_\nu A^\nu \quad , \tag{13.40}$$

while a Killing vector automatically satisfies

$$\nabla_\mu K_\nu + \nabla_\nu K_\mu = 0 \quad \Rightarrow \quad \nabla_\mu K^\mu = 0 \tag{13.41}$$

and the identity (13.11),

$$\nabla^\nu\nabla_\mu K^\nu = R_{\mu\nu}K^\nu \quad \Leftrightarrow \quad \nabla^\nu\nabla_\nu K^\mu = -R^\mu_\nu K^\nu \quad . \tag{13.42}$$

Thus the sign of the Ricci tensor in (13.40) and (13.42) is different, but evidently this difference disappears for a metric with vanishing Ricci tensor. This does not imply at all that the Riemann tensor is zero. Indeed, we will learn in section 19 that the vacuum Einstein equations (i.e. the gravitational field equations without or outside of matter sources) are simply the "Ricci flatness" conditions $R_{\mu\nu} = 0$ (19.36).

In that case (13.42) reduces to $\nabla^\nu \nabla_\nu K_\mu = 0$ which is of the same form as (13.40). Alternatively, because of the anti-symmetry of $\nabla_\mu K_\nu$, we can equivalently write (13.42) as

$$R_{\mu\nu} = 0 \quad \Rightarrow \quad \nabla^\mu (\nabla_\mu K_\nu - \nabla_\nu K_\mu) = 0 \ , \tag{13.43}$$

which, with the dictionary

$$A_\mu = K_\mu \quad , \quad F_{\mu\nu} = \nabla_\mu K_\mu - \nabla_\nu K_\mu \quad \Rightarrow \quad \nabla^\mu F_{\mu\nu} = 0 \ , \tag{13.44}$$

is identical to (13.39).

This means that any Killing vector of a solution to the vacuum Einstein equations automatically gives rise to a solution of the vacuum Maxwell equations in that gravitational background. Depending on the Killing vector this may or may not be a non-trivial ($F_{\mu\nu} \neq 0$) solution to the Maxwell equations, "rotational" Killing vectors typically giving rise to non-trivial solutions while for "translational" Killing vectors A_μ is pure gauge (see section 14.1 for a more precise characterisation of what is meant by "rotational" and "translational" Killing vectors at a given point).

For example, taking the general Killing vector (9.48) of Minkowski space (which certainly has vanishing Ricci tensor),

$$K^\alpha = \omega^\alpha_{\ \beta}\, x^\beta + \epsilon^\alpha \quad \Rightarrow \quad A_\alpha \equiv K_\alpha = \omega_{\alpha\beta}\, x^\beta + \epsilon_\alpha \ , \tag{13.45}$$

one finds that the associated Maxwell field strength tensor is

$$F_{\alpha\beta} = \partial_\alpha K_\beta - \partial_\beta K_\alpha = -2\omega_{\alpha\beta} \ . \tag{13.46}$$

Thus it vanishes for a purely translational Killing vector while a boost is associated with a constant electric field ($E_k \sim \omega_{0k}$) and a spatial rotation gives rise to a constant magnetic field ($B_k \sim \epsilon_{kij}\omega_{ij}$).

13.7 KILLING VECTORS AND KOMAR CURRENTS

Because the Einstein tensor $G_{\mu\nu}$ (8.97) is symmetric and conserved (the contracted Bianchi identity (8.96)), to any Killing vector one can associate (cf. the discussion in section 10.1) the conserved current

$$J_1^\mu = G^\mu_{\ \nu} K^\nu = R^\mu_{\ \nu} K^\nu - \tfrac{1}{2} R \delta^\mu_{\ \nu} K^\nu = R^\mu_{\ \nu} K^\nu - \tfrac{1}{2} R K^\mu \ . \tag{13.47}$$

However, because K^μ is Killing, one has $\nabla_\mu K^\mu = 0$ identically, as well as $K^\mu \nabla_\mu R = 0$ (as shown above), and hence one has a conserved current

$$J_a^\mu = R^\mu_{\ \nu} K^\nu - \tfrac{1}{2} a\, R K^\mu \quad , \quad \nabla_\mu J_a^\mu = 0 \ , \tag{13.48}$$

for any value of the real parameter a. Among this 1-parameter family of conserved currents, the choice

$$J_{a=0}^\mu \equiv J^\mu(K) = R^{\mu\nu} K_\nu \tag{13.49}$$

(the *Komar current*) is singled out by the fact that, by (13.11), it is not only conserved but can actually be written as the divergence of an anti-symmetric tensor,

$$J^{\mu}(K) = \nabla_{\nu} A^{\mu\nu} \quad , \quad A^{\mu\nu} = -A^{\nu\mu} = \nabla^{\mu} K^{\nu} \tag{13.50}$$

(which also shows directly, by (8.47), that $\nabla_{\mu} J^{\mu}(K) = 0$).

Thus the corresponding conserved charge, written as a hypersurface integral, can actually be written as a *surface integral* of components of $A_{\mu\nu}$. These define the so-called *Komar charges* associated to symmetries of the metric. They will make a brief appearance in section 23.4.

As an aside, note that while in the above we started off with Killing vectors, a similar story is actually true for any vector field. Namely, for any vector field ξ^{μ} define the current

$$J^{\mu}(\xi) = \nabla_{\nu}(\nabla^{[\mu}\xi^{\nu]}) = \tfrac{1}{2}\nabla_{\nu}(\nabla^{\mu}\xi^{\nu} - \nabla^{\nu}\xi^{\mu}) \ . \tag{13.51}$$

Note that this reduces to (13.50) for $\xi^{\mu} = K^{\mu}$ a Killing vector. Moreover, by (8.47) this current is conserved,

$$\nabla_{\mu} J^{\mu}(\xi) = 0 \quad \forall\, \xi^{\mu} \ . \tag{13.52}$$

When $\xi^{\mu} = K^{\mu}$ is a Killing vector, the current can alternatively be written in terms of the Ricci tensor as in (13.49). For a general ξ^{μ} one has, instead,

$$\begin{aligned} J^{\mu}(\xi) &= \tfrac{1}{2}\nabla_{\nu}(\nabla^{\mu}\xi^{\nu} - \nabla^{\nu}\xi^{\mu}) = \nabla_{\nu}\nabla^{\mu}\xi^{\nu} - \tfrac{1}{2}\nabla_{\nu}(\nabla^{\nu}\xi^{\mu} + \nabla^{\mu}\xi^{\nu}) \\ &= [\nabla^{\nu}, \nabla^{\mu}]\xi_{\nu} + \nabla^{\mu}(\nabla_{\nu}\xi^{\nu}) - \tfrac{1}{2}\nabla_{\nu}(\nabla^{\nu}\xi^{\mu} + \nabla^{\mu}\xi^{\nu}) \\ &= R^{\mu}_{\ \nu}\xi^{\nu} + \tfrac{1}{2}(g^{\alpha\beta}g^{\mu\nu} - g^{\mu\alpha}g^{\nu\beta})\nabla_{\nu}(\nabla_{\alpha}\xi_{\beta} + \nabla_{\beta}\xi_{\alpha}) \ , \end{aligned} \tag{13.53}$$

where we made use of (8.40). Note that this indeed reduces to (13.49) for a Killing vector, for which the second term on the right-hand side is absent.

The existence of these identically conserved currents and the corresponding surface charge densities $\nabla^{[\mu}\xi^{\nu]}$ reflects the fact that in general relativity (more generally, in any generally covariant theory) all vector fields can be considered as the generators of symmetries (in the sense of coordinate transformations). Indeed, the currents $J^{\mu}(\xi)$ can be shown to be precisely the corresponding Noether currents arising from the Lagrangian formulation of general relativity to be discussed in section 20. We will establish this result in section 20.6. Nevertheless, the currents and charges associated with Killing vectors turn out to play a privileged role, and we will in particular relate the Komar charge for a timelike Killing vector to the ADM mass of an isolated (asymptotically) static system in section 23.4.

14 CURVATURE V: MAXIMAL SYMMETRY AND CONSTANT CURVATURE

As a preparation for our discussion of cosmology in sections 33 - 38, in this section we will discuss some aspects of what are known as *maximally symmetric spaces*. These are spaces that admit the maximal number of Killing vectors (which turns out to be $n(n+1)/2$ for an n-dimensional space or space-time).

As we will discuss later on, in the context of the *Cosmological Principle*, such spaces, which are simultaneously homogeneous ("the same at every point") and isotropic ("the same in every direction") provide an (admittedly highly idealised) description of space in a cosmological space-time.

If you already know (or are willing to believe) that in any spatial dimension n there are essentially only 3 such spaces, namely the Euclidean space $\mathbb{R}^n$, the sphere S^n, and its negative curvature counterpart, the hyperbolic space H^n (all equipped with their standard metrics), you can skip this section, and may just want to refer to section 14.3 where it is shown that these 3 standard metrics can be written in a unified way as

$$ds^2 = \frac{dr^2}{1-kr^2} + r^2 d\Omega^2_{n-1} \tag{14.1}$$

for $k = 0, \pm 1$ respectively.

The discussion of maximally symmetric spaces and, in particular, space-times will be taken up again and continued in section 39 (which can also be read as a direct sequel to this section, without the intervening sections 33 - 38 on cosmology).

14.1 HOMOGENEOUS, ISOTROPIC AND MAXIMALLY SYMMETRIC SPACES

In order to understand how to define and characterise maximally symmetric spaces, we will need to obtain some more information about how Killing vectors can be classified.

Our starting point is, as in the previous section, the identity (13.3), reproduced here with the explicit x-dependence included for present purposes,

$$\nabla_\lambda \nabla_\mu K_\nu(x) = R^\rho{}_{\lambda\mu\nu}(x) K_\rho(x) \quad . \tag{14.2}$$

In particular, this shows that the second derivatives of the Killing vector at a point x_0 are again expressed in terms of the value of the Killing vector itself at that point. This means (think of Taylor expansions) that, remarkably, a Killing vector field $K^\mu(x)$ is completely and uniquely determined everywhere by the values of $K_\mu(x_0)$ and $\nabla_\mu K_\nu(x_0)$ at a single point x_0.

A set of Killing vectors $\{K^{(i)}_\mu(x)\}$ is said to be *linearly independent* if any linear relation of the form

$$\sum_i c_i K^{(i)}_\mu(x) = 0 \quad , \tag{14.3}$$

with *constant* coefficients c_i implies $c_i = 0$ (the reason for insisting on constant coefficients rather than functions $c_i(x)$ in this definition is of course that if K^μ is a Killing vector, then so is cK^μ iff c is constant).

Since, in an n-dimensional space(-time) there can be at most n linearly independent vectors ($K_\mu(x_0)$) at a point, and at most $n(n-1)/2$ independent anti-symmetric matrices ($\nabla_\mu K_\nu(x_0)$), we reach the conclusion that an n-dimensional space(-time) can have at most

$$n + \frac{n(n-1)}{2} = \frac{n(n+1)}{2} \tag{14.4}$$

independent Killing vectors. A space(-time) with this maximal number of Killing vectors is called *maximally symmetric*.

An example of a metric with the maximal number of Killing vectors is, none too surprisingly, n-dimensional Minkowski space, where $n(n+1)/2$ agrees with the dimension of the Poincaré group, the group of transformations that leave the Minkowski metric invariant.

Other examples of spaces that are maximally symmetric spaces are provided by spheres with their standard metric (e.g. we already know that the 2-sphere has $3 = 2(2+1)/2$ linearly independent Killing vectors, given explicitly in (9.55)). We will show below that spheres and their negative curvature hyperbolic counterparts are the unique non-trivial maximally symmetric spaces (with a corresponding statement for maximally symmetric space-times, which we will study in detail in section 39).

We will now see how the data $K^\mu(x_0)$ and $\nabla_\mu K_\nu(x_0)$ are related to translations and rotations:

- We define a *homogeneous space* to be such that it has infinitesimal isometries that carry any given point x_0 into any other point in its immediate neighbourhood (this could be stated in more fancy terms!). Thus the metric must admit Killing vectors that, at any given point, can take all possible values. Thus we require the existence of Killing vectors for arbitrary $K_\mu(x_0)$. This means that the n-dimensional space admits the maximal number n of *translational Killing vectors.*
- We define a space to be *isotropic at a point* x_0 if it has isometries that leave the given point x_0 fixed and such that they can rotate any vector at x_0 into any other vector at x_0. Therefore the metric must admit Killing vectors such that $K_\mu(x_0) = 0$ but such that $\nabla_\mu K_\nu(x_0)$ is an arbitrary anti-symmetric matrix (for instance to be thought of as an element of the Lie algebra of $SO(n)$). This means that the n-dimensional space admits the maximal number $n(n-1)/2$ of *rotational Killing vectors.*
- Finally, we define a *maximally symmetric space* to be a space with a metric with the maximal number $n(n+1)/2$ of Killing vectors.

For example, as mentioned before, the 2-sphere is maximally symmetric, with 3 linearly independent Killing vectors, given explicitly e.g. in (9.55). The decomposition of these 3 Killing vectors into 1 rotational and 2 translational Killing vectors depends on the point on the 2-sphere, the rotational Killing vector always being associated with the rotations around the axis through that point, and the translational Killing vectors being formed by the remaining 2 linearly independent combinations of Killing vectors. The decomposition given in (9.55) is adapted to rotations around the north (or south) pole, with $V_{(3)} = \partial_\phi$ the corresponding rotational Killing vector. Note that this Killing vector acts as a rotation at / around the poles but that it acts as a translation away from the poles (where some other linear combination of the 3 Killing vectors would be the rotational Killing vector). We will come back to this in slightly more general terms below.

Some simple and fairly obvious consequences of these definitions are the following:

1. A homogeneous and isotropic space is maximally symmetric.
2. A space that is isotropic for all x is also homogeneous.
3. (1) and (2) now imply that a space which is isotropic around every point is maximally symmetric.
4. Finally one also has the converse, namely that a maximally symmetric space is homogeneous and isotropic.

Property (2) is a consequence of the fact that constant linear combinations of Killing vectors are again Killing vectors and that, as mentioned above in the context of the 2-sphere, away from the origin of the rotation a rotation acts just like a translation. Technically, the difference between two rotational Killing vectors at x and $x + dx$ can be shown to be a translational Killing vector. To see this (roughly), consider 2 Killing vectors K and L describing rotations about a point x_0 and a point $x_0 + dx$ respectively, i.e.

$$K^\mu(x_0) = 0 \quad , \quad L^\mu(x_0 + dx) = 0 \ . \tag{14.5}$$

and, in particular,

$$(\nabla_\mu L_\nu)(x_0 + dx) \neq 0 \ . \tag{14.6}$$

Now consider the difference

$$M^\mu(x) = K^\mu(x) - L^\mu(x) \tag{14.7}$$

which is still a Killing vector. At $x = x_0$ one has

$$M^\mu(x_0) = K^\mu(x_0) - L^\mu(x_0) = -L^\mu(x_0 + dx - dx) \ . \tag{14.8}$$

Now expanding $L^\mu(x)$ around the point $x+dx$, one has (in an inertial coordinate system at x_0, say)

$$M_\mu(x_0) = dx^\lambda \nabla_\lambda L_\mu(x_0 + dx) \neq 0 \tag{14.9}$$

while its matrix of covariant derivatives ∇M vanishes there due to the crucial identity $\nabla\nabla L \sim L$ (14.2). Thus M defines a translational Killing vector at x_0.

In practice the characterisation of a maximally symmetric space which is easiest to use is (3) because it requires consideration of only one type of symmetries, namely rotational symmetries.

14.2 CURVATURE TENSOR OF A MAXIMALLY SYMMETRIC SPACE

On the basis of these simple considerations we can already determine the form of the Riemann curvature tensor of a maximally symmetric space. We will see that maximally symmetric spaces are spaces of constant curvature in the sense that the Riemann curvature tensor is simply and purely algebraically related to the metric by

$$R_{ijkl} = k(g_{ik}g_{jl} - g_{il}g_{jk}) \tag{14.10}$$

for some constant k.

This result could be obtained by making systematic use of the higher order integrability conditions for the existence of a maximal number of Killing vectors. The argument given below is less covariant but more elementary.

Assume for starters that the space is isotropic at x_0 and choose a Riemann normal coordinate system centered at x_0. Thus the metric at x_0 is $g_{ij}(x_0) = \eta_{ij}$ where we may just as well be completely general and assume that

$$\eta_{ij} = \text{diag}(\underbrace{-1,\ldots,-1}_{p \text{ times}}\underbrace{+1,\ldots,+1}_{q \text{ times}}) \quad , \tag{14.11}$$

where $p + q = n$ and we only assume $n > 2$.

If the metric is supposed to be isotropic at x_0 then, in particular, the curvature tensor at the origin must be invariant under Lorentz rotations. Now we know (i.e. you should know from your Special Relativity course) that the only invariants of the Lorentz group are the Minkowski metric and products thereof, and the totally anti-symmetric Levi-Civita tensor. Thus the Riemann curvature tensor has to be of the form

$$R_{ijkl}(x_0) = a\eta_{ij}\eta_{kl} + b\eta_{ik}\eta_{jl} + c\eta_{il}\eta_{jk} + d\epsilon_{ijkl} \quad , \tag{14.12}$$

where the last term is only possible for $D = 4$. The symmetries of the Riemann tensor imply that $a = d = b + c = 0$, and hence we are left with

$$R_{ijkl}(x_0) = b(\eta_{ik}\eta_{jl} - \eta_{il}\eta_{jk}) \quad , \tag{14.13}$$

Thus in an arbitrary coordinate system we will have

$$R_{ijkl}(x_0) = b(g_{ik}(x_0)g_{jl}(x_0) - g_{il}(x_0)g_{jk}(x_0)) \ , \tag{14.14}$$

If we now assume that the space is isotropic around every point, then we can deduce that

$$R_{ijkl}(x) = b(x)(g_{ik}(x)g_{jl}(x) - g_{il}(x)g_{jk}(x)) \tag{14.15}$$

for some function $b(x)$. Therefore the Ricci tensor and the Ricci scalar are

$$\begin{aligned} R_{ij}(x) &= (n-1)b(x)g_{ij} \\ R(x) &= n(n-1)b(x) \ . \end{aligned} \tag{14.16}$$

and the Riemann curvature tensor can also be written as

$$R_{ijkl} = \frac{R}{n(n-1)}(g_{ik}g_{jl} - g_{il}g_{jk}) \ , \tag{14.17}$$

while the Einstein tensor is

$$G_{ij} = b[(n-1)(1-n/2)]g_{ij} \ . \tag{14.18}$$

For $n > 2$ the contracted Bianchi identity $\nabla^i G_{ij} = 0$ now implies that $b(x)$ has to be a constant, and we have thus established (14.10). Note that we also have

$$R_{ij} = k(n-1)g_{ij} \ , \tag{14.19}$$

so that a maximally symmetric space(-time) is automatically a solution to the vacuum Einstein equations with a cosmological constant. In the physically relevant case $p = 1$ these are known as de Sitter or anti de Sitter space-times. We will come back to them in detail later on, in section 39.

14.3 MAXIMALLY SYMMETRIC METRICS I: SOLVING THE CONSTANT CURVATURE CONDITIONS

We are interested not just in the curvature tensor of a maximally symmetric space but in the metric itself. I will give you two derivations of the metric of a maximally symmetric space, one by directly solving the differential equation

$$R_{ij} = k(n-1)g_{ij} \tag{14.20}$$

for the metric g_{ij}, the other by a direct geometrical construction of the metric which makes the isometries of the metric manifest.

As a maximally symmetric space is in particular spherically symmetric, we can write its metric in the form

$$ds^2 = B(r)dr^2 + r^2 d\Omega^2_{(n-1)} \ , \tag{14.21}$$

where $d\Omega^2_{(n-1)} = d\theta^2 + \dots$ is the volume-element for the $(n-1)$-dimensional sphere or its counterpart in other signatures. For concreteness, we now fix on $n = 3$, but the argument given below goes through in general.

It is straighforward to calculate the components of the Ricci tensor of this metric. This can be viewed as a special case of the calculations leading to the Schwarzschild metric in section 24, setting the function called $A(r)$ there to zero (of course before having divided by it anywhere ...).

The only independent components are R_{rr} and $R_{\theta\theta}$,

$$\begin{aligned} R_{rr} &= \frac{1}{r}\frac{B'}{B} \\ R_{\theta\theta} &= -\frac{1}{B} + 1 + \frac{rB'}{2B^2} \ . \end{aligned} \tag{14.22}$$

We now want to solve the equations

$$\begin{aligned} R_{rr} &= 2kg_{rr} = 2kB(r) \\ R_{\theta\theta} &= 2kg_{\theta\theta} = 2kr^2 \ . \end{aligned} \tag{14.23}$$

From the first equation we obtain

$$B' = 2krB^2 \ , \tag{14.24}$$

and from the second equation we deduce

$$\begin{aligned} 2kr^2 &= -\frac{1}{B} + 1 + \frac{rB'}{2B^2} \\ &= -\frac{1}{B} + 1 + \frac{2kr^2B^2}{2B^2} \\ &= -\frac{1}{B} + 1 + kr^2 \ . \end{aligned} \tag{14.25}$$

This is an algebraic equation for B solved by

$$B = \frac{1}{1-kr^2} \tag{14.26}$$

(and this also solves the first equation). Therefore we have determined the metric of a a maximally symmetric space to be

$$ds^2 = \frac{dr^2}{1-kr^2} + r^2 d\Omega^2_{(n-1)} \ . \tag{14.27}$$

Clearly, for $k = 0$ this is just the flat metric on $\mathbb{R}^n$. For $k = 1$, this should also look familiar as the standard metric on the sphere. If not, don't worry, we will be more explicit about this below.

We will also rederive these metrics in the next section in a way that makes the isometries of the metric manifest (and which thus also excludes the possibility, not logically ruled out by the arguments given so far, that the metrics we have found here for $k \neq 0$ are spherically symmetric and have constant Ricci curvature but are not actually maximally symmetric).

REMARKS:

1. First of all let us note that for $k \neq 0$ essentially only the sign of k matters as $|k|$ only affects the overall size of the space and nothing else (and can therefore be absorbed in the scale factor $a(t)$ of the metric (33.1) that will be the starting point for our investigations of cosmology). To see this note that a metric of the form (14.27), but with k replaced by k/L^2,
$$ds^2 = \frac{dr^2}{1-kr^2/L^2} + r^2 d\Omega^2 \ , \tag{14.28}$$
can, by introducing $\tilde{r} = r/L$, be put into the form
$$ds^2 = \frac{dr^2}{1-kr^2/L^2} + r^2 d\Omega^2 = L^2 \left(\frac{d\tilde{r}^2}{1-k\tilde{r}^2} + \tilde{r}^2 d\Omega^2 \right) \ . \tag{14.29}$$
We now see explicitly that a rescaling of k by a constant factor is equivalent to an overall rescaling of the metric, and thus we will just need to consider the cases $k = 0, \pm 1$. However, occasionally it will also be convenient to think of k as a continuous parameter, the 3 geometries then being distinguished by $k < 0, k = 0$ and $k > 0$ respectively.

2. For $k = +1$, we have
$$ds^2 = \frac{dr^2}{1-r^2} + r^2 d\Omega^2_{(n-1)} \ . \tag{14.30}$$
Thus, obviously the range of r is restricted to $r \leq 1$ and by the change of variables $r = \sin\psi$, the metric can be put into the standard form of the metric on S^n in polar coordinates,
$$ds^2 \equiv d\Omega^2_n = d\psi^2 + \sin^2\psi d\Omega^2_{n-1} \ . \tag{14.31}$$
This makes it clear that the singularity at $r = 1$ is just a coordinate singularity.

3. For $k = -1$, on the other hand, we have
$$ds^2 = \frac{dr^2}{1+r^2} + r^2 d\Omega^2_{n-1} \ . \tag{14.32}$$
Thus the range of r is $0 \leq r < \infty$, and we can use the change of variables $r = \sinh\psi$ to write the metric as
$$ds^2 \equiv d\tilde{\Omega}^2_n = d\psi^2 + \sinh^2\psi d\Omega^2_{n-1} \ . \tag{14.33}$$
This is the standard metric of a hyperboloid H^n in polar coordinates, and I have introduced the notation $d\tilde{\Omega}^2_n$ for the line-element on the "unit" n-hyperboloid in analogy with the standard notation $d\Omega^2_n$ for the line-element on the unit n-sphere.

4. Thus, collectively we can write the three metrics as

$$ds^2 = \frac{dr^2}{1-kr^2} + r^2 d\Omega^2_{(n-1)} = d\psi^2 + g_k(\psi)^2 d\Omega^2_{n-1} \tag{14.34}$$

where

$$g_k(\psi) = \begin{cases} \psi & k=0 \\ \sin\psi & k=+1 \\ \sinh\psi & k=-1 \end{cases} \tag{14.35}$$

5. Finally, by making the change of variables

$$r = \bar{r}(1+k\bar{r}^2/4)^{-1} \;\; , \tag{14.36}$$

one can put the metric into the isotropic form

$$ds^2 = (1+k\bar{r}^2/4)^{-2}(d\bar{r}^2 + \bar{r}^2 d\Omega^2_{(n-1)}) = (1+k\vec{x}^2/4)^{-2}\, d\vec{x}^2 \;\; . \tag{14.37}$$

Note that this differs by the *conformal factor* $(1+k\bar{r}^2/4)^{-2} > 0$ from the flat metric. One says that such a metric is *conformally flat*. Thus what we have shown is that every maximally symmetric space is conformally flat. Conformally flat, on the other hand, does not by any means imply maximally symmetric (the conformal factor could be any function of the radial and angular variables).

Note also that the metric in this form is just the 3- (or n-) dimensional generalisation of the 2-dimensional constant curvature metric on the 2-sphere in stereographic coordinates (11.62) (for $k=+1$) or of the Poincaré disc metric of H^2 (11.66) (for $k=-1$).

14.4 MAXIMALLY SYMMETRIC METRICS II: EMBEDDINGS

Recall that the standard metric on the n-sphere can be obtained by restricting the flat metric on an ambient $\mathbb{R}^{n+1}$ to the sphere. We will generalise this construction a bit to allow for $k<0$ and other signatures as well.

Consider a flat auxiliary vector space V of dimension $(n+1)$ with metric

$$ds^2 = d\vec{x}^2 + \frac{1}{k}dz^2 \;\; , \tag{14.38}$$

where $\vec{x} = (x^1,\ldots,x^n)$ and $d\vec{x}^2 = \eta_{ij}dx^i dx^j$. Thus the metric on V has signature $(p,q+1)$ for k positive and $(p+1,q)$ for k negative. The group $G = SO(p,q+1)$ or $G = SO(p+1,q)$ has a natural action on V by isometries of the metric. The full isometry group of V is the semi-direct product of this group with the Abelian group of translations (just as in the case of the Euclidean or Poincaré group).

Now consider in V the hypersurface Σ defined by

$$k\vec{x}^2 + z^2 = 1 \;\; . \tag{14.39}$$

This equation breaks all the translational isometries, but by the very definition of the group G it leaves this equation, and therefore the hypersurface Σ, invariant. It follows that G will act by isometries on Σ with its induced metric. Since $\dim G = n(n+1)/2$, the n-dimensional space has $n(n+1)/2$ Killing vectors and is therefore maximally symmetric.

REMARKS:

1. In fact, G acts transitively on Σ (thus Σ is homogeneous) and the stabiliser at a given point is isomorphic to $H = SO(p, q)$ (so Σ is isotropic), and therefore Σ can also be described as the homogeneous space
$$\begin{aligned} \Sigma_{k>0} &= SO(p, q+1)/SO(p, q) \\ \Sigma_{k<0} &= SO(p+1, q)/SO(p, q) \ . \end{aligned} \tag{14.40}$$
2. The Killing vectors of the induced metric are simply the restriction to Σ of the standard generators of G on the vector space V.
3. For Euclidean signature, these spaces are spheres for $k > 0$ and hyperboloids for $k < 0$, and in other signatures they are the corresponding generalisations. In particular, for $(p, q) = (1, n-1)$ we obtain *de Sitter space-time* for $k = 1$ and *anti-de Sitter space-time* for $k = -1$. We will discuss their embeddings, and coordinate systems for them, in much more detail in section 39.

It just remains to determine explicitly this induced metric. For this we start with the defining relation of Σ and differentiate it to find that on Σ one has
$$dz = -\frac{k\vec{x}.d\vec{x}}{z} \ , \tag{14.41}$$
so that
$$dz^2 = \frac{k^2(\vec{x}.d\vec{x})^2}{1 - k\vec{x}^2} \ . \tag{14.42}$$
Thus the metric (14.38) restricted to Σ is
$$\begin{aligned} ds^2|_\Sigma &= d\vec{x}^2 + \frac{1}{k}dz^2|_\Sigma \\ &= d\vec{x}^2 + \frac{k(\vec{x}.d\vec{x})^2}{1 - k\vec{x}^2} \ . \end{aligned} \tag{14.43}$$
Passing from Cartesian coordinates $\vec{x}$ to spherical coordinates (r, θ, ϕ), with
$$r^2 = \vec{x}^2 = \eta_{ij}x^i x^j \quad , \quad r dr = \vec{x}.d\vec{x} \quad , \quad dr^2 = (\vec{x}.d\vec{x})^2/\vec{x}^2 \ , \tag{14.44}$$
this metric can also be written as
$$ds^2 = \frac{dr^2}{1 - kr^2} + r^2 d\Omega^2_{(n-1)} \ . \tag{14.45}$$
This is precisely the metric (14.27) we obtained in the previous section.

Finally, a word of warning: there are a large number of sign conventions involved in the definition of the Riemann tensor (and its contractions we will discuss below), so whenever reading a book or article, in particular when you want to use results or equations presented there, make sure what conventions are being used and either adopt those or translate the results into some other convention. As a check: the conventions used here are such that $R_{\phi\theta\phi\theta}$ as well as the curvature scalar (to be introduced below) are *positive* for the standard metric on the two-sphere.

8.4 TIDAL FORCES: INFLUENCE OF CURVATURE ON PARTICLE TRAJECTORIES

In a certain sense the main effect of curvature (or gravity) is that initially parallel trajectories of freely falling non-interacting particles (dust, pebbles,…) do not remain parallel, i.e. that gravity is an attractive force that has the tendency to focus matter. This statement find its mathematically precise formulation in equations describing the influence of space-time curvature on the behaviour of (families of) geodesics.

Let us, as we will need this later anyway, recall first the situation in the Newtonian theory. One particle moving under the influence of a gravitational field is governed by the equation

$$\tfrac{d^2}{dt^2}x^i = -\partial^i\phi(x) \;\;, \tag{8.29}$$

where ϕ is the potential. Now consider a family of particles, or just two nearby particles, one at $x^i(t)$ and the other at $x^i(t) + \delta x^i(t)$. The other particle will of course obey the equation

$$\tfrac{d^2}{dt^2}(x^i + \delta x^i) = -\partial^i\phi(x + \delta x) \;\;. \tag{8.30}$$

From these two equations one can deduce an equation for δx itself, namely

$$\tfrac{d^2}{dt^2}\delta x^i = -\partial^i\partial_j\phi(x)\delta x^j \;\;. \tag{8.31}$$

It describes the effect of *gravitational tidal forces* (the gradient of the gravitational force) on a family of particles moving in a gravitational field.

In particular, when there is no gravitational force, and the trajectories are straight lines, one has

$$\tfrac{d^2}{dt^2}\delta x^i = 0 \quad \Rightarrow \quad \delta x^i = (\delta x^i)_0 + (\delta v^i)t \;\;. \tag{8.32}$$

Thus one recovers Euclid's parallel axiom, that two straight lines intersect at most once (for suitable choices of $\delta v^i \neq 0$) and that they never intersect when they are initially parallel ($\delta v^i = 0$). Any departure from this equation or its Minkowskian counterpart

$$\tfrac{d^2}{d\tau^2}\delta\xi^a = 0 \;\;, \tag{8.33}$$

will therefore indicate a departure from Euclidean geometry!

It is the counterpart of (8.31) that we will be seeking in the context of General Relativity. One derivation of this can be modelled on the Newtonian derivation above. It is elementary but looks non-covariant (and therefore somewhat messy) at intermediate stages of the calculation (see section 12.1 for a manifestly covariant derivation).

The starting point is of course the geodesic equation for x^μ and for its nearby partner $x^\mu + \delta x^\mu$,

$$\tfrac{d^2}{d\tau^2}x^\mu + \Gamma^\mu_{\ \nu\lambda}(x)\tfrac{d}{d\tau}x^\nu \tfrac{d}{d\tau}x^\lambda = 0 \quad , \tag{8.34}$$

and

$$\tfrac{d^2}{d\tau^2}(x^\mu + \delta x^\mu) + \Gamma^\mu_{\ \nu\lambda}(x+\delta x)\tfrac{d}{d\tau}(x^\nu + \delta x^\nu)\tfrac{d}{d\tau}(x^\lambda + \delta x^\lambda) = 0 \quad . \tag{8.35}$$

As above, from these one can deduce an equation for δx, namely

$$\tfrac{d^2}{d\tau^2}\delta x^\mu + 2\Gamma^\mu_{\ \nu\lambda}(x)\tfrac{d}{d\tau}x^\nu \tfrac{d}{d\tau}\delta x^\lambda + \partial_\rho \Gamma^\mu_{\ \nu\lambda}(x)\delta x^\rho \tfrac{d}{d\tau}x^\nu \tfrac{d}{d\tau}x^\lambda = 0 \quad . \tag{8.36}$$

Now this does not look particularly covariant. Thus instead of in terms of $d/d\tau$ we would like to rewrite this in terms of the covariant operator D_τ, with

$$D_\tau \delta x^\mu = \frac{d}{d\tau}\delta x^\mu + \Gamma^\mu_{\ \nu\lambda}\frac{dx^\nu}{d\tau}\delta x^\lambda \quad . \tag{8.37}$$

Calculating $(D_\tau)^2\delta x^\mu$, replacing $\ddot{x}^\mu$ appearing in that expression by $-\Gamma^\mu_{\ \nu\lambda}\dot{x}^\nu\dot{x}^\lambda$ (because x^μ satisfies the geodesic equation) and using (8.36), one eventually finds the nice covariant *geodesic deviation equation*

$$(D_\tau)^2\delta x^\mu = R^\mu_{\ \nu\lambda\rho}\dot{x}^\nu\dot{x}^\lambda\delta x^\rho \tag{8.38}$$

REMARKS:

1. This shows very clearly that curvature, as captured by the Riemann curvature tensor, leads to non-Euclidean geometry in which e.g. the parallel axiom is not necessarily satisifed.

2. In general, solutions to the geodesic deviation equation are called *Jacobi fields.* They describe the difference between the given geodesic and a (hypothetical) infinitely close neighbouring geodesic.

3. Clearly the present derivation of this result leaves something to be desired. It is also possible to give a manifestly covariant, and thus perhaps slightly more satisfactory, derivation of the above geodesic deviation equation, and we will return to this in section 12.1.

11.3 CURVATURE OF SURFACES: EULER, GAUSS(-BONNET) AND LIOUVILLE

We can generalise the example of the curvature of the 2-sphere, discussed in section 8.6, somewhat, in this way connecting our considerations with the classical realm of the differential geometry of surfaces, in particular with the *Gauss Curvature*, the *Euler characteristic*, the *Gauss-Bonnet* theorem and the *Liouville Equation*.

For any 2-dimensional metric g_{ab} it is a simple exercise to derive the relation between the one independent component, say R_{1212}, of the Riemann tensor, and the scalar curvature. First of all, the Ricci tensor is

$$R_{ab} = R^c{}_{acb} = R^1{}_{a1b} + R^2{}_{a2b} \tag{11.25}$$

so that the scalar curvature is

$$R(g_{ab}) = g^{ab}R_{ab} = g^{11}R^2{}_{121} + g^{12}R^1{}_{112} + g^{21}R^2{}_{221} + g^{22}R^1{}_{212} \ . \tag{11.26}$$

Using the fact that in 2 dimensions the components of the inverse metric are explicitly given by

$$\left(g^{ab}\right) = \frac{1}{g_{11}g_{22} - g_{12}g_{21}} \begin{pmatrix} g_{22} & -g_{12} \\ -g_{21} & g_{11} \end{pmatrix} \tag{11.27}$$

and the (anti-)symmetry properties (1) and (2) of the Riemann tensor, one finds

$$R(g_{ab}) = \frac{2}{g_{11}g_{22} - g_{12}g_{21}} R_{1212} \ . \tag{11.28}$$

This is precisely the relation (8.44) between the Riemann tensor and Ricci scalar. The factor of 2 in this equation is a consequence of our (and the conventional) definition of the Riemann curvature tensor, and is responsible for the fact that the scalar curvature of the unit 2-sphere is $R = +2$. We can also write this result as

$$R_{abcd} = \tfrac{1}{2}(g_{ac}g_{bd} - g_{ad}g_{bc})R \quad \Leftrightarrow \quad R^a{}_{bcd} = \tfrac{1}{2}(\delta^a{}_c g_{bd} - \delta^a{}_d g_{bc})R \ . \tag{11.29}$$

In two dimensions, it is often convenient and natural to absorb this ubiquitous factor of 2 into the definition of the (scalar) curvature, and what one then gets is the classical Gauss Curvature

$$K := \frac{1}{2}R(g_{ab}) \tag{11.30}$$

of a two-dimensional surface.

It follows from (11.29) that the Ricci tensor is related to the Ricci scalar by

$$R_{ab} = (R/2)g_{ab} = K g_{ab} \ . \tag{11.31}$$

This generalises the result for the standard metric on the 2-sphere found by explicit calculation in section 8.6. It shows that in complete generality the Ricci tensor of a two-dimensional space or space-time, thought of as the linear map

$$R^a_b = K\delta^a_b : \quad v^a \mapsto R^a_b v^b \ , \tag{11.32}$$

has only one (double) eigenvalue, namely the Gauss curvature K. It can also be interpreted as saying that in 2 dimensions the Einstein tensor (8.97) is identically zero,

$$G_{ab} = R_{ab} - \tfrac{1}{2} g_{ab} R = 0 \ . \tag{11.33}$$

We will now briefly look at two important and interesting consequences of the above formulae, one related to the Euler characteristic of a surface and its integral representation (the Gauss-Bonnet theorem), and the other to the Liouville equation describing metrics with constant Gauss curvauter $K = k = \pm 1$.

1. Euler Characteristic and the Gauss-Bonnet Theorem

   Let us consider a compact closed surface S, i.e. topologically something like a sphere, or a torus (a sphere with one handle), or a sphere with several handles. A surface S_h with h handles is called a surface of *genus h*.

   Given a metric on S_h, we can associate to S_h its area with respect to the metric,

$$A(S_h) := \int_{S_h} \sqrt{g} d^2x \ . \tag{11.34}$$

   Clearly, this areas depends on a choice of metric, and under a variation δ_g of the metric it transforms as

$$\delta_g A(S_h) = \int_{S_h} \delta_g \sqrt{g} d^2x = \tfrac{1}{2} \int_{S_h} \sqrt{g} d^2x \ g^{ab} \delta g_{ab} \ . \tag{11.35}$$

   Given a metric on S_g, we can also naturally associate to it the real number

$$\chi(S_h) = \frac{1}{2\pi} \int \sqrt{g} d^2x \ K = \frac{1}{4\pi} \int \sqrt{g} d^2x \ R \ . \tag{11.36}$$

   Remarkably, this number turns out to be independent of the metric, in particular *$\chi(S_h)$ is invariant under variations of the metric g_{ab}*,

$$\delta_g \chi(S_h) = 0 \ . \tag{11.37}$$

   Here are two rather explicit ways of establishing this remarkable result:

   (a) The variation of the integrand is

$$\delta_g(\sqrt{g} R) = \delta_g(\sqrt{g} g^{ab} R_{ab}) \ . \tag{11.38}$$

   Since $R = g^{ab} R_{ab}$, it is convenient to express variations of the metric in terms of variations of the inverse metric, with (5.85)

$$\delta \sqrt{g} = \tfrac{1}{2} g^{ab} \delta g_{ab} = -\tfrac{1}{2} g_{ab} \delta g^{ab} \ . \tag{11.39}$$

Then one finds

$$\begin{aligned}\delta_g(\sqrt{g}R) &= (\delta_g\sqrt{g})g^{ab}R_{ab} + \sqrt{g}(\delta g^{ab})R_{ab}) + \sqrt{g}g^{ab}\delta_g R_{ab} \\ &= \sqrt{g}(-\tfrac{1}{2}Rg_{ab} + R_{ab})\delta g^{ab} + \sqrt{g}g^{ab}\delta_g R_{ab} \\ &= \sqrt{g}G_{ab}\delta g^{ab} + \sqrt{g}g^{ab}\delta_g R_{ab} \quad .\end{aligned} \tag{11.40}$$

Now, as shown above, in 2 dimensions the Einstein tensor is identically zero, $G_{ab} = 0$. Moreover, in section 20.2 we will show that in any dimension the 2nd term is a total derivative (20.18),

$$g^{ab}\delta_g R_{ab} = \nabla_a B^a \tag{11.41}$$

for some well-defined B^a built from the covariant derivatives of the variations of the metric, as in (20.19). Taken together, these two facts imply that for a closed surface S_h (without boundary) one has

$$\delta_g\chi(S_h) = \frac{1}{4\pi}\int \sqrt{g}d^2x(G_{ab}\delta g^{ab} + \nabla_a B^a) = 0 \ \ , \tag{11.42}$$

as was to be shown.

(b) Alternatively, somewhat less covariantly but very explicitly, one can show that the integrand $\sqrt{g}K$ or $\sqrt{g}R$ can itself locally be written as a total derivative. Indeed, using (11.29) to write

$$R^1{}_{212} = \tfrac{1}{2}g_{11}R \quad \Leftrightarrow \quad K = \frac{1}{g_{11}}R^2{}_{121} \tag{11.43}$$

and simply writing out explicitly this Riemann curvature tensor component in terms of the Christoffel symbols,

$$R^2{}_{121} = \partial_2\Gamma^2{}_{11} - \partial_1\Gamma^2{}_{12} + \Gamma^2{}_{2a}\Gamma^a{}_{11} - \Gamma^2{}_{1a}\Gamma^a{}_{12} \ \ , \tag{11.44}$$

one finds that $\sqrt{g}K$ can be written as

$$\sqrt{g}K = \in^{ab}\partial_a\beta_b \tag{11.45}$$

with $\in^{12} = -\in^{21} = 1$ the Levi-Civita symbol, and

$$\beta_b = -\frac{\sqrt{g}}{g_{11}}\,\Gamma^2{}_{1b} \quad . \tag{11.46}$$

The fact that the integrand is locally a total derivative does not mean that the integral is zero (because of the non-tensorial nature of β_a, which will typically exhibit coordinate singularities). It does mean however, that the integral of the metric variation of this expression is zero (because that is tensorial and well-defined on S_h),

$$\sqrt{g}K = \varepsilon^{ab}\partial_a\beta_b \quad \Rightarrow \quad \delta_g\chi(S_h) = \frac{1}{2\pi}\int d^2x\delta_g(\sqrt{g}K) = 0 \ \ . \tag{11.47}$$

Either way we have seen that the real number $\chi(S_h)$ is independent of the metric one uses to calculate it. For example, for $h = 0$ and for the standard metric on the sphere S^2 one finds

$$\chi(S_{h=0}) = \chi(S^2) = \frac{1}{4\pi}\int \sqrt{g}R = \frac{1}{2\pi}\int \sqrt{g} = 2 \ , \tag{11.48}$$

and this will therefore be the result for any metric on S^2. Likewise, for $h = 1$, i.e. a torus, by choosing the flat metric on T^2 (see e.g. the discussion and construction in section 18.1), one finds

$$\chi(S_{h=1}) = \chi(T^2) = 0 \ , \tag{11.49}$$

and this will therefore be the result for any metric on T^2 (and it is instructive to check this explicitly for the non-trivial, non-flat metric on T^2 induced by its embedding into $\mathbb{R}^3$ constructed in section 18.1). I am not aware of an equally elementary calculation to determine $\chi(S_h)$ for $h > 1$ in this way but fact of the matter is that

$$\chi(S_h) = 2 - 2h \tag{11.50}$$

is the *Euler characteristic* of S_h, which can also be defined purely combinatorially as the number

$$\chi(S) = n_F - n_E + n_V \tag{11.51}$$

of faces minus vertices plus edges of any cubist rendition of a surface S (and $\chi(S)$ is independent of such a cubist realisation or *triangulation*). The remarkable fact that this *topological invariant* of a surface S can be calculated in terms of differential geometric quantities, namely as the integral of the curvature scalar, is known as the *Gauss-Bonnet theorem.*

2. Constant Curvature and the Liouville Equation

When we specialise the above to the class of *conformally flat* metrics with line element

$$ds^2 = \mathrm{e}^{2h(x,y)}(dx^2 + dy^2) \quad \Leftrightarrow \quad g_{ab} = \exp 2h(x,y)\delta_{ab} \tag{11.52}$$

the calculation of the Riemann tensor is particularly simple and one finds the (easy to memorise) results

$$R^x{}_{yxy} = -\Delta h \tag{11.53}$$

and

$$K = -\mathrm{e}^{-2h}\Delta h \tag{11.54}$$

where $\Delta = \partial_x^2 + \partial_y^2$ is the 2-dimensional Laplacian with respect to the flat Euclidean metric $dx^2 + dy^2$. Thus a surface with *constant curvature* $K = k$ is given by a solution to the non-linear differential equation

$$\Delta h + k\mathrm{e}^{2h} = 0 \ . \tag{11.55}$$

This is the (in-)famous *Liouville equation*, which plays a fundamental role in many branches of mathematics (and mathematical physics).

In terms of the intrinsic Laplacian Δ_g associated to the metric g_{ab}, the Gaussian cuvature and the Liouville equation can also simply be written as

$$K = -\Delta_g h \quad , \quad \Delta_g h + k = 0 \ , \tag{11.56}$$

since, due to the peculiarities of 2 dimensions, $\sqrt{g}g^{ab}$ in independent of h, i.e. is conformally invariant (as we already observed in a different context in section 7.7, cf. (7.120)),

$$\begin{aligned} & \sqrt{g}g^{ab} = \mathrm{e}^{2h}\mathrm{e}^{-2h}\delta^{ab} = \delta^{ab} \\ \Rightarrow \quad & \Delta_g = \frac{1}{\sqrt{g}}\partial_a(\sqrt{g}g^{ab}\partial_b) = \frac{1}{\sqrt{g}}\partial_a(\delta^{ab}\partial_b) = \mathrm{e}^{-2h}\Delta \ . \end{aligned} \tag{11.57}$$

I will not attempt to say anything about the general (local) solution of this equation (which roughly speaking depends on an arbitrary meromorphic function of the complex coordinate $z = x + iy$), but close this section with some special (and particularly prominent) solutions of this equation.

(a) It is easy to see that

$$\mathrm{e}^{2h(x,y)} = y^{-2} \quad \Leftrightarrow \quad h(x,y) = -\ln y \tag{11.58}$$

solves the Liouville equation with $k = -1$. The corresponding space of constant negative curvature is the *Poincaré upper-half plane* model of the hyperbolic geometry,

$$ds^2 = \frac{dx^2 + dy^2}{y^2} \qquad (\ (x,y) \in \mathbb{R}^2,\ y > 0\ )\ . \tag{11.59}$$

By the coordinate transformation $y = e^z$ this is mapped to the equivalent metric

$$ds^2 = dz^2 + \mathrm{e}^{-2z}dx^2 \tag{11.60}$$

on the entire (x, z)-plane.

(b) Another solution (for any k) is the rotationally invariant function

$$\mathrm{e}^{2h(x,y)} = 4(1 + k(x^2 + y^2))^{-2} \quad \Leftrightarrow \quad h = -\ln(1 + k(x^2 + y^2)) + \text{const.} \tag{11.61}$$

  i. For $k = 0$ one finds the flat (zero curvature) Euclidean metric on $\mathbb{R}^2$.

  ii. For $k = +1$, one obtains the metric

$$ds^2 = 4\frac{dx^2 + dy^2}{(1 + x^2 + y^2)^2} \ . \tag{11.62}$$

This is the constant positive curvature metric on the *Riemann sphere* one gets by stereographic projection of the standard metric on the two-sphere S^2 to the (x,y)-plane.

In terms of polar coordinates (r,ϕ) on the Euclidean plane, this metric takes the form

$$ds^2 = 4\frac{dr^2 + r^2 d\phi^2}{(1+r^2)^2} \quad , \tag{11.63}$$

and the further change of variables $r = \tan\theta/2$ shows that this is indeed the standard line element $d\Omega^2$ on the 2-sphere,

$$r = \tan\theta/2 \quad \Rightarrow \quad ds^2 = d\theta^2 + \sin^2\theta d\phi^2 = d\Omega^2 \quad . \tag{11.64}$$

Read backwards, this can also be read as the statement that via the above change of variables the Euclidean metric on $\mathbb{R}^2$ can be written as

$$dr^2 + r^2 d\phi^2 = \frac{(1+r(\theta)^2)^2}{4}(d\theta^2 + \sin^2\theta d\phi^2) = \frac{1}{4\cos^4\theta/2}d\Omega^2 \quad . \tag{11.65}$$

In this process the points “at infinity” in $\mathbb{R}^2$ (where $r \to \infty$) are mapped to the south pole $\theta = \pi$ of the sphere (where the conformal factor in front of the line element of the sphere diverges accordingly). This exhibits S^2 as the *conformal compactification* of $\mathbb{R}^2$.

iii. For $k = -1$, one finds

$$ds^2 = 4\frac{dx^2 + dy^2}{(1-(x^2+y^2))^2} \qquad (\ \{x,y\} \in \mathbb{R}^2, x^2 + y^2 < 1\ ) \quad . \tag{11.66}$$

This is the *Poincaré disc* model of the hyperbolic geometry, defined in the interior of the unit disc in $\mathbb{R}^2$. In terms of polar coordinates, it can also be written as

$$ds^2 = 4\frac{dr^2 + r^2 d\phi^2}{(1-r^2)^2} \qquad (\ 0 \leq r < 1\ ) \tag{11.67}$$

The two metrics (11.59) and (11.66) are isometric, i.e. related by a (albeit not completely evident) coordinate transformation.

(c) As our final example, one other solution (given here only for $k = -1$) is

$$\mathrm{e}^{2h(x,y)} = \mathrm{e}^{2h(x)} = 4\frac{\mathrm{e}^{2x}}{(1-\mathrm{e}^{2x})^2} \quad . \tag{11.68}$$

This leads to the form (2.31) of the unit metric on H^2,

$$ds^2 = d\sigma^2 + \sinh^2\sigma\, d\phi^2 \quad . \tag{11.69}$$

Indeed, we can write this in conformally flat form as

$$ds^2 = \sinh^2\sigma(x)(dx^2 + d\phi^2) \tag{11.70}$$

where

$$x = \log\tanh(\sigma/2) \quad \Rightarrow \quad dx = d\sigma/\sinh\sigma \ . \tag{11.71}$$

Performing the exponential / hyperbolic gymnastics required to write the conformal factor $\sinh^2\sigma$ as a function of x, one finds

$$\sinh^2\sigma(x) = 4\frac{\mathrm{e}^{2x}}{(1-\mathrm{e}^{2x})^2} \ , \tag{11.72}$$

giving rise to the solution given in (11.68).

It is worth remarking that the Poincaré upper-half plane model of a space with constant negative curvature readily generalises to arbitrary dimensions and signature. Thus

$$ds^2 = \frac{d\vec{x}^2 + dy^2}{y^2} \quad , \quad d\vec{x}^2 = \delta_{ab}dx^a dx^b \quad \text{or} \quad d\vec{x}^2 = \eta_{ab}dx^a dx^b \tag{11.73}$$

is the metric of a $D = (d+1)$-dimensional space(-time) with constant negative curvature.

The Lorentzian metric will reappear later as a solution to the Einstein equations with a negative cosmological constant, and is in this context known as the *anti-de Sitter metric* (in Poincaré coordinates, which cover only a part of the complete space-time), and we will discuss this solution in some detail in section 39.

11.4 THE WEYL TENSOR AND ITS USES

In section 8 from the Riemann tensor we have extracted its traces, the Ricci tensor and the Ricci scalar, as well as a particular linear combination of them, the Einstein tensor. We can therefore also explicitly decompose the Riemann tensor into these trace parts and the remaining traceless part.

We noted in section 8.5 that for $D = 2$ and $D = 3$ the Riemann tensor would be "pure trace", i.e. could be written entirely in terms of the Ricci tensor and Ricci scalar. For $D = 2$ we have already established this explicitly by proving the relation (11.29),

$$D = 2: \quad R_{\alpha\beta\gamma\delta} = \tfrac{1}{2}(g_{\alpha\gamma}g_{\beta\delta} - g_{\alpha\delta}g_{\beta\gamma})R \tag{11.74}$$

in section 11.3.

We now look at this issue for $D \geq 3$. Simply by linear algebra one finds, for $D \geq 3$, the decomposition

$$\begin{aligned} R_{\mu\nu\rho\sigma} &= C_{\mu\nu\rho\sigma} \\ &\quad + \frac{1}{D-2}(g_{\mu\rho}R_{\nu\sigma} + R_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}R_{\mu\sigma} - R_{\nu\rho}g_{\mu\sigma}) \\ &\quad - \frac{1}{(D-1)(D-2)}R(g_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}g_{\mu\sigma}) \ . \end{aligned} \tag{11.75}$$

This definition is such that $C_{\mu\nu\rho\sigma}$ has all the symmetries of the Riemann tensor (this is manifest) and such that all of its traces are zero, i.e.

$$C^{\mu}_{\ \nu\mu\sigma} = 0 \ , \tag{11.76}$$

as is easily verified. This traceless part $C_{\mu\nu\rho\sigma}$ of the Riemann tensor is called the *Weyl tensor*.

Occasionally it is more convenient and transparent to decompose the Riemann tensor not into the Weyl tensor, the Ricci tensor and the Ricci scalar, but to perform an orthogonal decomposition (with respect to the metric) into the Weyl tensor, the traceless part $S_{\mu\nu}$ of the Ricci tensor,

$$S_{\mu\nu} = R_{\mu\nu} - \frac{1}{D} g_{\mu\nu} R \ , \tag{11.77}$$

and the trace R. Then the decomposition becomes

$$\begin{aligned} R_{\mu\nu\rho\sigma} &= C_{\mu\nu\rho\sigma} \\ &\quad + \frac{1}{D-2}(g_{\mu\rho}S_{\nu\sigma} + S_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}S_{\mu\sigma} - S_{\nu\rho}g_{\mu\sigma}) \\ &\quad + \frac{1}{D(D-1)} R(g_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}g_{\mu\sigma}) \ . \end{aligned} \tag{11.78}$$

One other common and convenient decomposition is in terms of a tensor $P_{\mu\nu}$ such that (11.75) takes the form

$$R_{\mu\nu\rho\sigma} = C_{\mu\nu\rho\sigma} + (g_{\mu\rho}P_{\nu\sigma} + P_{\mu\rho}g_{\nu\sigma} - g_{\nu\rho}P_{\mu\sigma} - P_{\nu\rho}g_{\mu\sigma}) \ . \tag{11.79}$$

Comparison with (11.75) shows that this is accomplished by the choice

$$P_{\mu\nu} = \frac{1}{D-2}\left(R_{\mu\nu} - \frac{1}{2(D-1)} g_{\mu\nu} R\right) \ . \tag{11.80}$$

This tensor $P_{\mu\nu}$ is known as the *Schouten Tensor*.

Regardless of how we write the trace part of the Riemann tensor, it turns out that for $D = 3$ the Weyl tensor vanishes identically,

$$D = 3: \quad C_{\alpha\beta\gamma\delta} \equiv 0 \tag{11.81}$$

(I will give an elementary proof of this momentarily). Therefore, for $D = 3$ one has the decomposition

$$\begin{aligned} D = 3: \quad R_{\alpha\beta\gamma\delta} &= (g_{\alpha\gamma}R_{\beta\delta} + R_{\alpha\gamma}g_{\beta\delta} - g_{\alpha\delta}R_{\beta\gamma} - R_{\alpha\delta}g_{\beta\gamma}) \\ &\quad + \tfrac{1}{2}(g_{\alpha\delta}g_{\beta\gamma} - g_{\alpha\gamma}g_{\beta\delta})R \end{aligned} \tag{11.82}$$

This is precisely the result claimed previously in (8.45).

To establish (11.81), in order to trivialise the algebra let us fix a point x_0 and choose coordinates there such that $g_{\alpha\beta}(x_0) = \delta_{\alpha\beta}$ (or $\eta_{\alpha\beta}$, depending on the signature of the metric, but let us assume that we are in the case of Euclidean signature - the same argument works in the Lorentzian case). Now the proof consists of the following elementary steps:

- Since we are in $D = 3$, at least two of the indices in $C_{\alpha\beta\gamma\delta}$ must be equal. Since the Weyl tensor has all the symmetries of the Riemann tensor, if more than two indices are equal, the Weyl tensor component is zero. Thus we only need to consider the components where 2 indices are equal and we can without loss of generality choose these to be $C_{1\beta 1\delta}$, say, with $\beta, \delta \neq 1$.

- Because the Weyl tensor is traceless, one has the relation

  $$C_{1\beta 1\delta} = -C_{2\beta 2\delta} - C_{3\beta 3\delta} \quad . \tag{11.83}$$

  This implies that $C_{1213} = C_{1312} = 0$, so a non-zero component requires $\beta = \delta$.

- For $\beta = \delta$, one derives from this

  $$C_{1212} = -C_{3232} \quad \text{and} \quad C_{1313} = -C_{2323} \tag{11.84}$$

  and likewise for $\alpha = \gamma = 2$ and $\alpha = \gamma = 3$.

- Thus all in all the Weyl tensor can have only 3 independent non-zero components, namely $C_{1212} = C_{2121}, C_{1313} = C_{3131}, C_{2323} = C_{3232}$, and they are all required to be pairwise negatives of each other. This is impossible for non-trivial $C_{\alpha\beta\gamma\delta}$,

  $$C_{1212} = -C_{3232} = +C_{3131} = -C_{2121} = -C_{1212} \quad \Rightarrow \quad C_{1212} = 0 \ , \tag{11.85}$$

  and implies that all of the components of the Weyl tensor are identically zero in $D = 3$.

Thus the Weyl tensor is only non-trivial for $D \geq 4$. Using the Bianchi identies discussed in section 8.8, in particular also (8.94),

$$\nabla^\mu R_{\mu\nu\rho\sigma} = \nabla_\rho R_{\nu\sigma} - \nabla_\sigma R_{\nu\rho} \tag{11.86}$$

from (11.75) one finds a simple expression for the divergence, namely

$$\nabla^\mu C_{\mu\nu\rho\sigma} = (D-3)\left(\nabla_\rho P_{\nu\sigma} - \nabla_\sigma P_{\nu\rho}\right) \quad . \tag{11.87}$$

The tensor appearing on the right-hand side also has its own name. It is called the *Cotton Tensor* $C_{\nu\rho\sigma}$,

$$C_{\nu\rho\sigma} = \nabla_\rho P_{\nu\sigma} - \nabla_\sigma P_{\nu\rho} \quad . \tag{11.88}$$

The content of (11.87) is evidently trivial in $D = 3$, but the Cotton tensor itself is not (and I will briefly come back to this below).

The Weyl tensor plays an important role in many aspects of gravitational physics:

1. For example, the Weyl tensor has traditionally been one of the central objects of interest in the invariant algebraic classification of gravitational fields and in

the characterisation of what are known as algebraically special solutions to the Einstein equations (the so-called *Petrov classification* and related procedures). Originally, this was (of course) developed for $D = 4$, and this case has a number of special features. It is based on the classification of the properties of the eigenvalues λ of the Weyl tensor (at a point x_0), thought of as a map on the space of anti-symmetric $(2,0)$-tensors (*bivectors*),

$$\tfrac{1}{2}C^{\alpha\beta}{}_{\gamma\delta}X^{\gamma\delta} = \lambda X^{\alpha\beta} \tag{11.89}$$

or

$$C^A_B X^B = \lambda X^A \tag{11.90}$$

with $C_{\alpha\beta\gamma\delta} \equiv C_{AB}$ thought of as a symmetric (6×6) matrix.[26]

An equivalent (as it turns out) classification arises from determining the number and multiplicity of linearly independent null vectors ℓ satisfying the condition

$$\ell_{[\gamma}C_{\alpha]\mu\nu[\beta}\ell_{\delta]}\ell^{\mu}\ell^{\nu} = 0 \ . \tag{11.91}$$

Such ℓ^α are called the *principal null directions* of the Weyl tensor. More recently, this classification scheme (based on the latter approach) has been (partially) extended to higher dimensions.[27]

2. As we will see in section 19.6, the Einstein equations imply that the Weyl tensor describes the gravitational field in vacuum. Specifically, when (or where) the energy-momentum tensor is zero, the Riemann curvature tensor is equal to the Weyl tensor,

$$T_{\alpha\beta}(x) = 0 \quad \Rightarrow \quad R_{\alpha\beta\gamma\delta}(x) = C_{\alpha\beta\gamma\delta}(x) \ . \tag{11.92}$$

   The Weyl tensor thus encodes the information about things like gravitational waves and the asymptotic behaviour of a gravitational field and has been studied extensively from this point of view.

3. In the presence of matter, on the other hand, (11.87), in conjunction with the Einstein equations, becomes an evolution equation for these vacuum components of the gravitational field in terms of the sources - see equations (19.57) and (19.58).

The Weyl tensor also plays an important role in geometry, as it is *conformally invariant*, i.e. $C^{\mu}_{\nu\rho\sigma}$ is invariant under conformal (Weyl) rescalings of the metric,

$$g_{\mu\nu}(x) \to \mathrm{e}^{2f(x)}g_{\mu\nu}(x) \quad \Rightarrow \quad C^{\mu}_{\ \nu\rho\sigma} \to C^{\mu}_{\ \nu\rho\sigma} \ , \tag{11.93}$$

equivalently

$$g_{\mu\nu}(x) \to \mathrm{e}^{2f(x)} g_{\mu\nu}(x) \quad \Rightarrow \quad C_{\mu\nu\rho\sigma} \to \mathrm{e}^{2f(x)} C_{\mu\nu\rho\sigma} \ . \tag{11.94}$$

In particular, the Weyl tensor is zero if the metric is *conformally flat*, i.e. related by a conformal transformation to the flat metric $\eta_{\mu\nu}$ (of any signature),

$$g_{\mu\nu}(x) = \mathrm{e}^{2f(x)} \eta_{\mu\nu}(x) \quad \Rightarrow \quad C^{\mu}_{\ \nu\rho\sigma} = 0 \ . \tag{11.95}$$

This can be established by brute force calculation and is not *per se* particularly enlightning.

Conversely for $D \geq 4$ vanishing of the Weyl tensor is also a sufficient condition for a metric to be (locally) conformal to the flat metric. This is a non-trivial result because at face value one seems to obtain a completely overdetermined system of equations for the single function f, of the form

$$P_{\mu\nu} = \{\text{1st and 2nd derivatives of } f\}_{\mu\nu} \ . \tag{11.96}$$

However, it turns out that the integrability conditions for this system of equations are equivalent to the vanishing of the Weyl tensor, and then a variant of the *Frobenius integrability theorem* (mentioned in a different context in section 15.5) can be used to establish the local existence of a solution f.

For $D = 3$, the situation is slightly (but not fundamentally) different. We see from (11.88) that for any $D \geq 4$ conformal flatness implies vanishing of the Cotton tensor. It turns out that for $D = 3$ the Cotton tensor takes over the role of the Weyl tensor (which, as proven above, is itself trivial for $D = 3$), i.e. one has the statement that for $D = 3$ a metric is (locally) conformally flat if and only if the Cotton tensor vanishes.

11.5 GENERALISATIONS: TORSION AND NON-METRICITY

In section 5.4 we had seen that the Levi-Civita connection (defined by the Christoffel symbols) is characterised by the fact that

1. the metric is covariantly constant, $\nabla_\mu g_{\nu\lambda} = 0$, and
2. the torsion is zero, i.e. the second covariant derivatives of a scalar commute.

It is of course possible to relax either of the conditions (1) or (2), or both of them and, in particular, connections with torsion (relaxation of condition 2) are popular in certain circles and/or arise naturally in certain generalised (gauge) theories of gravity and in string theory.

To discuss this a bit more systematically, we consider a general connection

$$\tilde{\Gamma}^{\mu}_{\ \nu\lambda} = \Gamma^{\mu}_{\ \nu\lambda} + C^{\mu}_{\ \nu\lambda} \tag{11.97}$$

with $\Gamma^{\mu}_{\ \nu\lambda}$ the canonical Levi-Civita connection, and $C^{\mu}_{\ \nu\lambda}$ a $(1,2)$-tensor. We will also use the corresponding $(0,3)$-tensor

$$C_{\mu\nu\lambda} = g_{\mu\rho}C^{\rho}_{\ \nu\lambda} \quad . \tag{11.98}$$

Associated with $\tilde{\Gamma}^{\mu}_{\ \nu\lambda}$ we have the covariant derivative $\tilde{\nabla}_{\mu}$. Since $\tilde{\Gamma}^{\mu}_{\ \nu\lambda}$ will in general not be symmetric in its lower indices, in this section we need to be particularly careful with (and choose a convention for) the ordering of the lower indices in the covariant derivative. We will choose the convention that the last index always refers to the direction along which one is differentiating, i.e.

$$\tilde{\nabla}_{\mu}V^{\nu} = \partial_{\mu}V^{\nu} + \tilde{\Gamma}^{\nu}_{\ \lambda\mu}V^{\lambda} \tag{11.99}$$

etc. The reason for this choice is that one should think of the collection of objects $\Gamma^{\nu}_{\ \lambda\mu}$ (and $\tilde{\Gamma}^{\nu}_{\ \lambda\mu}$) as the coefficients of a matrix-valued 1-form (cf. section 4.6) $\Gamma^{\nu}_{\ \lambda} = \Gamma^{\nu}_{\ \lambda\mu}dx^{\mu}$, the matrices acting by rotation on vectors (and more general tensors), as in (5.21).

We now define the *torsion tensor* $T^{\lambda}_{\ \mu\nu}$ by

$$[\tilde{\nabla}_{\mu}, \tilde{\nabla}_{\nu}]\phi = T^{\lambda}_{\ \mu\nu}\partial_{\lambda}\phi \quad , \quad T_{\lambda\mu\nu} = g_{\lambda\rho}T^{\rho}_{\ \mu\nu} \quad , \tag{11.100}$$

and the *non-metricity tensor* $Q_{\nu\lambda\mu}$ by

$$\tilde{\nabla}_{\mu}g_{\nu\lambda} = -Q_{\nu\lambda\mu} \quad . \tag{11.101}$$

In terms of the $C^{\mu}_{\ \nu\lambda}$ these tensors can be written as

$$\begin{aligned} T_{\lambda\mu\nu} &= C_{\lambda\mu\nu} - C_{\lambda\nu\mu} = 2C_{\lambda[\mu\nu]} \\ Q_{\nu\lambda\mu} &= C_{\nu\lambda\mu} + C_{\lambda\nu\mu} = 2C_{(\nu\lambda)\mu} \quad . \end{aligned} \tag{11.102}$$

Thus the torsion is zero iff $C^{\lambda}_{\ \mu\nu}$ (and hence $\tilde{\Gamma}^{\lambda}_{\ \mu\nu}$) is symmetric in its lower indices, and the connection is compatible with the metric iff $C_{\nu\lambda\mu}$ is anti-symmetric in its first two indices. In particular, if the torsion is zero and the connection is metric-compatible, one has

$$C_{\lambda\mu\nu} = C_{\lambda\nu\mu} \quad \text{and} \quad C_{\lambda\mu\nu} = -C_{\mu\lambda\nu} \quad \Rightarrow \quad C_{\lambda\mu\nu} = 0 \quad , \tag{11.103}$$

as one can see by the gymnastics

$$C_{\lambda\mu\nu} = C_{\lambda\nu\mu} = -C_{\nu\lambda\mu} = -C_{\nu\mu\lambda} = C_{\mu\nu\lambda} = C_{\mu\lambda\nu} = -C_{\lambda\mu\nu} \quad . \tag{11.104}$$

Conversely, since the absence of torsion and non-metricity characterises the Levi-Civita connection, it should be possible to express the deviation $C_{\lambda\mu\nu}$ from the Levi-Civita connection entirely in terms of torsion and non-metricity. This is indeed the case. By repeating the calculation (5.44) in this more general context, one finds

$$2C_{\lambda(\mu\nu)} = Q_{\nu\lambda\mu} + Q_{\mu\lambda\nu} - Q_{\mu\nu\lambda} - T_{\mu\lambda\nu} - T_{\nu\lambda\mu} \quad . \tag{11.105}$$

Combining this with $2C_{\lambda[\mu\nu]} = T_{\lambda\mu\nu}$, one obtains

$$\begin{aligned} C_{\lambda\mu\nu} &= \tfrac{1}{2}(T_{\lambda\mu\nu} - T_{\mu\lambda\nu} - T_{\nu\lambda\mu}) + \tfrac{1}{2}(Q_{\mu\lambda\nu} + Q_{\nu\lambda\mu} - Q_{\mu\nu\lambda}) \\ &\equiv \tilde{T}_{\lambda\mu\nu} + \tilde{Q}_{\lambda\mu\nu} \quad , \end{aligned} \tag{11.106}$$

with

$$\tilde{T}_{\lambda\mu\nu} = \tfrac{1}{2}(T_{\lambda\mu\nu} - T_{\mu\lambda\nu} - T_{\nu\lambda\mu}) = -\tilde{T}_{\mu\lambda\nu} \tag{11.107}$$

and

$$\tilde{Q}_{\lambda\mu\nu} = \tfrac{1}{2}(Q_{\mu\lambda\nu} + Q_{\nu\lambda\mu} - Q_{\mu\nu\lambda}) = \tilde{Q}_{\lambda\nu\mu} \quad . \tag{11.108}$$

Thus we can now split a general connection more informatively into the 3 pieces

$$\tilde{\Gamma}^{\lambda}{}_{\mu\nu} = \Gamma^{\lambda}{}_{\mu\nu} + \tilde{T}^{\lambda}{}_{\mu\nu} + \tilde{Q}^{\lambda}{}_{\mu\nu} \quad . \tag{11.109}$$

REMARKS:

1. The tensor $\tilde{T}_{\lambda\mu\nu}$ is known as the *contorsion tensor* (frequently (mis-)spelled as "contortion" tensor). I am not aware of a commonly used name for $\tilde{Q}_{\lambda\mu\nu}$, and will not try to invent one. The contorsion tensor is the linear combination of components of the torsion tensor that appear as the connection coefficents of a general metric-compatible connection with torsion,

$$Q_{\lambda\mu\nu} = 0 \quad \Rightarrow \quad \tilde{\Gamma}^{\lambda}{}_{\mu\nu} = \Gamma^{\lambda}{}_{\mu\nu} + \tilde{T}^{\lambda}{}_{\mu\nu} \quad . \tag{11.110}$$

   In general it can have both symmetric and anti-symmetric components,

$$\tilde{T}_{\lambda(\mu\nu)} = -\tfrac{1}{2}(T_{\mu\lambda\nu} + T_{\nu\lambda\mu}) = T_{(\mu\nu)\lambda} \quad , \quad \tilde{T}^{\lambda}{}_{[\mu\nu]} = \tfrac{1}{2}T^{\lambda}{}_{\mu\nu} \quad , \tag{11.111}$$

   but it cannot be symmetric (if the contorsion were symmetric, the torsion, and hence the contorsion, would be zero). If its symmetric part vanishes, then $\tilde{T}_{\lambda\mu\nu}$ is completely anti-symmetric,

$$\tilde{T}^{\lambda}{}_{(\mu\nu)} = 0 \quad \Rightarrow \quad \tilde{T}_{\lambda\mu\nu} = \tilde{T}_{[\lambda\mu\nu]} \quad . \tag{11.112}$$

2. Since $\Gamma_{\lambda\mu\nu}$ contains a part that is antisymmetric in the first 2 indices,

$$\Gamma_{\lambda\mu\nu} = \tfrac{1}{2}g_{\lambda\mu,\nu} + \tfrac{1}{2}(g_{\nu\lambda,\mu} - g_{\nu\mu,\lambda}) \quad , \tag{11.113}$$

   one might be tempted to think that that part can be cancelled (or absorbed) by a metric-compatible $C_{\lambda\mu\nu} = C_{[\lambda\mu]\nu}$, so that a very simple metric-compatible connection would be

$$\tilde{\Gamma}_{\lambda\mu\nu} \overset{?}{=} \tfrac{1}{2}g_{\lambda\mu,\nu} \quad , \quad \tilde{\Gamma}^{\lambda}{}_{\mu\nu} \overset{?}{=} \tfrac{1}{2}g^{\lambda\rho}g_{\rho\mu,\nu} \quad . \tag{11.114}$$

   However, the term that one has cancelled (or absorbed) is *not* a tensor. Therefore, this candidate "connection" does not transform as (and therefore does not qualify as) a connection and cannot be used to define a covariant derivative.

3. In general, for a connection $\tilde{\nabla}$, the notions of autoparallels (section 5.8),

$$\tilde{\nabla}_\tau X^\mu = 0 \quad \Leftrightarrow \quad \ddot{x}^\mu + \tilde{\Gamma}^\mu_{\ \nu\lambda}\dot{x}^\nu\dot{x}^\lambda = 0 \ , \tag{11.115}$$

(i.e. curves characterised by the fact that their tangent vectors are parallel transported along the curve - this depends on a choice of connection) no longer coincides with the notion of geodesics (which are obtained by extremising proper time or distance, and which always lead to the Levi-Civita connection). However, this difference disappears if $C^\mu_{\ \nu\lambda}$ happens to be anti-symmetric in its lower indices (e.g. for a metric-compatible connection with totally anti-symmetric contorsion tensor), as one then has

$$\ddot{x}^\mu + \tilde{\Gamma}^\mu_{\ \nu\lambda}\dot{x}^\nu\dot{x}^\lambda = \ddot{x}^\mu + \Gamma^\mu_{\ \nu\lambda}\dot{x}^\nu\dot{x}^\lambda \ . \tag{11.116}$$

We have defined the Riemann tensor via the commutator of covariant derivatives (8.2)

$$[\nabla_\mu, \nabla_\nu]V^\lambda = R^\lambda_{\ \sigma\mu\nu}V^\sigma \tag{11.117}$$

associated to the Levi-Civita connection (Christoffel symbols), or, equivalently, by the relation (8.5) (now being careful with the positioning of the lower indices)

$$R^\lambda_{\ \sigma\mu\nu} = \partial_\mu\Gamma^\lambda_{\ \sigma\nu} - \partial_\nu\Gamma^\lambda_{\ \sigma\mu} + \Gamma^\lambda_{\ \rho\mu}\Gamma^\rho_{\ \sigma\nu} - \Gamma^\lambda_{\ \rho\nu}\Gamma^\rho_{\ \sigma\mu} \ . \tag{11.118}$$

In order to show explicitly (rather than by appealing to (11.117)) that this transforms as a tensor, all that one needs is the characteristic non-tensorial transformation behaviour of the Christoffel symbols $\Gamma^\lambda_{\ \mu\nu}$. As discussed in section 5.4 and above, an arbitrary connection $\tilde{\Gamma}^\lambda_{\ \mu\nu}$ that can be used to define a tensorial covariant derivative has the same non-tensorial transformation behaviour. Therefore

$$\tilde{R}^\lambda_{\ \sigma\mu\nu} \equiv R^\lambda_{\ \sigma\mu\nu}(\tilde{\Gamma}) = \partial_\mu\tilde{\Gamma}^\lambda_{\ \sigma\nu} - \partial_\nu\tilde{\Gamma}^\lambda_{\ \sigma\mu} + \tilde{\Gamma}^\lambda_{\ \rho\mu}\tilde{\Gamma}^\rho_{\ \sigma\nu} - \tilde{\Gamma}^\lambda_{\ \rho\mu}\tilde{\Gamma}^\rho_{\ \sigma\mu} \tag{11.119}$$

defines a tensor for any connection, namely the curvature tensor of the connection $\tilde{\Gamma}^\lambda_{\ \mu\nu}$. It is related to the commutator of covariant derivatives by

$$[\tilde{\nabla}_\mu, \tilde{\nabla}_\nu]V^\lambda = \tilde{R}^\lambda_{\ \sigma\mu\nu}V^\sigma + (\tilde{\Gamma}^\rho_{\ \mu\nu} - \tilde{\Gamma}^\rho_{\ \nu\mu})\nabla_\rho V^\lambda = \tilde{R}^\lambda_{\ \sigma\mu\nu}V^\sigma + T^\rho_{\mu\nu}\nabla_\rho V^\lambda \ , \tag{11.120}$$

where $T^\rho_{\mu\nu}$ is the torsion tensor. As before, one can also define the Ricci tensor and Ricci scalar by

$$\tilde{R}_{\mu\nu} \equiv R_{\mu\nu}(\tilde{\Gamma}) = \tilde{R}^\lambda_{\ \mu\lambda\nu} \quad , \quad \tilde{R} \equiv R(\tilde{\Gamma}) = g^{\mu\nu}\tilde{R}_{\mu\nu} \ . \tag{11.121}$$

However, it is crucial to keep in mind that the symmetry properties and Bianchi identities satisfied by these generalised curvature tensors will in general differ from those of the Riemann-Christoffel tensor. This should be clear from the way we derived the symmetries of the Riemann tensor in section 8.3, where we related the symmetries to the properties (metricity, no torsion) that characterise the canonical Levi-Civita connection (Christoffel symbols). For example, in general the Ricci tensor will not be symmetric, the Bianchi identity $R_{\alpha[\beta\gamma\delta]} = 0$ will be replaced by an identity relating $\tilde{R}_{\alpha[\beta\gamma\delta]}$ to the torsion (and its covariant derivative), etc.[28]

11.3 Curvature of Surfaces: Euler, Gauss(-Bonnet) and Liouville

... We can generalise the example of the curvature of the 2-sphere, discussed in section 8.6, somewhat, in this way connecting our considerations with the classical realm of the differential geometry of surfaces, in particular with the Gauss curvature, the Euler characteristic, the Gauss-Bonnet theorem and the Liouville Equation.

space-time translational gauge symmetry for the motion of quantum particles in the classical limit. In the first-order approximation, Yang–Mills gravity is consistent with the experimentally measured gravitational redshift. In the second-order approximation, it correctly predicts the perihelion shift of Mercury and the gravitational quadrupole radiation of binary pulsars.[13] Furthermore, Yang–Mills gravity allows a quantum theory of gravity to be formulated and Feynman–Dyson rules for the gravitational tensor fields and the associated "ghost particles"[13] to be derived, as we will show in Chapters 10 and 11. Thus, Yang–Mills gravity brings the gravitational interaction back into the experimentally established arena of gauge fields based on flat space-time.

In contrast, Einstein's approach involving the geometrization of physical fields in curved space-time appears to be successful only in the formulation of classical gravity, with the conservation of the energy–momentum pseudo-tensor, rather than the true energy–momentum tensor. If one were to adopt a similar approach to, say, the electromagnetic interaction, which is velocity-dependent, it would be natural to employ the Finsler geometry, where the fundamental metric tensors depend on both positions and velocities (i.e., the differentials of coordinates), rather than the Riemannian geometry.[14] However, all attempts thus far to geometrize classical electrodynamics have not even begun to approach the usefulness of quantum electrodynamics.

The classical theory of Einstein gravity is usually considered to be the most coherent mathematically and satisfying aesthetically.[2] However, there is little chance of making progress simply by going over its successes. Because of the success of Einstein gravity, many have made arguments that attempted to make it unique or necessary.[15,h] There is an old argument due to Feynman (and perhaps others) that the only consistent theory (with no more than two derivatives) of a spin-2 field coupled to itself is, in fact, general relativity. It is not necessary to analyze the detailed arguments one by one, all that is necessary is to present a counterexample.

---

[h] A century ago, Einstein observed "Concepts which have proved useful for ordering things easily assume so great an authority over us, that we forget their terrestrial origin and accept them as unalterable facts. They then become labeled as "conceptual necessities," "*a priori situations*," etc. The road to scientific progress is frequently blocked for long periods by such errors. It is therefore not just an idle game to exercise our ability to analyze familiar concepts, and to demonstrate the conditions on which their justification and usefulness depend, and the way in which these developed, little by little, from the data of experience. In this way they are deprived of their excessive authority."

Yang–Mills gravity, with its translational gauge symmetry in flat space-time and consistency with all known experiments, as well as other desirable features such as the preservation of the conservation law of energy–momentum, operational definitions of space-time coordinates, and quantizability of gravitational fields, is just such a counterexample from outside the curved space-time framework of general relativity.[i]

0.4. Unification of All Interactions Based on the Yang–Mills–Utiyama–Weyl Framework

In Chapters 14–16, we consider a model for unifying all interactions in nature (including gravity) within the taiji symmetry and the generalized Yang–Mills frameworks, following the ideas of Glashow, Salam, Ward, and Weinberg for the unified electroweak interaction.[16] We here present a brief preview of the unification of the gravitational interaction with just the electroweak interaction.

The T_4 gauge covariant derivative (0.5) paves the way for a unification of the gravitational and electroweak ("gravity-electroweak") interactions based on $T_4 \times SU_2 \times U_1$. Consider a unified "gravity-electroweak" model based on a generalized covariant derivative d_μ,[17]

$$d_\mu \equiv J_\mu^\nu \partial_\nu - if W_\mu^a t^a - if' U_\mu t_o, \quad J_\mu^\nu = \delta_\mu^\nu + g\phi_\mu^\nu. \tag{0.8}$$

This is a linear combination of the usual gauge covariant derivative in the electroweak theory and the gravitational T_4 gauge covariant derivative (0.5). The gauge curvatures, $C_{\mu\nu\alpha}$, $W_{\mu\nu}^a$, and $U_{\mu\nu}$, associated with each group in the "gravity-electroweak" covariant derivative d_μ are given by

$$[d_\mu, d_\nu] = C_{\mu\nu\alpha} T^\alpha - if W_{\mu\nu}^a t^a - if' U_{\mu\nu} t_o, \qquad [t^a, t^b] = i\epsilon^{abc} t^c, \tag{0.9}$$

and the $T(4)$ gauge curvature $C_{\mu\nu\alpha}$ in flat space-time is[17]

$$C_{\mu\nu\alpha} = J_{\mu\sigma}\partial^\sigma J_{\nu\alpha} - J_{\nu\sigma}\partial^\sigma J_{\mu\alpha} = \Delta_\mu J_{\nu\alpha} - \Delta_\nu J_{\mu\alpha} = -C_{\nu\mu\alpha}. \tag{0.10}$$

6.6.2 Cauchy-Riemann Equations

Functions of a complex variable can be defined by introducing another complex variable, as follows

$$f(z) = \phi(x, y) + \jmath\psi(x, y) \tag{6.162}$$

where $\phi(x, y)$ and $\psi(x, y)$ are real functions of x and y. If the function $f(z)$ is uniquely defined, and its derivatives are also uniquely defined within some region of the $f(z)$ plane, the function is called *analytic* or *holomorphic*. This last condition, however, is not trivial, as there are multiple paths along which a complex derivative may approach its limit as $z \to 0$, i.e.

$$\frac{df}{dz} = \lim_{\Delta z=0} \frac{f(z + \Delta z) - f(z)}{\Delta z}$$

If, for convenience, we select two paths along the Cartesian coordinate directions, x and y, respectively, the corresponding partial derivatives may be written as follows

$$\frac{\partial f}{\partial x} = \lim_{\Delta x=0} \frac{f(z + \Delta x) - f(z)}{\Delta x} \qquad \frac{1}{\jmath}\frac{\partial f}{\partial y} = \lim_{\Delta y=0} \frac{f(z + \Delta y) - f(z)}{\jmath\Delta y}$$

For the derivative of z to be unique, we must have

$$\frac{\partial f}{\partial x} = \frac{1}{\jmath}\frac{\partial f}{\partial y}$$

This can also be written in terms of the real and imaginary components of z, as follows

$$\frac{\partial \phi}{\partial x} + \jmath\frac{\partial \psi}{\partial x} = \frac{1}{\jmath}\left(\frac{\partial \phi}{\partial y} + \jmath\frac{\partial \psi}{\partial y}\right)$$

The *modulus* of the complex variable is given by

$$r = |z| = \sqrt{x^2 + y^2}$$

Therefore, the complex variable can be also expressed in polar coordinates in terms of its *argument*, θ, as follows

$$z = r\left(\cos\theta + \jmath\sin\theta\right) \tag{6.160}$$

Furthermore, using Taylor series expansions, the trigonometric functions can be related to the exponential function. Thus, based on what is known as *DeMoivre's theorem*, a complex variable can be written in exponential form, as follows (Streeter, 1948, p. 87)

$$z = re^{\jmath\theta} \tag{6.161}$$

6.6.2 Cauchy-Riemann Equations

Functions of a complex variable can be defined by introducing another complex variable, as follows

$$f(z) = \phi(x, y) + \jmath\psi(x, y) \tag{6.162}$$

where $\phi(x, y)$ and $\psi(x, y)$ are real functions of x and y. If the function $f(z)$ is uniquely defined, and its derivatives are also uniquely defined within some region of the $f(z)$ plane, the function is called *analytic* or *holomorphic*. This last condition, however, is not trivial, as there are multiple paths along which a complex derivative may approach its limit as $z \to 0$, i.e.

$$\frac{df}{dz} = \lim_{\Delta z = 0} \frac{f\left(z + \Delta z\right) - f\left(z\right)}{\Delta z}$$

If, for convenience, we select two paths along the Cartesian coordinate directions, x and y, respectively, the corresponding partial derivatives may be written as follows

$$\frac{\partial f}{\partial x} = \lim_{\Delta x = 0} \frac{f\left(z + \Delta x\right) - f\left(z\right)}{\Delta x} \qquad \frac{1}{\jmath}\frac{\partial f}{\partial y} = \lim_{\Delta y = 0} \frac{f\left(z + \Delta y\right) - f\left(z\right)}{\jmath\Delta y}$$

For the derivative of z to be unique, we must have

$$\frac{\partial f}{\partial x} = \frac{1}{\jmath}\frac{\partial f}{\partial y}$$

This can also be written in terms of the real and imaginary components of z, as follows

$$\frac{\partial\phi}{\partial x} + \jmath\frac{\partial\psi}{\partial x} = \frac{1}{\jmath}\left(\frac{\partial\phi}{\partial y} + \jmath\frac{\partial\psi}{\partial y}\right)$$

Thus, provided that the partial derivatives of ϕ and ψ are continuous, a necessary, but not sufficient, condition for $f(z)$ to be analytic is

$$\frac{\partial\phi}{\partial x}=\frac{\partial\psi}{\partial y} \qquad \text{and} \qquad \frac{\partial\phi}{\partial y}=-\frac{\partial\psi}{\partial x} \tag{6.163}$$

These are called the *Cauchy-Riemann equations*. Points on the complex plane where these equations are not satisfied are called *singular points*.

6.6.3 Complex Potential

For ideal fluid flow, it is convenient to identify the aforementioned real variables with the velocity potential, ϕ, and the stream function, ψ. For then, differentiation of the first of Eq. (6.163) with respect to x, the second with respect to y, and adding the results, leads to exactly the two-dimensional form of the Laplace equation for the velocity potential, i.e. Eq. (6.15). Similarly, differentiation of the first of Eq. (6.163) with respect to y, the second with respect to x, and subtracting the results, leads to the Laplace equation for the stream function, i.e. Eq. (6.17).

Because the velocity potential, ϕ, and the stream function, ψ, satisfy the Cauchy-Riemann equations, they may also be interpreted as the real and imaginary parts of an analytic function called the *complex potential*, i.e.

$$w(z)=\phi+\jmath\psi \tag{6.164}$$

The rate of change of w with respect to z is called the *complex velocity*. Since w is a function of z only, its derivative can be determined by first computing its total differential, as follows

$$dw=\frac{\partial\phi}{\partial x}dx+\frac{\partial\phi}{\partial x}dy+\jmath\frac{\partial\psi}{\partial x}dx+\jmath\frac{\partial\psi}{\partial y}dy$$

The partial derivatives with respect to y can be substituted using the Cauchy-Riemann equations, i.e. Eq. (6.163), leading to

$$dw=\frac{\partial\phi}{\partial x}\left(dx+\jmath dy\right)+\jmath\frac{\partial\psi}{\partial x}dx\left(dx+\jmath dy\right)$$

Therefore, the derivative of the complex potential is given by

$$\frac{dw}{dz}=\frac{\partial\phi}{\partial x}+\jmath\frac{\partial\psi}{\partial x} \tag{6.165}$$

Finally, recalling the relations between the velocity potential and stream function to the physical velocity components, i.e. Eqs. (6.3) and (5.17), the derivative of w if usually called the *complex velocity*, i.e.

$$\frac{dw}{dz}=u-\jmath v=Ve^{-\jmath\alpha} \tag{6.166}$$

Thus, provided that the partial derivatives of ϕ and ψ are continuous, a necessary, but not sufficient, condition for $f(z)$ to be analytic is

$$\frac{\partial \phi}{\partial x} = \frac{\partial \psi}{\partial y} \qquad \text{and} \qquad \frac{\partial \phi}{\partial y} = -\frac{\partial \psi}{\partial x} \tag{6.163}$$

These are called the *Cauchy-Riemann equations*. Points on the complex plane where these equations are not satisfied are called *singular points*.

6.6.3 Complex Potential

For ideal fluid flow, it is convenient to identify the aforementioned real variables with the velocity potential, ϕ, and the stream function, ψ. For then, differentiation of the first of Eq. (6.163) with respect to x, the second with respect to y, and adding the results, leads to exactly the two-dimensional form of the Laplace equation for the velocity potential, i.e. Eq. (6.15). Similarly, differentiation of the first of Eq. (6.163) with respect to y, the second with respect to x, and subtracting the results, leads to the Laplace equation for the stream function, i.e. Eq. (6.17).

Because the velocity potential, ϕ, and the stream function, ψ, satisfy the Cauchy-Riemann equations, they may also be interpreted as the real and imaginary parts of an analytic function called the *complex potential*, i.e.

$$w(z) = \phi + \jmath\psi \tag{6.164}$$

The rate of change of w with respect to z is called the *complex velocity*. Since w is a function of z only, its derivative can be determined by first computing its total differential, as follows

$$dw = \frac{\partial \phi}{\partial x}dx + \frac{\partial \phi}{\partial x}dy + \jmath\frac{\partial \psi}{\partial x}dx + \jmath\frac{\partial \psi}{\partial y}dy$$

The partial derivatives with respect to y can be substituted using the Cauchy-Riemann equations, i.e. Eq. (6.163), leading to

$$dw = \frac{\partial \phi}{\partial x}(dx + \jmath dy) + \jmath\frac{\partial \psi}{\partial x}dx\,(dx + \jmath dy)$$

Therefore, the derivative of the complex potential is given by

$$\frac{dw}{dz} = \frac{\partial \phi}{\partial x} + \jmath\frac{\partial \psi}{\partial x} \tag{6.165}$$

Finally, recalling the relations between the velocity potential and stream function to the physical velocity components, i.e. Eqs. (6.3) and (5.17), the derivative of w if usually called the *complex velocity*, i.e.

$$\frac{dw}{dz} = u - \jmath v = Ve^{-\jmath\alpha} \tag{6.166}$$

where V is the magnitude of the physical, two-dimensional velocity vector, and α is the angle that it makes with the x axis.

The conditions of irrotationality and incompressibility are automatically satisfied by the complex velocity. This is evident since the closed integral of w' on the complex plane vanishes, as it is comprised of the circulation around, and the flux through the path of integration on the physical plane, i.e.

$$\oint_C \frac{dw}{dz}\, dz = \oint_C \mathbf{V} \cdot \mathbf{t} ds + \oint_C \mathbf{V} \cdot \mathbf{n} ds = 0 \tag{6.167}$$

where $\mathbf{V}$ is the physical velocity vector, and $\mathbf{t}$ and $\mathbf{n}$ are the tangent and normal unit vectors to the path of integration C.

6.6.4 Conformal Transformations

The relations between the complex variables z and w allow a graphical transformation of ideal flow problems from the $x - y$ plane to the $\phi - \psi$ plane. These are commonly called the z and ζ planes, respectively, where ζ is an analytic function of z, i.e.

$$\zeta = f(z) \tag{6.168}$$

Thus, provided that z_0 is some non-singular point on the z plane, the transformation to the ζ plane is called a *conformal mapping* because infinitesimal configurations on the two planes are similar, and obey the relation

$$\delta\zeta = f'(z_0)\, \delta z \tag{6.169}$$

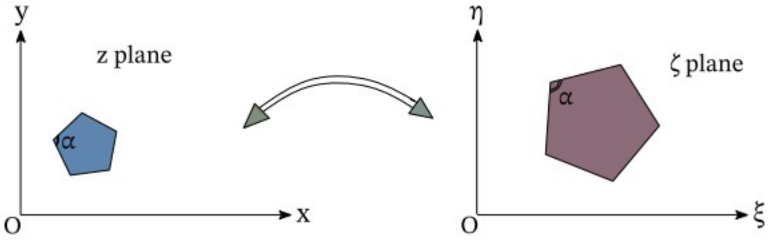

FIGURE 6.29 Schematic of conformal mapping

The goal of conformal mapping is to transform a geometrically complicated region on the z plane to a simpler region on the ζ plane. For example, a wedge shaped boundary may be transformed into the semi-infinite plane, where the flow pattern can be established easier. Thus, as shown in Fig. 6.29, images may be stretched and rotated, as they are transferred to the ζ plane, but always remain geometrically similar. This implies that conformal maps preserve the angles of geometric elements between the z and ζ planes. If an angle of an isolated point is changed in the transformation, that point is singular, and must be excluded from the map. However, singularities on the z plane are mapped to corresponding singularities on the ζ plane (Howe, 2006).

For an ideal fluid, a convenient analytic function for conformal mapping is the complex potential, $w(z)$, and its counterpart on the ζ plane

$$W(\zeta) = \Phi(\xi, \eta) + \jmath \Psi(\xi, \eta) \tag{6.170}$$

Then, the analytic property of Eq. (6.168) implies that

$$w(z) = W\left[f(z)\right] = \phi(x, y) + \jmath \psi(x, y) \tag{6.171}$$

Therefore, we must have

$$\Phi(\xi, \eta) = \phi(x, y) \qquad \text{and} \qquad \Psi(\xi, \eta) = \psi(x, y)$$

It follows that corresponding streamlines and equipotential lines on the z and ζ planes carry the same level set values although their shapes may be different. Furthermore, the flow net on the z plane is always transformed to a rectangular grid on the ζ plane, with its grid lines parallel to the ϕ and ψ axes, as shown in Fig. 6.30.

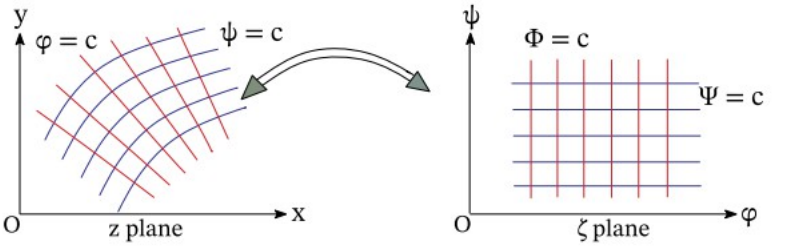

FIGURE 6.30 Conformal mapping of flow net

As a result, the flow on the ζ plane always corresponds to uniform flow directed along the ϕ axis. Since the flow between streamlines is constant, the transformation preserves the flow rate, and therefore the challenge is to find a mapping operator that can transform the uniform flow on the ζ plane to any desired flow on the z plane. The desired transformation operator is none other than the derivative of the complex potential, which according to the Cauchy-Riemann equations is uniquely defined at every point of the z plane where $\frac{dw}{dz} \neq 0$. Then, the general mapping of Eq. (6.169) can now be written as follows

$$\delta\zeta = \frac{dw}{dz}\,\delta z \tag{6.172}$$

In addition to assigning the same level set values to streamlines and equipotential lines, conformal maps also preserve the streamline property of solid boundaries. This is true because on the z plane, $\psi = C$ on the wall, where C is some arbitrary constant. The conformal transformation preserves this constant, regardless of the new orientation of the streamline, thus a solid wall always remains a solid wall.

When solving boundary-value problems on the ζ plane, essential boundary conditions are automatically satisfied because the values of ϕ and Φ are identical. When the values of normal derivatives are prescribed as natural boundary conditions, conformal mapping suggests that (Rouse, 1959)

$$\frac{\partial \phi}{\partial n} = \left| \frac{dw}{dz} \right| \frac{\partial \Phi}{\partial \nu} \tag{6.173}$$

where ν is the normal to the boundary in the ζ plane. A similar transformation is needed to map the complex velocity on the ζ plane, i.e.

$$\frac{dw}{dz} = \frac{dW}{d\zeta}\frac{d\zeta}{dz} \tag{6.174}$$

Finally, it should be mentioned that line sources and vortices map into identical sources and vortices on the ζ plane. The flow features correspond to singularities on both the z and ζ planes; however the strength of both sources and vortices is preserved during the conformal transformation, as it will be shown in the next section.

6.6.5 Power-Law Mapping

Any differential function may be used to accomplish the transform $w = f(z)$. Some simple examples are presented next corresponding to power-law functions of the form $w = Az^n$, where A is in general complex.

6.6.5.1 Uniform Stream; $n = 1$

Consider the uniform flow at an angle α to the x axis, as described in section 6.5.2. Therefore

$$\phi = Ur\cos(\theta - \alpha) \qquad \psi = Ur\sin(\theta - \alpha)$$

The simplest power law transformation employs an exponent of unity for z, thus we may define $z = re^{\dot{\jmath}\theta}$. Then, the complex potential can be written as follows

$$w = Uze^{-\dot{\jmath}\alpha} \tag{6.175}$$

Thus, elements on the z plane are elongated by a factor U and rotated by an angle $-\alpha$ when mapped to the ζ plane. This makes the problem marginally easier to solve on the ζ plane although more advantages can be found with higher exponents.

APPENDIX A

GAUSSIAN QUADRATURE FORMULAS FOR CONSTANT WEIGHT FUNCTION

Here we give values of the $A_k^{(n)}$ and $x_k^{(n)}$ which make the approximation

$$\int_{-1}^{1} f(x)\,dx \approx \sum_{k=1}^{n} A_k^{(n)} f(x_k^{(n)})$$

exact whenever $f(x)$ is a polynomial of degree $\leq 2n - 1$. These formulas are discussed in Section 7.2. The $A_k^{(n)}$ and $x_k^{(n)}$ are symmetric with respect to $x = 0$:

$$A_k^{(n)} = A_{n-k+1}^{(n)}, \qquad x_k^{(n)} = -x_{n-k+1}^{(n)}$$

and the tables give only the values corresponding to $0 \leq x_k^{(n)} \leq 1$.

The tabulated values are taken from

H. J. Gawlik, "Zeros of Legendre Polynomials of orders 2-64 and weight coefficients of Gauss quadrature formulae," Armament Research and Development Establishment, Memorandum (B) 77/58. Fort Halstead, Kent, 1958.

where the $A_k^{(n)}$ and $x_k^{(n)}$ are given to 20 decimal places. Values for n = 2, 4, 8, 16, 24, 32, 40, 48, 64, 80, 96 of the same accuracy are given in the two tables

P. Davis and P. Rabinowitz, "Abscissas and weights for Gaussian quadratures of high order," *J. Res. Nat. Bur. Standards*, Vol. 56, 1956, pp. 35–37.

P. Davis and P. Rabinowitz, "Additional abscissas and weights for Gaussian quadrature of high order: values for n = 64, 80 and 96," *J. Res. Nat. Bur. Standards*, Vol. 60, 1958, pp. 613–14.

These three tables are the most extensive values of the $A_k^{(n)}$ and $x_k^{(n)}$ which are known and are believed to be accurate to within a few units in the last significant figures.

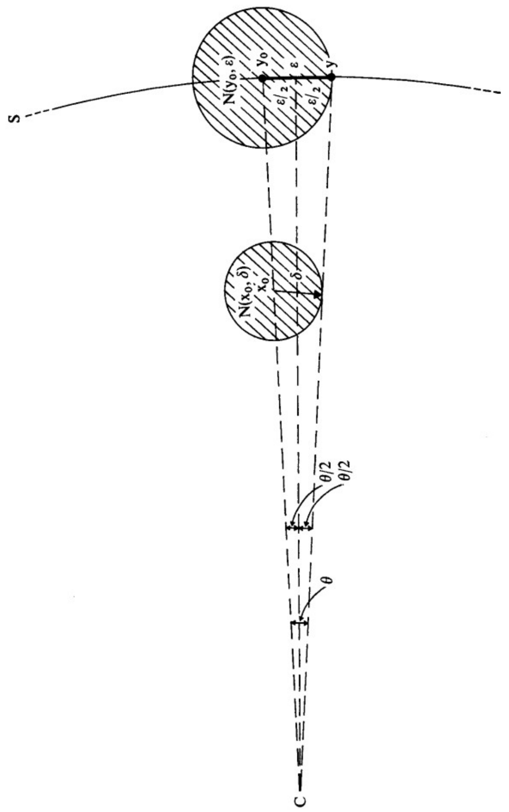

Fig. 16.3

tinuity cannot be established by the argument applying to exterior points.

The continuity of f may be established, however, as follows. Let x_0 be some point of $\mathbf{R}^3$ inside S, and let y_0 be the corresponding image $f(x_0)$ on S. Let a neighbourhood of y_0 be denoted by $N(y_0; \varepsilon)$ and let y be some point on the intersection of the sphere, having centre y_0 and radius ε, with the surface S. Now, let S be the perpendicular distance from x_0 to the radius c–y. The continuity of f at x_0 follows, since it is clear that for any ε the chosen δ will satisfy $f(N(x; \delta)) \subseteq N(y; \varepsilon)$, and since x_0 is an arbitrary point inside S, continuity follows for all points inside S, and hence also for all points belonging to $\mathbf{R}^3 - c$. The functional relationship between δ and ε is given by:

$$\begin{aligned}\delta &= d(x_0, c)\cdot\sin\theta\\ &= 2\cdot d(x_0, c)\cdot\sin\frac{\theta}{2}\cos\frac{\theta}{2}\\ &= 2\cdot d(x_0, c)\cdot\frac{\varepsilon}{2}\sqrt{\left(1-\frac{\varepsilon^2}{4}\right)}\\ &= d(x_0, c)\cdot\sqrt{\left(\varepsilon^2-\frac{\varepsilon^4}{4}\right)}\end{aligned}$$

Since topology is concerned with the study of properties which remain invariant under certain permitted transformations, and since these transformations are defined as *continuous functions having continuous inverses*, the establishment of continuity by the methods discussed in this chapter is an important stage in the investigation of topological invariants. However, these methods are dependent upon the existence of a metric, and so can apply to metric spaces only. A still more general approach is needed, and this will require continuity to be defined without recourse to any metric so that sets representing non-metric spaces may be embraced. It has already been seen that neighbourhoods are a particular kind of *open set*, and it is this concept of *open set* which provides the basis for a definition of continuity not requiring any reference to a metric. Such a general approach will be developed in the next chapter.

Metric Spaces

Distance in $\mathbf{R}^n$—definition of metric—neighbourhoods—continuity in terms of neighbourhoods—complete system of neighbourhoods—requirement for proof of non-continuity—functional relationships between δ and ε—limitations of metric.

In Chapter 13 it was seen that for three-dimensional Euclidean space, the distance between two points P_0, P_1 satisfies the conditions:

$$d(P_0, P_1) \geqq 0;$$

$$d(P_0, P_1) = 0 \text{ if and only if } P_0 = P_1;$$

$$d(P_0, P_1) = d(P_1, P_0);$$

$$d(P_0, P_1)+d(P_1, P_2) \geqq d(P_0, P_2).$$

Generally, for x and y belonging to $\mathbf{R}^n$, the distance $d(x, y)$ may be defined as

$$d(x, y) = \sqrt{[(x_1-y_1)^2+ \dots +(x_n-y_n)^2]},$$

where the n-tuples $(x_1, \dots, x_n)$, $(y_1, \dots, y_n)$ are the coordinates of x and y respectively. For any points x, y, z of $\mathbf{R}^n$, distance satisfies the conditions:

$$d(x, y) \geqq 0;$$

$$d(x, y) = 0 \text{ if and only if } x = y;$$

$$d(x, y) = d(y, x);$$

$$d(x, y)+d(y, z) \geqq d(x, z).$$

It is not, however, necessary to confine the concept of distance to n-dimensional Euclidean space. If X is any non-empty set for which a non-negative real number $d(x, y)$ is defined for all elements $x, y \in X$ satisfying the four conditions above, then d is termed a *metric* and the set X together with the metric d is termed a *metric space*. The metric d is a function $X \times X \to \mathbf{R}_0^+$. A simple example of a metric space is provided by any non-empty set X together with a metric d defined by

$$d(x, y) = \begin{cases} 0 \text{ if } x = y \\ a > 0 \text{ if } x \neq y \end{cases}$$

for all $x, y \in X$. It can easily be seen that the four conditions for a metric are satisfied by d as defined above.

Another example providing a set of metric spaces is the set of all n-figure binary numbers with the metric d defined as the number of changes of digits required in going from one number to another. Thus if in the set of five-figure binary numbers $x = 01101$ and $y = 10111$, then $d(x, y) = 3$, since there is a change in each of the first, second and fourth digit places (reading from left to right).

In Chapter 13, it was seen that for any point $x_0 \in \mathbf{R}$, the set of all points x of $\mathbf{R}$ satisfying

$$d(x_0, x) < \delta$$

(where d is the usual metric in $\mathbf{R}$) is termed a *neighbourhood* (or *open ball*) of x_0. Clearly, a different neighbourhood of x_0 is defined for each chosen value of δ. The subset satisfying $d(x_0, x) < \rho$ is termed the neighbourhood of x_0 of *radius* ρ and denoted by $N(x_0; \rho)$.

Figure 16.1 depicts a point x_0 belonging to a subset X of $\mathbf{R}^2$, where X is the set of all points within and on the continuous closed curve C. The neighbourhood of x_0 in $\mathbf{R}^2$ of radius ρ is represented by the circle with centre x_0 and radius r, excluding the circumference. The neighbourhood of x_0 in X of radius ρ is represented by that part of the interior of the circle which is shaded, including interior points of the circle belonging to C. Clearly,

$$N(x_0 \in X; \rho) = X \cap N(x_0 \in \mathbf{R}^2; \rho),$$

and a similar relationship will hold for any point $x \in X \subset \mathbf{R}^2$.

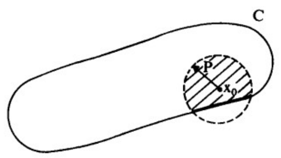

Fig. 16.1

In the case of the non-empty set X and the metric d defined by

$$d(x, y) = \begin{cases} 0 \text{ if } x = Y \\ a > 0 \text{ if } x \neq y, \end{cases}$$

the neighbourhood in X of any point $x \in X$ of radius a consists of the single point x itself, since any point other than x is defined to have distance a from x. In the case of the set of five-figure binary numbers with d defined as the number of changes of digits in going from one number to another, the neighbourhood of 01101 of radius 3 is the subset

$$\{01101,\ 11101,\ 00101,\ 01001,\ 01111,\ 01100,\ 10101,\ 11001,\ 11111,\ 11100,\ 00001,\ 00111,\ 00100,\ 01011,\ 01000,\ 01110\}.$$

This is the subset of all five-figure binary numbers differing by zero, one, or two digits from 01101. The concept of a neighbourhood of given radius may thus be generalised to sets other than subsets of $\mathbf{R}^n$.

The definition of continuity of functions, given in Chapter 13, may now be re-expressed in terms of neighbourhoods where functions are mapping one metric space to another. If X, Y are two metric spaces with metrics d, e respectively, and if $x_0 \in X$, then a function $f: X \to Y$ is said to be *continuous at* x_0 if, for each neighbourhood of $f(x_0)$ in Y, there is some neighbourhood of x_0 in X whose image is in the neighbourhood of $f(x_0)$ in Y. Symbolically, if for every radius ε there is a radius δ such that

$$f(N(x \in X;\delta)) \subseteq N(f(x) \in Y;\varepsilon),$$

then f is continuous at x_0. If this holds for all $x \in X$, then the function is continuous at each and every point of its domain and is said simply to be *continuous*. Thus 'continuous' means 'continuous everywhere'.

The term *open ball* for a neighbourhood of given radius arises from a consideration of neighbourhoods in $\mathbf{R}^3$. Such a neighbourhood in $\mathbf{R}^3$ has a radius defining its boundary and consists of the set of all the points *within* this boundary. Such a set is an open set, and a given point of $\mathbf{R}^3$ together with the given radius defines the interior of a sphere. Hence the term 'open ball' (rather than *open sphere*) is used to emphasise that it is not the surface of the sphere which is being considered. A neighbourhood of a general nature is simply a subset of points containing a given point together with some open ball about that point. The set of all neighbourhoods of a given point $x \in X$ is termed the *complete system of neighbourhoods* of x.

An example of a function which is continuous over a certain subset of $\mathbf{R}^2$ but not continuous everywhere was depicted in Figure 15.16 (page 148). The same function is depicted in Figure 16.2 where $X = \{(x, y): x < 0\}$, and $Y = \{(x, y): x \geqq 0\}$. The images $f(X)$, $f(Y)$ are as depicted in the figure. If $a = (0, a)$ is some point of the subset $\{(0, y)\}$, then $a' = f(a) = (-1, a)$ is a point of the subset $\{(-1, y)\}$. If $0 < \varepsilon < 2$, then the neighbourhood of a' in $\mathbf{R}^2$, $N(a';\varepsilon)$ contains no points of $f(X)$. However, all neighbourhoods of a in $\mathbf{R}^2$ do contain points belonging to X. There is thus no δ corresponding to ε such that

$$f(N(a;\delta)) \subseteq N(a';\varepsilon),$$

and the function is therefore not continuous at a. Since a was taken as an arbitrary point of $\{(0, y)\}$ it follows that f is nowhere continuous on $\{(0, y)\}$. If, however, any point of X or Y is chosen not belonging to $\{(0, y)\}$, there will always be some δ, however small, satisfying the continuity condition. The function is thus continuous everywhere in $\mathbf{R}$ except for the subset $\{(0, y)\}$.

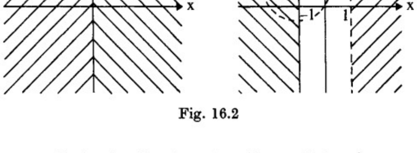

Fig. 16.2

To prove that a function is **not** continuous it is only necessary to find some ε for which no δ exists satisfying the continuity condition. Proving that a function **is** continuous is more difficult because it is necessary to establish that some δ exists for every point of its domain and every possible choice of ε. This may sometimes be done by finding a suitable functional relationship between δ and ε. In certain cases it is possible to take δ equal to ε, the simplest example of which is the identity function $f: \mathbf{R}^n \to \mathbf{R}^n$ for which $f(x) = x$. Other examples are provided by the various rigid transformations. In the case of similarity transformations δ may be taken equal to ε if the transformation is one of contraction. But, if the function increases distances by a factor a greater than unity it is necessary to take $\delta = \varepsilon/a$.

An example of finding an appropriate functional relationship between δ and ε is provided by consideration of the continuity of the radial projection $f: \mathbf{R}^3 - c \to S$, which projects all points of $\mathbf{R}^3$ except c on to the surface S of a sphere of unit radius and centre c. This is depicted in Figure 16.3. The distance between any two points exterior to the sphere is shrunk by the function f, and the distance between any two points on the surface S remains unchanged. Hence, f is continuous if its domain is restricted to elements x of $\mathbf{R}^3$ for which

$$d(x, c) \geqq 1.$$

For pairs of points inside S, however, the function f magnifies distances more and more as the points become closer and closer to c, and con-

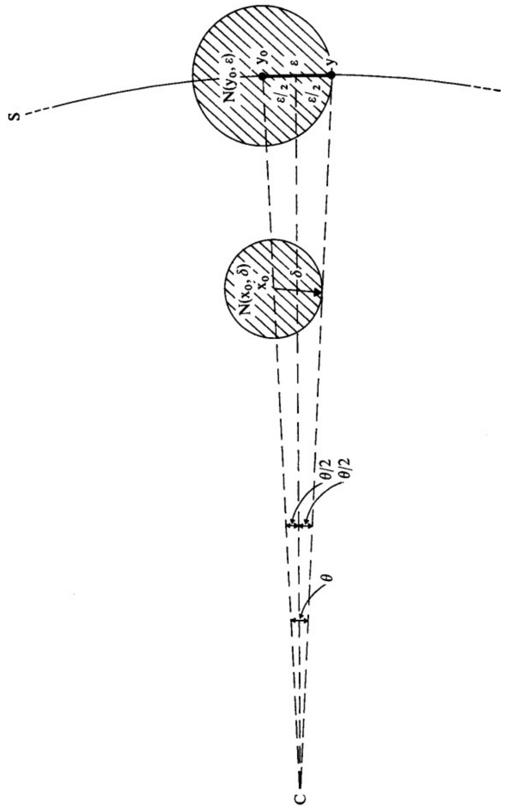

Fig. 16.3

tinuity cannot be established by the argument applying to exterior points.

The continuity of f may be established, however, as follows. Let x_0 be some point of $\mathbf{R}^3$ inside S, and let y_0 be the corresponding image $f(x_0)$ on S. Let a neighbourhood of y_0 be denoted by $N(y_0; \varepsilon)$ and let y be some point on the intersection of the sphere, having centre y_0 and radius ε, with the surface S. Now, let S be the perpendicular distance from x_0 to the radius c–y. The continuity of f at x_0 follows, since it is clear that for any ε the chosen δ will satisfy $f(N(x; \delta)) \subseteq N(y; \varepsilon)$, and since x_0 is an arbitrary point inside S, continuity follows for all points inside S, and hence also for all points belonging to $\mathbf{R}^3 - c$. The functional relationship between δ and ε is given by:

$$\begin{aligned}\delta &= d(x_0, c)\cdot\sin\theta \\ &= 2\cdot d(x_0, c)\cdot\sin\frac{\theta}{2}\cos\frac{\theta}{2} \\ &= 2\cdot d(x_0, c)\cdot\frac{\varepsilon}{2}\sqrt{\left(1-\frac{\varepsilon^2}{4}\right)} \\ &= d(x_0, c)\cdot\sqrt{\left(\varepsilon^2-\frac{\varepsilon^4}{4}\right)}\end{aligned}$$

Since topology is concerned with the study of properties which remain invariant under certain permitted transformations, and since these transformations are defined as *continuous functions having continuous inverses*, the establishment of continuity by the methods discussed in this chapter is an important stage in the investigation of topological invariants. However, these methods are dependent upon the existence of a metric, and so can apply to metric spaces only. A still more general approach is needed, and this will require continuity to be defined without recourse to any metric so that sets representing non-metric spaces may be embraced. It has already been seen that neighbourhoods are a particular kind of *open set*, and it is this concept of *open set* which provides the basis for a definition of continuity not requiring any reference to a metric. Such a general approach will be developed in the next chapter.

If there is no secondary flow in the layer, then $v_2 = 0$ everywhere. It follows therefore from equation (18) that

$$\frac{v_1^2}{h_1}\frac{\partial h_1}{\partial x_2} = \frac{1}{\rho}\frac{\partial p}{\partial x_2},$$

and if κ is the curvature of a streamline at any point,

$$\kappa = (h_1 h_2)^{-1}(\partial h_1/\partial x_2),$$

so that the above relation becomes

$$\kappa v_1^2 h_2 = \frac{1}{\rho}\frac{\partial p}{\partial x_2}. \tag{154}$$

Now the right-hand side of this relation is independent of x_3, as is also κ, whereas v_1 is a non-constant function of x_3 by virtue of the boundary conditions. It follows therefore that relation (154) cannot be true unless $\kappa = 0$ everywhere, in which case the streamlines are straight. Hence curvature of the streamlines in planes parallel to the plate implies the existence of secondary flow in the boundary layer.

In the case of steady flow over a curved surface, a special feature is associated with geodesic curves on the surface. L. C. Squire (1955) has shown that for streamlines which are geodesics on the surface the boundary-layer flow parallel to the surface is in the direction of the main stream. Let $x_2 =$ const be such a streamline, so that $\partial h_1/\partial x_2 = 0$ since it is a geodesic. Equations (18) and (21) then give

$$\frac{v_1}{h_1}\frac{\partial v_2}{\partial x_1} + \frac{v_2}{h_2}\frac{\partial v_2}{\partial x_2} + v_3\frac{\partial v_2}{\partial x_3} + \frac{v_1 v_2}{h_1 h_2}\frac{\partial h_2}{\partial x_1} = \nu\frac{\partial^2 v_2}{\partial x_3^2}, \tag{155}$$

since $V_2 = 0$. The boundary conditions on v_2 are $v_2 = 0$ when $x_3 = 0$ and $v_2 \to 0$ as $x_3 \to \infty$, and hence the required solution of equation (155) is $v_2 = 0$. Conversely, if v_2 and V_2 are zero on any curve, that curve must be a geodesic, for in this case equations (18) and (21) give

$$(h_1 h_2)^{-1}(V_1^2 - v_1^2)(\partial h_1/\partial x_2) = 0,$$

which is true for all values of x_3. Thus, since $V_1 \neq v_1$ for all values of x_3, it follows that $\partial h_1/\partial x_2 = 0$; that is, the curve is a geodesic.

20. Parabolic flow over a flat plate

An example of secondary flow in a boundary layer, arising from curvature of streamlines in the main-stream flow, was discussed by Sowerby (1954) and by Loos (1955). The case is that of the boundary layer on a flat plate at zero incidence; the flow in the main stream is steady, and the streamlines lie in planes parallel to the plate and form a system of parabolic translates. The common axis of the system is taken parallel to the leading edge of the plate.

A system of rectangular Cartesian coordinates $Oxyz$ may be chosen, with the plate forming the half-plane $z = 0$, $x \geqslant 0$. Thus, with the introduction of parameters as indicated in Fig. VIII. 7, the family of parabolic translates is represented by the equation

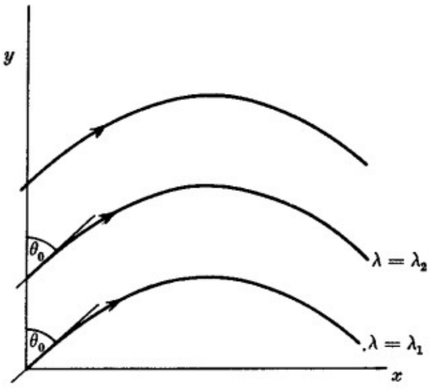

FIG. VIII. 7. Family of parabolic translates as streamlines of a curved external flow over a flat plate.

$$y = \lambda + x(\beta - \tfrac{1}{2}cx), \tag{156}$$

where
$$\beta = \cot\theta_0, \tag{157}$$

and β and c are constant for a given system of translates. Variation of the parameter λ gives different members of the family, while variation of c changes the scale of the parabolas; c may be regarded therefore as a parameter which determines the curvature of the streamlines, and in particular the streamlines are straight when $c = 0$.

The Cartesian components of the main-stream flow are

$$U = \text{constant}, \qquad V = U(\beta - cx), \tag{158}$$

so that the main-stream flow is rotational, and there is a spanwise pressure gradient. The flow everywhere is independent of y, and if u, v, w are the components of velocity in the boundary layer the equations of motion are

$$u\frac{\partial u}{\partial x} + w\frac{\partial u}{\partial z} = \nu\frac{\partial^2 u}{\partial z^2}, \tag{159}$$

$$u\frac{\partial v}{\partial x} + w\frac{\partial v}{\partial z} = -cU^2 + \nu\frac{\partial^2 v}{\partial z^2}, \tag{160}$$

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0, \tag{161}$$

with boundary conditions

$$u = v = w = 0 \quad \text{when } z = 0 \quad (x > 0),$$
$$u \to U, \quad v \to U(\beta - cx) \quad \text{when } z \to \infty \text{ or } x \to 0. \tag{162}$$

It is clear that the required solution of the above equations provides an extension of the Blasius solution for two-dimensional uniform flow over a flat plate (Section V. 12), since the latter is the case $\beta = 0$, $c = 0$; also the case of uniform flow across a sheared plate is obtained by taking $c = 0$. In the general case the additional term in the equations of motion is the term cU^2 in equation (160), which clearly arises from the curvature of the streamlines.

The solution is obtained by introducing Prandtl's transformation

$$\eta = \tfrac{1}{2}(U/\nu x)^{\frac{1}{2}}z, \tag{163}$$

and writing

$$u = \tfrac{1}{2}Uf'(\eta), \qquad v = U\{\beta g(\eta) - cxh(\eta)\}, \tag{164}$$

where f, g, h are functions of η only. Then all the equations of motion and boundary conditions are satisfied provided

$$w = \tfrac{1}{2}(U\nu/x)^{\frac{1}{2}}(\eta f' - f), \tag{165}$$

and f, g, h satisfy the equations

$$f''' + ff'' = 0, \tag{166}$$

$$g'' + fg' = 0, \tag{167}$$

$$h'' + fh' - 2f'h + 4 = 0, \tag{168}$$

with boundary conditions

$$f = f' = g = h = 0 \quad \text{when } \eta = 0,$$
$$f' \to 2, \quad g \to 1, \quad h \to 1 \text{ when } \eta \to \infty. \tag{169}$$

The required solution of equation (166) was obtained by Blasius, and the appropriate solution of equation (167) is

$$g = \tfrac{1}{2}f'. \tag{170}$$

The remaining equation (168) is linear, and was solved numerically by Sowerby with the use of Howarth's values (1938) for the coefficients f and f'. Loos has shown, however, that the solution is related to a solution of another equation given previously by Mager and Hansen (1952). The asymptotic form of (168) is of some interest, since the equation can be transformed, for large values of η, to a special case of Weber's equation. Numerical values of h and $h - \frac{1}{2}f'$ are given in Table VIII. 4.

The expressions for the components of velocity in the boundary layer are easily obtained. If the component along a streamline is denoted by

v_1 and the component normal to it by v_n, so that v_n is the secondary flow and is measured positive towards the centre of curvature, the results are

$$v_1 = U\{1+(\beta-cx)^2\}^{-\frac{1}{2}}\{\tfrac{1}{2}f'+(\beta-cx)(\tfrac{1}{2}\beta f'-cxh)\}, \tag{171}$$

$$v_n = Ucx\{1+(\beta-cx)^2\}^{-\frac{1}{2}}\{h-\tfrac{1}{2}f'\}. \tag{172}$$

The third component w, normal to the plate, is given by result (165).

It is clear that the secondary flow here is always directed towards the centre of curvature of the streamlines. As an illustration of its magnitude, consider the case where $\beta = 1$ and $c > 0$. Then when $cx = 2$,

$$v_1 = V_1 h \quad \text{and} \quad v_n = V_1(h-\tfrac{1}{2}f'),$$

where V_1 is the main-stream speed for this value of cx. These two profiles are shown in Fig. VIII. 8, and it will be seen that v_1 also departs from a normal profile. It appears that v_1 attains a maximum value (when $\eta = 1{\cdot}0$) at about $1{\cdot}17V_1$, and the secondary flow v_n a maximum value (when $\eta = 0{\cdot}7$) at about $0{\cdot}64V_1$. For the same value of cx the change in direction of flow through the boundary layer is shown in Fig. VIII. 9; the changes are seen to be considerable. Further illustrations may be found in the paper by Loos.

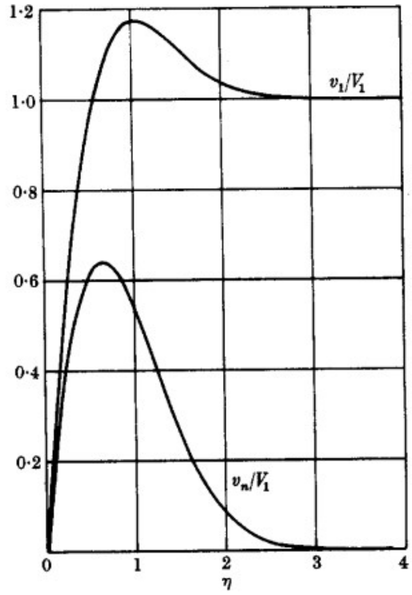

FIG. VIII. 8. Velocity components in the boundary layer on a flat plate with a parabolic main stream, for the values $\beta = 1$, $cx = 2$. The component v_n is the secondary flow in the layer.

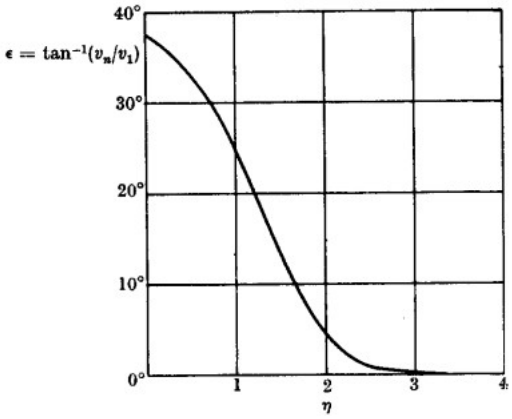

FIG. VIII. 9. Parabolic flow over a flat plate. ϵ is the deviation of the direction of flow in the boundary layer from an external streamline, for the values $\beta = 1$, $cx = 2$.

21. Flow near a stagnation point on a general curved surface

The discussion of the flow in the neighbourhood of a stagnation point on a general surface was given by Howarth (1951*c*). If A is a stagna-

Beware that Proposition 4.19 is false when the dimension of X is infinite and when $\overset{\circ}{A} = \emptyset$.

The proposition below gives a sufficient condition for a closed subset to be convex.

Proposition 4.20. *Let A be a closed subset with nonempty interior. If there is a supporting hyperplane for every point $a \in \partial A$, then A is convex.*

Proof. We leave it as an exercise (see Berger [8], Proposition 11.5.4). ☐

The condition that A has nonempty interior is crucial!

The proposition below characterizes closed convex sets in terms of (closed) half–spaces. It is another intuitive fact whose rigorous proof is nontrivial.

Proposition 4.21. *Let A be a nonempty closed and convex subset. Then, A is the intersection of all the closed half–spaces containing it.*

Proof. Let A' be the intersection of all the closed half–spaces containing A. It is immediately checked that A' is closed and convex and that $A \subseteq A'$. Assume that $A' \neq A$, and pick $a \in A' - A$. Then, we can apply Corollary 4.10 to $\{a\}$ and A and we find a hyperplane, H, strictly separating A and $\{a\}$; this shows that A belongs to one of the two half-spaces determined by H, yet a does not belong to the same half-space, contradicting the definition of A'. ☐

4.3 Polarity and Duality

Let $E = \mathbb{E}^n$ be the Euclidean affine space of dimension n. We will denote the origin $(0, \ldots, 0)$ in $\mathbb{E}^n$ by O. We know that the inner product on $E = \mathbb{E}^n$ induces a duality between E and its dual E^* (for example, see Chapter 6, Section 2 of Gallier [30]), namely, $u \mapsto \varphi_u$, where φ_u is the linear form defined by $\varphi_u(v) = u \cdot v$, for all $v \in E$. For geometric purposes, it is more convenient to recast this duality as a correspondence between points and hyperplanes, using the notion of polarity with respect to the unit sphere, $S^{n-1} = \{a \in \mathbb{E}^n \mid \|\mathbf{Oa}\| = 1\}$.

First, we need the following simple fact: For every hyperplane H not passing through O, there is a *unique* point h, so that

$$H = \{a \in \mathbb{E}^n \mid \mathbf{Oh} \cdot \mathbf{Oa} = 1\}.$$

Indeed, any hyperplane H in $\mathbb{E}^n$ is the null set of some equation of the form

$$\alpha_1 x_1 + \cdots + \alpha_n x_n = \beta,$$

and if $O \notin H$, then $\beta \neq 0$. Thus, any hyperplane H not passing through O is defined by an equation of the form

$$h_1 x_1 + \cdots + h_n x_n = 1,$$

if we set $h_i = \alpha_i/\beta$. So, if we let $h = (h_1, \ldots, h_n)$, we see that

$$H = \{a \in \mathbb{E}^n \mid \mathbf{Oh} \cdot \mathbf{Oa} = 1\},$$

as claimed. Now, assume that

$$H = \{a \in \mathbb{E}^n \mid \mathbf{Oh_1} \cdot \mathbf{Oa} = 1\} = \{a \in \mathbb{E}^n \mid \mathbf{Oh_2} \cdot \mathbf{Oa} = 1\}.$$

The functions $a \mapsto \mathbf{Oh_1} \cdot \mathbf{Oa} - 1$ and $a \mapsto \mathbf{Oh_2} \cdot \mathbf{Oa} - 1$ are two affine forms defining the same hyperplane, so there is a nonzero scalar λ so that

$$\mathbf{Oh_1} \cdot \mathbf{Oa} - 1 = \lambda(\mathbf{Oh_2} \cdot \mathbf{Oa} - 1) \quad \text{for all } a \in \mathbb{E}^n$$

(see Gallier [30], Chapter 2, Section 2.10). In particular, for $a = O$, we find that $\lambda = 1$, and so,

$$\mathbf{Oh_1} \cdot \mathbf{Oa} = \mathbf{Oh_2} \cdot \mathbf{Oa} \quad \text{for all } a,$$

which implies $h_1 = h_2$. This proves the uniqueness of h.

Using the above, we make the following definition:

Definition 4.2. Given any point $a \neq O$, the *polar hyperplane of a (w.r.t. S^{n-1})* or *dual of a* is the hyperplane $a^\dagger$ given by

$$a^\dagger = \{b \in \mathbb{E}^n \mid \mathbf{Oa} \cdot \mathbf{Ob} = 1\}.$$

Given a hyperplane H not containing O, the *pole of H (w.r.t S^{n-1})* or *dual of H* is the (unique) point $H^\dagger$ so that

$$H = \{a \in \mathbb{E}^n \mid \mathbf{OH}^\dagger \cdot \mathbf{Oa} = 1\}.$$

We often abbreviate polar hyperplane to polar. We immediately check that $a^{\dagger\dagger} = a$ and $H^{\dagger\dagger} = H$, so we obtain a bijective correspondence between $\mathbb{E}^n - \{O\}$ and the set of hyperplanes not passing through O.

When a is outside the sphere S^{n-1}, there is a nice geometric interpetation for the polar hyperplane $H = a^\dagger$. Indeed, in this case, since

$$H = a^\dagger = \{b \in \mathbb{E}^n \mid \mathbf{Oa} \cdot \mathbf{Ob} = 1\}$$

and $\|\mathbf{Oa}\| > 1$, the hyperplane H intersects S^{n-1} (along an $(n-2)$-dimensional sphere) and if b is any point on $H \cap S^{n-1}$, we claim that $\mathbf{Ob}$ and $\mathbf{ba}$ are orthogonal. This means that $H \cap S^{n-1}$ is the set of points on S^{n-1} where the lines through a and tangent to S^{n-1} touch S^{n-1} (they form a cone tangent to S^{n-1} with apex a). Indeed, as $\mathbf{Oa} = \mathbf{Ob} + \mathbf{ba}$ and $b \in H \cap S^{n-1}$ i.e., $\mathbf{Oa} \cdot \mathbf{Ob} = 1$ and $\|\mathbf{Ob}\|^2 = 1$, we get

$$1 = \mathbf{Oa} \cdot \mathbf{Ob} = (\mathbf{Ob} + \mathbf{ba}) \cdot \mathbf{Ob} = \|\mathbf{Ob}\|^2 + \mathbf{ba} \cdot \mathbf{Ob} = 1 + \mathbf{ba} \cdot \mathbf{Ob},$$

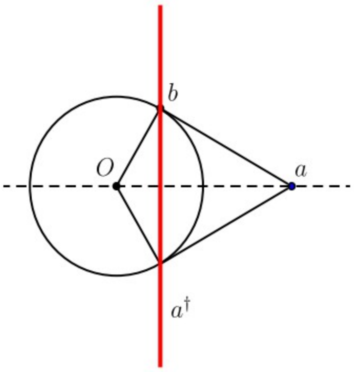

Figure 4.10: The polar, $a^\dagger$, of a point, a, outside the sphere S^{n-1}

which implies $\mathbf{ba} \cdot \mathbf{Ob} = 0$. When $a \in S^{n-1}$, the hyperplane $a^\dagger$ is tangent to S^{n-1} at a.

Also, observe that for any point $a \neq O$, and any hyperplane H not passing through O, if $a \in H$, then, $H^\dagger \in a^\dagger$, i.e, the pole $H^\dagger$ of H belongs to the polar $a^\dagger$ of a. Indeed, $H^\dagger$ is the unique point so that

$$H = \{b \in \mathbb{E}^n \mid \mathbf{OH}^\dagger \cdot \mathbf{Ob} = 1\}$$

and

$$a^\dagger = \{b \in \mathbb{E}^n \mid \mathbf{Oa} \cdot \mathbf{Ob} = 1\};$$

since $a \in H$, we have $\mathbf{OH}^\dagger \cdot \mathbf{Oa} = 1$, which shows that $H^\dagger \in a^\dagger$.

If $a = (a_1, \ldots, a_n)$, the equation of the polar hyperplane $a^\dagger$ is

$$a_1X_1 + \cdots + a_nX_n = 1.$$

Remark: As we noted, polarity in a Euclidean space suffers from the minor defect that the polar of the origin is undefined and, similarly, the pole of a hyperplane through the origin does not make sense. If we embed $\mathbb{E}^n$ into the projective space, $\mathbb{P}^n$, by adding a "hyperplane at infinity" (a copy of $\mathbb{P}^{n-1}$), thereby viewing $\mathbb{P}^n$ as the disjoint union $\mathbb{P}^n = \mathbb{E}^n \cup \mathbb{P}^{n-1}$, then the polarity correspondence can be defined everywhere. Indeed, the polar of the origin is the hyperplane at infinity ($\mathbb{P}^{n-1}$) and since $\mathbb{P}^{n-1}$ can be viewed as the set of hyperplanes through the origin in $\mathbb{E}^n$, the pole of a hyperplane through the origin is the corresponding "point at infinity" in $\mathbb{P}^{n-1}$.

Now, we would like to extend this correspondence to subsets of $\mathbb{E}^n$, in particular, to convex sets. Given a hyperplane, H, not containing O, we denote by H_- the closed half-space containing O.

Definition 4.3. Given any subset A of $\mathbb{E}^n$, the set

$$A^* = \{b \in \mathbb{E}^n \mid \mathbf{Oa} \cdot \mathbf{Ob} \leq 1, \quad \text{for all } a \in A\} = \bigcap_{\substack{a \in A \\ a \neq O}} (a^\dagger)_-,$$

is called the *polar dual* or *reciprocal* of A.

For simplicity of notation, we write $a^\dagger_-$ for $(a^\dagger)_-$. Observe that $\{O\}^* = \mathbb{E}^n$, so it is convenient to set $O^\dagger_- = \mathbb{E}^n$, even though $O^\dagger$ is undefined. By definition, A^* is convex even if A is not. Furthermore, note that

(1) $A \subseteq A^{**}$.

(2) If $A \subseteq B$, then $B^* \subseteq A^*$.

(3) If A is convex and closed, then $A^* = (\partial A)^*$.

It follows immediately from (1) and (2) that $A^{***} = A^*$. Also, if $B^n(r)$ is the (closed) ball of radius $r > 0$ and center O, it is obvious by definition that $B^n(r)^* = B^n(1/r)$.

In Figure 4.11, the polar dual of the polygon $(v_1, v_2, v_3, v_4, v_5)$ is the polygon shown in green. This polygon is cut out by the half-planes determined by the polars of the vertices $(v_1, v_2, v_3, v_4, v_5)$ and containing the center of the circle. These polar lines are all easy to determine by drawing for each vertex, v_i, the tangent lines to the circle and joining the contact points. The construction of the polar of v_3 is shown in detail.

Remark: We chose a different notation for polar hyperplanes and polars ($a^\dagger$ and $H^\dagger$) and polar duals (A^*), to avoid the potential confusion between $H^\dagger$ and H^*, where H is a hyperplane (or $a^\dagger$ and $\{a\}^*$, where a is a point). Indeed, they are completely different! For example, the polar dual of a hyperplane is either a line orthogonal to H through O, if $O \in H$, or a semi-infinite line through O and orthogonal to H whose endpoint is the pole, $H^\dagger$, of H, whereas, $H^\dagger$ is a single point! Ziegler ([67], Chapter 2) use the notation $A^\triangle$ instead of A^* for the polar dual of A.

We would like to investigate the duality induced by the operation $A \mapsto A^*$. Unfortunately, it is not always the case that $A^{**} = A$, but this is true when A is closed and convex, as shown in the following proposition:

Proposition 4.22. *Let A be any subset of $\mathbb{E}^n$ (with origin O).*

(i) If A is bounded, then $O \in \overset{\circ}{A^*}$; if $O \in \overset{\circ}{A}$, then A^* is bounded.

(ii) If A is a closed and convex subset containing O, then $A^{**} = A$.

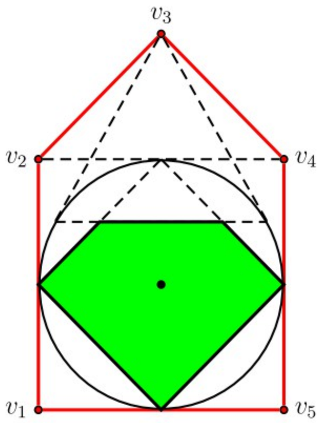

Figure 4.11: The polar dual of a polygon

Proof. (i) If A is bounded, then $A \subseteq B^n(r)$ for some $r > 0$ large enough. Then, $B^n(r)^* = B^n(1/r) \subseteq A^*$, so that $O \in \overset{\circ}{A^*}$. If $O \in \overset{\circ}{A}$, then $B^n(r) \subseteq A$ for some r small enough, so $A^* \subseteq B^n(r)^* = B^r(1/r)$ and A^* is bounded.

(ii) We always have $A \subseteq A^{**}$. We prove that if $b \notin A$, then $b \notin A^{**}$; this shows that $A^{**} \subseteq A$ and thus, $A = A^{**}$. Since A is closed and convex and $\{b\}$ is compact (and convex!), by Corollary 4.10, there is a hyperplane, H, strictly separating A and b and, in particular, $O \notin H$, as $O \in A$. If $h = H^\dagger$ is the pole of H, we have

$$\mathbf{Oh} \cdot \mathbf{Ob} > 1 \quad \text{and} \quad \mathbf{Oh} \cdot \mathbf{Oa} < 1, \quad \text{for all } a \in A$$

since $H_- = \{a \in \mathbb{E}^n \mid \mathbf{Oh} \cdot \mathbf{Oa} \leq 1\}$. This shows that $b \notin A^{**}$, since

$$\begin{aligned} A^{**} &= \{c \in \mathbb{E}^n \mid \mathbf{Od} \cdot \mathbf{Oc} \leq 1 \quad \text{for all } d \in A^*\} \\ &= \{c \in \mathbb{E}^n \mid (\forall d \in \mathbb{E}^n)(\text{if} \quad \mathbf{Od} \cdot \mathbf{Oa} \leq 1 \quad \text{for all } a \in A, \quad \text{then} \quad \mathbf{Od} \cdot \mathbf{Oc} \leq 1)\}, \end{aligned}$$

just let $c = b$ and $d = h$. ☐

Remark: For an arbitrary subset $A \subseteq \mathbb{E}^n$, it can be shown that $A^{**} = \overline{\mathrm{conv}(A \cup \{O\})}$, the topological closure of the convex hull of $A \cup \{O\}$.

Proposition 4.22 will play a key role in studying polytopes, but before doing this, we need one more proposition.

Proposition 4.23. *Let A be any closed convex subset of $\mathbb{E}^n$ such that $O \in \overset{\circ}{A}$. The polar hyperplanes of the points of the boundary of A constitute the set of supporting hyperplanes of A^*. Furthermore, for any $a \in \partial A$, the points of A^* where $H = a^\dagger$ is a supporting hyperplane of A^* are the poles of supporting hyperplanes of A at a.*

Proof. Since $O \in \overset{\circ}{A}$, we have $O \notin \partial A$, and so, for every $a \in \partial A$, the polar hyperplane $a^\dagger$ is well-defined. Pick any $a \in \partial A$ and let $H = a^\dagger$ be its polar hyperplane. By definition, $A^* \subseteq H_-$, the closed half-space determined by H and containing O. If T is any supporting hyperplane to A at a, as $a \in T$, we have $t = T^\dagger \in a^\dagger = H$. Furthermore, it is a simple exercise to prove that $t \in (T_-)^*$ (in fact, $(T_-)^*$ is the interval with endpoints O and t). Since $A \subseteq T_-$ (because T is a supporting hyperplane to A at a), we deduce that $t \in A^*$, and thus, H is a supporting hyperplane to A^* at t. By Proposition 4.22, as A is closed and convex, $A^{**} = A$; it follows that all supporting hyperplanes to A^* are indeed obtained this way. ☐

3.3 Geometric transformation

The geometric transformation of a curvilinear triangle into the standard triangle is usually based on the following point transformation expression

$$x = \sum_{j=0}^{N} \sum_{i=0}^{N-j} f_{\overline{pqr}} x_{\overline{pqr}}, \quad y = \sum_{j=0}^{N} \sum_{i=0}^{N-j} f_{\overline{pqr}} y_{\overline{pqr}} \tag{3.36}$$

where N is the order of transformation; $(x_{\overline{pqr}}, y_{\overline{pqr}})$ are the Cartesian coordinates of the transformation point in the curvilinear triangle, $f_{\overline{pqr}}$ are functions given in the similar form as Eq. (3.30). The three digit subscripts $(\overline{p}, \overline{q}, \overline{r}) = (N - j - i, i, j)$ are introduced to identify the nodes in the transformation. Unlike in finite element analysis where piecewise lower order isoparametric transformations suffice to provide accurate modelling of curved domain boundaries, a global transformation of the curvilinear triangle onto the standard triangle is sought herein. In principle, high order transformations in Eq. (3.36) should be able to model the curved boundary adequately. In practice, however, difficulty may arise since the transformation is rather sensitive to the location of inner transformation points as reported in Mitchell and Wait (1977), Zhong (2002). Ideally, the difficulty can be circumvented by employing transformations leaving out inner transformation points. Fortunately, this can be realized by adopting the "serendipity" idea in finite element method. Thus, a triangular serendipity transformation is developed as

$$x = \sum_{j=1}^{15} f_j x_j, \; y = \sum_{j=1}^{15} f_j y_j \tag{3.37}$$

to a space variable at a grid point is approximated by a weighted linear sum of the function values at grid points in a local small triangle containing the grid point in question rather than at all the grid points in the entire triangular domain. Analogous to Eq. (3.28), the expression of a partial derivative at a grid point (α, β, γ) is changed in

$$D_n \{f(\xi, \eta)\}_{\alpha\beta\gamma} = \sum_{j=0}^{m'} \sum_{i=0}^{m'-j} C^{(n)}_{\alpha\beta\gamma,pqr} f_{pqr}$$

$$\alpha + \beta + \gamma = m, \quad (p, q, r) = (m' - i - j, i, j) \tag{3.35}$$

where m'(¡m) is the number of the equal segments of an edge in a local triangle containing the grid point (α, β, γ). The weighting coefficients $C^{(n)}_{\alpha\beta\gamma,pqr}$ are also determined in the local triangle.

3.3 Geometric transformation

The geometric transformation of a curvilinear triangle into the standard triangle is usually based on the following point transformation expression

$$x = \sum_{j=0}^{N} \sum_{i=0}^{N-j} f_{\overline{pqr}} x_{\overline{pqr}}, \quad y = \sum_{j=0}^{N} \sum_{i=0}^{N-j} f_{\overline{pqr}} y_{\overline{pqr}} \tag{3.36}$$

where N is the order of transformation; $(x_{\overline{pqr}}, y_{\overline{pqr}})$ are the Cartesian coordinates of the transformation point in the curvilinear triangle, $f_{\overline{pqr}}$ are functions given in the similar form as Eq. (3.30). The three digit subscripts $(\overline{p}, \overline{q}, \overline{r}) = (N - j - i, i, j)$ are introduced to identify the nodes in the transformation. Unlike in finite element analysis where piecewise lower order isoparametric transformations suffice to provide accurate modelling of curved domain boundaries, a global transformation of the curvilinear triangle onto the standard triangle is sought herein. In principle, high order transformations in Eq. (3.36) should be able to model the curved boundary adequately. In practice, however, difficulty may arise since the transformation is rather sensitive to the location of inner transformation points as reported in Mitchell and Wait (1977), Zhong (2002). Ideally, the difficulty can be circumvented by employing transformations leaving out inner transformation points. Fortunately, this can be realized by adopting the "serendipity" idea in finite element method. Thus, a triangular serendipity transformation is developed as

$$x = \sum_{j=1}^{15} f_j x_j, \ y = \sum_{j=1}^{15} f_j y_j \tag{3.37}$$

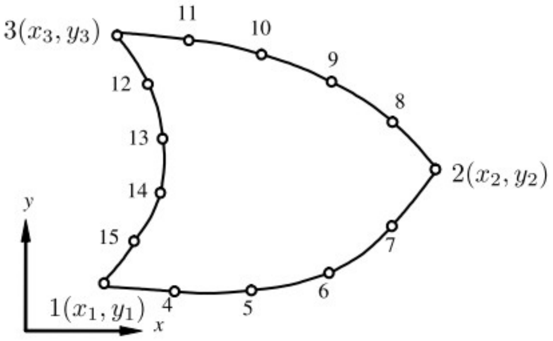

FIGURE 3.5: Points for quintic transformation of a curvilinear triangle.

It is well-known that the quintic order transformation often meets the accuracy requirement of geometric modelling. The shape functions associated with the fifteen nodes on the boundary of a curvilinear triangle (see Fig. 3.5) are given in Appendix A at the end of this chapter. It is worth noting that the high-order serendipity transformation for triangles is developed without the use of inner grid points, different from transformation for quadrilaterals. Thus, the present serendipity transformation enables the TDQM to deal with the problem on complex geometric domains.

The Jacobian matrix of the transformation is

$$[J] = \begin{bmatrix} x_\xi & y_\xi \\ x_\eta & y_\eta \end{bmatrix} \tag{3.38}$$

Its inverse matrix is given as follows:

$$\begin{bmatrix} \xi_x & \eta_x \\ \xi_y & \eta_y \end{bmatrix} = [J]^{-1} = \frac{1}{|J|} \begin{bmatrix} y_\eta & -y_\xi \\ -x_\eta & x_\xi \end{bmatrix}, \; |J| = x_\xi y_\eta - x_\eta y_\xi \tag{3.39}$$

where $|J|$ is the determinant of the Jacobian matrix. With the chain rule of differentiation, the second derivatives of a function in the two coordinate systems are related as

$$\begin{aligned}
\xi_{xx} &= |J|^{-3}\left[|J|\left(y_\eta y_{\xi\eta} - y_\xi y_{\eta\eta}\right) - y_\eta(y_\eta\left.|J|\right|_\xi - y_\xi\left.|J|\right|_\eta)\right] \\
\xi_{yy} &= |J|^{-3}\left[|J|\left(x_\eta x_{\xi\eta} - x_\xi x_{\eta\eta}\right) - x_\eta(x_\eta\left.|J|\right|_\xi - x_\xi\left.|J|\right|_\eta)\right] \\
\eta_{xx} &= |J|^{-3}\left[|J|\left(y_\xi y_{\xi\eta} - y_\eta y_{\xi\xi}\right) - y_\xi(y_\eta\left.|J|\right|_\xi - y_\xi\left.|J|\right|_\eta)\right] \\
\eta_{yy} &= |J|^{-3}\left[|J|\left(x_\xi x_{\xi\eta} - x_\eta x_{\xi\xi}\right) - x_\xi(x_\eta\left.|J|\right|_\xi - x_\xi\left.|J|\right|_\eta)\right] \qquad (3.40) \\
\xi_{xy} &= |J|^{-3}\left[|J|\left(x_\xi y_{\eta\eta} - x_\eta y_{\xi\eta}\right) - y_\eta(x_\eta\left.|J|\right|_\xi - x_\xi\left.|J|\right|_\eta)\right] \\
\eta_{xy} &= |J|^{-3}\left[|J|\left(x_\eta y_{\xi\xi} - x_\xi y_{\xi\eta}\right) - y_\xi(x_\eta\left.|J|\right|_\xi - x_\xi\left.|J|\right|_\eta)\right]
\end{aligned}$$

The above relations will be used later to transform the governing equations and boundary conditions from the $x - y$ domain into the $\xi - \eta$ domain.

3.4 Governing equations of Reissner-Mindlin plates on Pasternak foundation

The TMDQ coupled with geometric transformation is employed to deal with elliptic Reissner-Mindlin plates on Pasternak foundation under uniformly distributed load. Due to the double symmetry of the problem, a quadrant of the plate is considered in the analysis and a triangular serendipity transformation is adopted to map the quadrant into the computational domain−the unit isosceles right triangle.

3.4.1 Governing equations in physical coordinate system

For flexural analysis of Reissner plates on a Pasternak foundation, the differential equilibrium equations are given as follows (Kobayashi and Sonoda, 1989):

$$\frac{D}{2}\left((1-\nu)\nabla^2\psi_x + (1+\nu)\frac{\partial\phi}{\partial x}\right) + \kappa Gh\left(\frac{\partial w}{\partial x} - \psi_x\right) = 0, \qquad (3.41a)$$

$$\frac{D}{2}\left((1-\nu)\nabla^2\psi_y + (1+\nu)\frac{\partial\phi}{\partial y}\right) + \kappa Gh\left(\frac{\partial w}{\partial y} - \psi_y\right) = 0, \qquad (3.41b)$$

$$\kappa Gh\left(\nabla^2 w - \phi\right) + q - p = 0. \qquad (3.41c)$$

where

$$\phi = \frac{\partial\psi_x}{\partial x} + \frac{\partial\psi_y}{\partial y}, \qquad (3.42)$$

$$D = \frac{Eh^3}{12(1-\nu^2)} \tag{3.43}$$

$$p = k_f w - G_f \nabla^2 w \tag{3.44}$$

and $w(x,y)$ is the transverse deflection; $\psi_x(x,y)$ and $\psi_y(x,y)$ the rotations of the normal about $y-$axis and $x-$axis; D, E, G and ν the plate flexural rigidity, Young's modulus, shear modulus and Poisson's ratio, respectively; h is the plate thickness; $q(x,y)$ the surface load intensity; and ∇^2 is the Laplacian operator in Cartesian coordinates. The shear correction factor κ is taken to be $5/6$, p is the subgrade reaction intensity, k_f and G_f are the subgrade reaction coefficient and shear modulus of foundation, respectively. The force resultants are given by:

$$M_x = -D\left(\frac{\partial\psi_x}{\partial x} + \nu\frac{\partial\psi_y}{\partial y}\right) \tag{3.45}$$

$$M_y = -D\left(\nu\frac{\partial\psi_x}{\partial x} + \frac{\partial\psi_y}{\partial y}\right) \tag{3.46}$$

$$M_{xy} = -\frac{1-\nu}{2}D\left(\frac{\partial\psi_x}{\partial y} + \frac{\partial\psi_y}{\partial x}\right) \tag{3.47}$$

$$Q_x = \kappa Gh\left(\frac{\partial w}{\partial x} - \psi_x\right) \tag{3.48}$$

$$Q_y = \kappa Gh\left(\frac{\partial w}{\partial y} - \psi_y\right) \tag{3.49}$$

where M_x, M_y and M_{xy} are the moments and twisting moment; Q_x and Q_y the shear forces.

3.4.2 Governing equations in the standard triangle

By using the geometric coordinate mapping relations, the governing equations in Eqs. (3.41) in the physical domain $x-y$ can be transformed into the computational domain $\xi-\eta$ as follows:

$$[K]_{3\times 18}\begin{bmatrix} [\partial]_{6\times 1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & [\partial]_{6\times 1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & [\partial]_{6\times 1} \end{bmatrix}\begin{Bmatrix} \psi_x \\ \psi_y \\ w \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ q/D \end{Bmatrix} \tag{3.50}$$

where

$$[\partial]_{6\times 1} = \left\{ \tfrac{\partial^2}{\partial\xi^2} \; \tfrac{\partial^2}{\partial\xi\partial\eta} \; \tfrac{\partial^2}{\partial\eta^2} \; \tfrac{\partial}{\partial\xi} \; \tfrac{\partial}{\partial\eta} \; 1 \right\}^T \tag{3.51}$$

is a differential operator vector and the entries in $[K]_{3\times 18}$ are given in Appendix B. With the TDQ approximation, Eq. (3.50) will be recast into a set of algebraic equations at any inner grid point in the standard triangular domain.

3.4.3 Boundary conditions

To impose boundary conditions, the following transformations of displacement components and internal forces are used

$$\psi_n = n_1\psi_x + n_2\psi_y;\ \psi_s = -n_2\psi_x + n_1\psi_y. \tag{3.52}$$

$$\begin{aligned} M_n &= n_1^2 M_x + 2n_1 n_2 M_{xy} + n_2^2 M_y;\\ M_{ns} &= n_1 n_2(M_y - M_x) + (n_1^2 - n_2^2)M_{xy};\\ Q_n &= n_1 Q_x + n_2 Q_y. \end{aligned} \tag{3.53}$$

where (n_1, n_2) are the directional cosines of a unit normal at an arbitrary point on the boundary of the physical domain (see Fig. 3.6). Two typical boundary conditions are considered in this chapter, the clamped and the simply supported boundary conditions, which are mathematically expressed as follows:

(a) *Clamped (C)*

$$w = 0, \quad \psi_n = 0, \quad \psi_s = 0; \tag{3.54}$$

(b) *Simply supported (S):*

$$(i)\ \mathrm{Type\,I(S)} : \mathrm{w} = 0, \mathrm{M_n} = 0, \psi_\mathrm{s} = 0; \tag{3.55}$$

$$(ii)\ \mathrm{Type\,II(S')} : \mathrm{w} = 0, \mathrm{M_n} = 0, \mathrm{M_{ns}} = 0. \tag{3.56}$$

In Eqs. (3.53), (3.55) and (3.56), M_n, M_{ns} are the bending and twisting moments on the edge of the plate respectively; ψ_n and ψ_s are the rotations of the mid-plane in the normal plane, nz, and in the tangent plane, sz, to the boundary; the subscripts n and s represent the normal and tangent directions at a point on the boundary, respectively. Equation (3.55) is designated for plates with simply supported boundary conditions.

3.4.4 Symmetry consideration

In the present case, all elliptic plates on Pasternak foundation are assumed subjected to uniformly distributed load. Consequently, the flexural deformation symmetry of plates can be employed to reduce the computational effort

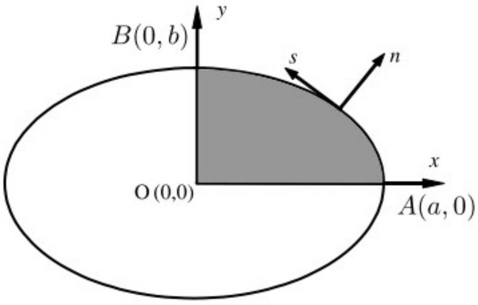

FIGURE 3.6: A quadrant of an elliptic plate.

and increase the computational accuracy. The deformation symmetry conditions of the Reissner/Mindlin plate about a symmetric plane are expressed as

$$\psi_n = 0, \quad \frac{\partial \psi_s}{\partial n} = 0, \quad \frac{\partial w}{\partial n} = 0 \tag{3.57}$$

By combining the boundary conditions and symmetric conditions at the boundary nodes with Eqs. (3.50) at all inner grid points, a set of algebraic equations with at most $3M$ unknowns is established.

Example 3.3 *Plates*

For clarity of presentation, the following normalized quantities are introduced

$$r_0 = \frac{rD}{qb^4}, w_0 = \frac{wD}{qb^4}, M_{r0} = \frac{M_r}{qb^2}, M_{x0} = \frac{M_x}{qb^2}, M_{y0} = \frac{M_y}{qb^2} \tag{3.58}$$

The following parameters are taken in all computations: flexural rigidity $D = 10^6$kNm, Poisson's ratio $\nu = 0.3$, subgrade reaction coefficient $k_f = 2 \times 10^4$kN/m^3. The foundation shear modulus is taken as $G_f = 3 \times 10^4$kN/m unless otherwise stated.

(a) Convergence study

First a circular plate resting on a Pasternak foundation under uniformly distributed load is studied to examine the convergence of the present method. The thickness to width ratio is taken as $h/b = 0.01$. Both simply supported and clamped boundary conditions are considered and the results are compared with the analytical ones (Yu, 1957).

In view of the double symmetry of the plate, a quadrant of the plate is analyzed. The central deflection and the central moment of circular plates are given in Table 3.2. It is found that results with relative error less than

TABLE 3.2: Central deflection and central moment of thin circular plates on a Pasternak foundation with clamped or simply supported edge

Analytic[15]		0.004648	0.01791	0.005771	0.01050

1% can be achieved when the global approximation order m is increased to 18. It is seen clearly that the errors are reduced with the increase of the global approximation order. It is worth mentioning that the localized TDQ ($m' = 9$) is implemented in all computations for the sake of consistency and coding simplicity. As reported by Zhong et al., (2003), the loss of efficiency or accuracy is insignificant as long as the local approximation order is higher than 5. On the other hand, the localized implementation leads to remarkable numerical stability.

The radial variation of deflection and the radial variation of bending moment are shown in Figs. 3.7 and 3.8. The shear modulus of foundation are taken as the following different values $G_f = 0.3 \times 10^4$kN/m,2.82843×10^5kN/m and 3×10^6 kN/m in order to investigate the effects of the shear modulus on the behavior of plates. Excellent agreement with the available analytical solution (Yu, 1957) is achieved for both simply supported and clamped plates resting on Pasternak foundation as demonstrated in Figs. 3.7 and 3.8.

(b) Results for clamped and simply supported elliptic plates

To investigate the effect of thickness-to-width ratio, the central deflection and moments for clamped and simply supported elliptic plates are shown in Tables 3.3 and 3.4. Also listed is the least order of global approximation m from which results with four stabilized digits are obtained. It is clearly seen that more grid points are needed to attain convergent results for thin

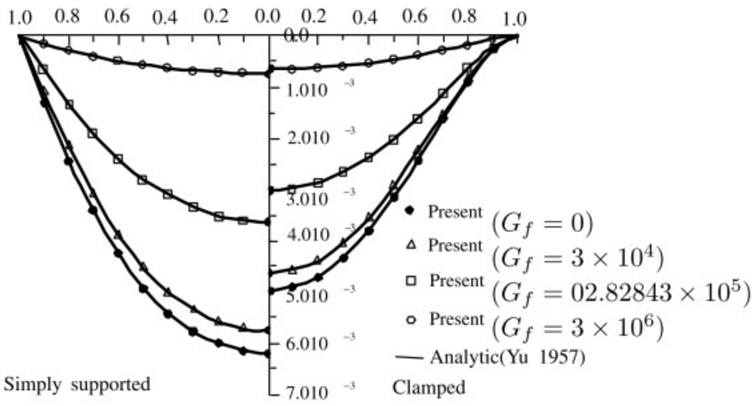

FIGURE 3.7: Deflections of the circular plate.

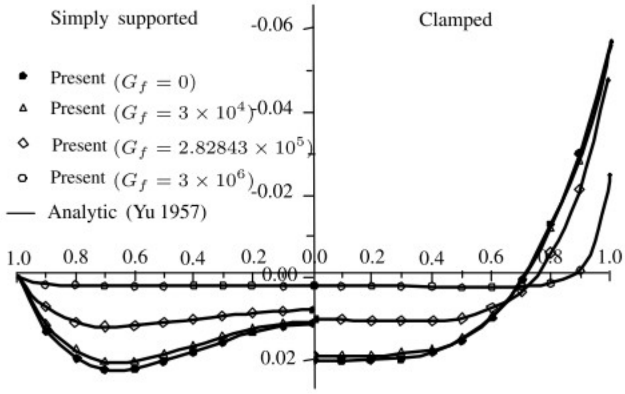

FIGURE 3.8: Radial bending moments of the circular plate.

plates. It is worth mentioning that $m + 1$ merely denotes the number of grid points on an edge of the triangular domain to furnish convergent results with four stabilized digits and a localized TDQ approximation of order $m' = 9$ is adopted in all cases. For clamped elliptic plates, the normalized deflection and the two moments decrease with the increase of thickness-to-width ratio except for circular plates. For simply supported plates, the normalized central deflection decreases with the increase of thickness-to-width ratio while the two moments at the center of elliptic plates show the reverse trend. It should be pointed out that the relative extremes of moments M_x and M_y may not occur at the center of the elliptic plates even for circular plates in the presence of elastic foundation, as shown in Fig. 3.8.

The effect of ellipticity on the deflection and moments is also investigated. Moderately thick elliptic plates ($h/b = 0.1$) with clamped or simply supported edges resting on Pasternak foundations are studied for plates with ellipticity $a/b = 1.5$, 2.0, 2.5, 3.0 and 5.0. The distributions of normalized deflection and moments along the major and the minor axes are plotted for simply supported and clamped boundary conditions (see Figs. 3.9–3.14). It is noted that the convergence rate drops with the increase of ellipticity a/b of plates. In addition, the convergence rate for simply supported elliptic plates is somewhat slower than that for fully clamped elliptic plates and the convergence rate of bending moments is slower than that of the deflection of plates. In the case of elliptic plates with $a/b = 5.0$, four significant digits are stabilized at $m = 20$ and $m = 27$ for the deflection and bending moments at the center of fully clamped elliptic plates, respectively; whereas $m = 22$ and $m = 28$ are required to keep the same level of convergence of the deflection and bending moments at the center of the simply supported elliptic plates.

3.5 Conclusions

The TDQM introduced in this chapter overcomes the difficulties associated with the direct DQ method in dealing with problems on a triangular domain. Transformation of the physical domain is avoided, resulting in simple algebraic equations. Singularity does not appear in the process of the TDQ analysis. In the two examples provided, excellent agreement with the theoretical values is achieved with rather fewer grid points, indicating that the present method is an attractive new numerical tool. In view of the great geometric flexibility of triangles, various geometric domains may be decomposed into a number of triangles. Therefore, the potential applications of the present method lie in the incorporation of domain decomposition technique into the TDQM.

Herein an effort has been made to extend the TDQM to problems with arbitrary geometric domains. A triangular serendipity transformation with

no inner points is introduced. Consequently, the sensitivity associated with the usual geometric transformations with inner points is removed. Although the triangular serendipity transformation of any order can be developed in the same manner, the quintic order transformation is accurate enough in all cases. Static flexural analysis of elliptic Reissner-Mindlin plates resting on a Pasternak foundation is investigated using the TDQM. Parametric study of elliptic plates with various aspect ratios is performed. The excellent agreement with the available analytical solution for circular plates verifies the effectiveness of the present technique.

Of course, the present strategy may only be applied successfully to the problems with simple and relatively regular geometry. However, it should be pointed out that the geometric transformation is not the only way to make TDQM applicable to problems with curvilinear boundaries. By using the localized TDQM (Zhong et al., 2003), the TDQM can be applied directly to the problems with curvilinear boundaries without the use of geometric transformation. In view of this, the TDQM is more attractive in the analysis of problems with irregular geometric domain.

Appendix A

Although the selection of transformation points on the boundary of a curvilinear domain is a simple matter, uniform distribution is desirable to avoid severe distortion. The functions for the transformation (see Fig. 3.5) are given as

$$f_4 = \frac{3125}{24} L_1 L_2 (L_1 - \frac{1}{5})(L_1 - \frac{2}{5})(L_1 - \frac{3}{5}), \tag{A1}$$

$$f_5 = -\frac{3125}{12} L_1 L_2 (L_1 - \frac{1}{5})(L_1 - \frac{2}{5})(L_1 - \frac{4}{5}) \tag{A2}$$

$$f_6 = \frac{3125}{12} L_1 L_2 (L_1 - \frac{1}{5})(L_1 - \frac{3}{5})(L_1 - \frac{4}{5}) \tag{A3}$$

$$f_7 = -\frac{3125}{24} L_1 L_2 (L_1 - \frac{2}{5})(L_1 - \frac{3}{5})(L_1 - \frac{4}{5}) \tag{A4}$$

$$f_8 = \frac{3125}{24} L_2 L_3 (L_2 - \frac{1}{5})(L_2 - \frac{2}{5})(L_2 - \frac{3}{5}) \tag{A5}$$

$$f_9 = -\frac{3125}{12} L_2 L_3 (L_2 - \frac{1}{5})(L_2 - \frac{2}{5})(L_2 - \frac{4}{5}) \tag{A6}$$

$$f_{10} = \frac{3125}{12} L_2 L_3 (L_2 - \frac{1}{5})(L_2 - \frac{3}{5})(L_2 - \frac{4}{5}) \tag{A7}$$

$$f_{11} = -\frac{3125}{24} L_2 L_3 (L_2 - \frac{2}{5})(L_2 - \frac{3}{5})(L_2 - \frac{4}{5}) \tag{A8}$$

$$f_{12} = \frac{3125}{24} L_3 L_1 (L_3 - \frac{1}{5})(L_3 - \frac{2}{5})(L_3 - \frac{3}{5}) \tag{A9}$$

$$f_{13} = -\frac{3125}{12} L_3 L_1 (L_3 - \frac{1}{5})(L_3 - \frac{2}{5})(L_3 - \frac{4}{5}) \tag{A10}$$

$$f_{14} = \frac{3125}{12} L_3 L_1 (L_3 - \frac{1}{5})(L_3 - \frac{3}{5})(L_3 - \frac{4}{5}) \tag{A11}$$

$$f_{15} = -\frac{3125}{24} L_3 L_1 (L_3 - \frac{2}{5})(L_3 - \frac{3}{5})(L_3 - \frac{4}{5}) \tag{A12}$$

$$f_1 = L_1 - \frac{4}{5}(f_4 + f_{15}) - \frac{3}{5}(f_5 + f_{14}) - \frac{2}{5}(f_6 + f_{13}) - \frac{1}{5}(f_7 + f_{12}) \tag{A13}$$

$$f_2 = L_2 - \frac{4}{5}(f_7 + f_8) - \frac{3}{5}(f_6 + f_9) - \frac{2}{5}(f_5 + f_{10}) - \frac{1}{5}(f_4 + f_{11}) \tag{A14}$$

$$f_3 = L_3 - \frac{4}{5}(f_{11} + f_{12}) - \frac{3}{5}(f_{10} + f_{13}) - \frac{2}{5}(f_9 + f_{14}) - \frac{1}{5}(f_8 + f_{15}) \tag{A15}$$

where $L_1 = 1 - \xi - \eta$, $L_2 = \xi$ and $L_3 = \eta$ are the three area coordinates of an arbitrary point in the standard triangle.

Appendix B

The entries in matrix $[K]$ of Eq. (3.50) are given as

$$\begin{aligned}
&K_{1,1} = \xi_x^2 + c_1\xi_y^2, K_{1,2} = 2\xi_x\eta_x + 2c_1\xi_y\eta_y, K_{1,3} = \eta_x^2 + c_1\eta_y^2,\\
&K_{1,4} = \xi_{xx} + c_1\xi_{yy}, K_{1,5} = \eta_{xx} + c_1\eta_{yy}, K_{1,6} = -c_3,\\
&K_{1,7} = c_2\xi_x\xi_y, K_{1,8} = c_2\left(\xi_x\eta_y + \xi_y\eta_x\right), K_{1,9} = c_2\eta_x\eta_y,\\
&K_{1,10} = c_2\xi_{xy}, K_{1,11} = c_2\eta_{xy}, K_{1,12} = K_{1,13} = K_{1,14} = K_{1,15} = 0,\\
&K_{1,16} = c_3\xi_x, K_{1,17} = c_3\eta_x, K_{1,18} = 0,
\end{aligned} \tag{B1}$$

$$\begin{aligned}
&K_{2,1} = c_2\xi_x\xi_y, K_{2,2} = c_2\left(\xi_x\eta_y + \xi_y\eta_x\right), K_{2,3} = c_2\eta_x\eta_y, K_{2,4} = c_2\xi_{xy},\\
&K_{2,5} = c_2\eta_{xy}, K_{2,6} = 0, K_{2,7} = c_1\xi_x^2 + \xi_y^2, K_{2,8} = 2(c_1\xi_x\eta_x + \xi_y\eta_y),\\
&K_{2,9} = c_1\eta_x^2 + \eta_y^2, K_{2,10} = c_1\xi_{xx} + \xi_{yy}, K_{2,11} = c_1\eta_{xx} + \eta_{yy}, K_{2,12} = -c_3,\\
&K_{2,13} = K_{2,14} = K_{2,15} = 0, K_{2,16} = c_3\xi_y, K_{2,17} = c_3\eta_y, K_{2,18} = 0,
\end{aligned} \tag{B2}$$

$$\begin{aligned}
&K_{3,1} = K_{3,2} = K_{3,3} = K_{3,6} = 0, K_{3,4} = c_3\xi_x, K_{3,5} = c_3\eta_x,\\
&K_{3,7} = K_{3,8} = K_{3,9} = K_{3,12} = 0, K_{3,10} = c_3\xi_y, K_{3,11} = c_3\eta_y,\\
&K_{3,13} = -\left(c_3 + \tfrac{G_f}{D}\right)\left(\xi_x^2 + \xi_y^2\right), K_{3,14} = -2\left(c_3 + \tfrac{G_f}{D}\right)\left(\xi_x\eta_x + \xi_y\eta_y\right),\\
&K_{3,15} = -\left(c_3 + \tfrac{G_f}{D}\right)\left(\eta_x^2 + \eta_y^2\right), K_{3,16} = -\left(c_3 + \tfrac{G_f}{D}\right)\left(\xi_{xx} + \xi_{yy}\right),\\
&K_{3,17} = -\left(c_3 + \tfrac{G_f}{D}\right)\left(\eta_{xx} + \eta_{yy}\right), K_{3,18} = -\left(c_3 + \tfrac{G_f}{D}\right)\tfrac{k_f}{D}
\end{aligned} \tag{B3}$$

with

$$c_1 = \frac{1-\nu}{2}; \quad c_2 = \frac{1+\nu}{2}; \quad c_3 = \frac{6\kappa(1-\nu)}{h^2} \tag{B4}$$

Chapter 8

Mathematical Compendium

The mathematical compendium consists of four independent sections dealing in detail with specific mathematics used in the main text. It is provided as an aid to the readers who may not be familiar with these mathematical applications and thus may find it difficult to collect and study the necessary literature.

8.1 Gauss elimination

In linear algebra, Gauss elimination, named after German mathematician and scientist Carl Friedrich Gauss (1777-1855), is one of the most important numerical methods for solving a system of linear equations. The process of Gauss elimination consists of two steps, i.e., Forward and Backward eliminations. First, Forward elimination is performed to reduce a given system of linear equations to triangular forms, or lead to a degenerate equation with no solution, indicating that the system has no solution. This can be achieved by using elementary row operation. In triangular form, the solutions of the system can than be determined by back-substitution (Backward elimination).

A system of linear equations with n unknowns $x_1, x_2, \cdots, x_n$ is a set of n equations of the form

$$\begin{cases} a_{11}x_1 + a_{12}x_2 + \ldots + a_{1n}x_n = b_1 \\ a_{21}x_1 + a_{22}x_2 + \ldots + a_{2n}x_n = b_2 \\ \vdots \\ a_{n1}x_1 + a_{n2}x_2 + \ldots + a_{nn}x_n = b_n \end{cases} \tag{8.1}$$

In matrix form, we have

$$\mathbf{Ax} = \mathbf{b} \tag{8.2}$$

with

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} \quad \mathbf{b} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{bmatrix} \tag{8.3}$$

The system is homogeneous if all the b_i are zero, otherwise it is non-homogeneous.

Gauss elimination consists of combining the coefficient matrix **A** with the right-hand side b to the "augmented" $(n, n+1)$ matrix

$$\begin{bmatrix} \mathbf{A}\ \mathbf{b} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} & b_1 \\ a_{21} & a_{22} & \cdots & a_{2n} & b_2 \\ \vdots & \vdots & & \vdots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} & b_n \end{bmatrix} \tag{8.4}$$

A sequence of elementary row operations is then applied to this matrix so as to transform the coefficient part to upper triangular form:

(1) multiply a row by a non-zero real number c,

(2) swap two rows,

(3) add c times one row to another one.

$\begin{bmatrix} \mathbf{A}\ \mathbf{b} \end{bmatrix}$ will then have taken the following form:

$$\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} & b_1 \\ 0 & a'_{22} & \cdots & a'_{2n} & b'_2 \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & \cdots & a'_{nn} & b'_n \end{bmatrix} \tag{8.5}$$

and the original equation is transformed to $\mathbf{Rx} = \mathbf{c}$ with an upper triangular matrix R, from which the unknowns x can be found by back substitution.

Assume we have transformed the first column, and we want to continue the elimination with the following matrix

$$\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} & b_1 \\ 0 & a'_{22} & \cdots & a'_{2n} & b'_2 \\ 0 & a'_{32} & \ldots & a'_{3n} & b'_3 \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & a'_{n2} & \cdots & a'_{nn} & b'_n \end{bmatrix} \tag{8.6}$$

To zero a'_{32} we want to divide the second row by the "pivot" a'_{22}, multiply it with a'_{32} and subtract it from the third row. If the pivot is zero we have to swap two rows. This procedure frequently breaks down, not only for ill-conditioned matrices. Therefore, most programs perform "partial pivoting", i.e. they swap with the row that has the maximum absolute value of that column.

"Complete pivoting", always putting the absolute biggest element of the whole matrix into the right position, implying reordering of rows and columns, is normally not necessary.

Another variant is Gauss-Jordan elimination, which is closely related to Gaussian elimination. With the same elementary operations it does not only zero the elements below the diagonal but also above. The resulting augmented matrix will then look like:

$$\begin{bmatrix} a_{11} & 0 & \cdots 0 & b_1 \\ 0 & a'_{22} & \cdots 0 & b'_2 \\ & & & \\ 0 & 0 & \cdots a'_{nn} & b'_n \end{bmatrix} \tag{8.7}$$

Therefore, back substitution is not necessary and the values of the unknowns can be computed directly.

Example 8.1 *A system of linear equations with three unknowns*

In the following, a simple system of linear equations with three unknowns is considered to demonstrate the procedure of Gauss elimination. The given system is written as

$$\begin{cases} x_1 & +2x_2 & +2x_3 & = & 2 & L_1 \\ x_1 & +3x_2 & -2x_3 & = & -1 & L_2 \\ 3x_1 & +5x_2 & +8x_3 & = & 8 & L_3 \end{cases} \tag{8.8}$$

with

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 2 \\ 1 & 3 & -2 \\ 3 & 5 & 8 \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} 2 \\ -1 \\ 8 \end{bmatrix} \tag{8.9}$$

First, we eliminate x_2 in the lines L_2 and L_3:

$$\begin{cases} x_1 & + & 2x_2 & + & 2x_3 & = & 2 & L_1 \\ & & x_2 & - & 4x_3 & = & -3 & L_2 \leftarrow L_2 - L_1 \\ & & -x_2 & + & 2x_3 & = & 2 & L_3 \leftarrow L_3 - 3L_1 \end{cases} \tag{8.10}$$

Next, x_1 is eliminated in the line L_3 as

$$\begin{cases} x_1 & + & 2x_2 & + & 2x_3 & = & 2 & L_1 \\ & & x_2 & - & 4x_3 & = & -3 & L_2 \\ & & & - & 2x_3 & = & -1 & L_3 \leftarrow L_3 + L_2 \end{cases} \tag{8.11}$$

Now it is obvious that the coefficient matrix A is reduced in triangular form as

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 2 \\ 0 & 1 & -4 \\ 0 & 0 & -2 \end{bmatrix} \tag{8.12}$$

The first step of Gauss elimination−Forward elimination, is completed. The second step, backward elimination, aims to solve the triangular form of linear equations in reverse order. It can be readily seen from the line L_3 that

$$x_3 = \frac{1}{2} \qquad (L_3) \tag{8.13}$$

Then back-substituting $x_3 = \frac{1}{2}$ into the line L_2, we have

$$x_2 = -1 \qquad (L_2) \tag{8.14}$$

Finally, $x_3 = 1/2$ and $x_2 = -1$ can be substituted into line L_1 for the solution of x_1 as

$$x_1 = 3 \qquad (L_1) \tag{8.15}$$

Thus the solutions of the system are determined.

For a system of linear equations with n unknowns solved by Gauss elimination, approximately $2n^3/3$ operations are required. Therefore, Gauss elimination requires $O(n^3)$ order of computation. The algorithm can be coded by any computer language and applied for systems with thousands of equations and unknowns. However, for millions of equations, the algorithm is computationally expensive. In this case, these large systems are generally solved by interactive methods instead (Kreyszig, 1999; Press et al., 1986).

8.2 Successive over-relaxation (SOR) method

There are two approaches that can be used to determine the solutions of a linear system, i.e., direct methods and iterative methods. Direct methods, such as Gauss elimination method, aim to solve a system of linear equations by performing a finite number of operations to obtain the exact solutions. Direct methods are effective for a relatively small system of equations. However, the intensive computation prohibits the direct methods from solving large systems. In this case, we should resort to iterative methods, a very effective one of which is Successive Over-Relaxation (SOR) iterative method.

Suppose a system of linear equations is of the form

$$\mathbf{Ax} = \mathbf{b} \tag{8.16}$$

The coefficient matrix A can be expressed as the sum of the diagonal, lower triangular, and upper triangular matrices denoted by D, L and U, respectively. The three matrices can be expressed as

$$\mathbf{L} = \begin{pmatrix} 0 & 0 & \cdots & 0 \\ l_{21} & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ l_{n1} & l_{n2} & \cdots & 0 \end{pmatrix}, \quad \mathbf{D} = \begin{pmatrix} d_{11} & 0 & \cdots & 0 \\ 0 & d_{22} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & d_{nn} \end{pmatrix}, \quad \mathbf{U} = \begin{pmatrix} 0 & u_{12} & \cdots & u_{1n} \\ 0 & 0 & \cdots & u_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 \end{pmatrix}$$

(5 % 5 / 0+ :

The equations above (except the last equation) are vector equations. Denoting the i-th component of $\mathbf{k}$ by k_{ij} (j = 1, 2, 3, 4) and denoting the i-th component of $\mathbf{y}_k$ by y_{ik} (k = 1, 2, 3,...), we obtain by equating components

$$\begin{aligned}
&k_{i1} = hf_i(t^n, y_1^n, \cdots, y_m^n) \\
&k_{i2} = hf_i(t^n + \frac{h}{2}, y_1^n + \frac{a_{11}}{2}, \cdots, y_m^n + \frac{a_{m1}}{2}) \\
&k_{i3} = hf_i(t^n + \frac{h}{2}, y_1^n + \frac{a_{12}}{2}, \cdots, y_m^n + \frac{a_{m2}}{2}) \quad i = 1, 2, \cdots, m \\
&k_{i4} = hf_i(t^n + h, y_1^n + a_{13}, \cdots, y_m^n + a_{m3}) \\
&y_i^{n+1} = y_i^n + \frac{1}{6}(k_{i1} + 2k_{i2} + 2k_{i3} + k_{i4}) + O(h^5) \\
&t^{n+1} = t^n + h
\end{aligned} \tag{8.33}$$

8.5 Complex analysis

8.5.1 Complex variable

Complex analysis, traditionally known as the theory of functions of a complex variable, is the branch of mathematics investigating functions of complex numbers. It is useful in many branches of mathematics, including number theory and applied mathematics, and in physics.

Complex analysis is particularly concerned with the analytic functions of complex variables, which are commonly divided into two main classes: the holomorphic functions and the meromorphic functions. Because the separable real and imaginary parts of any analytic function must satisfy Laplace's equation, complex analysis is widely applicable to two-dimensional problems in physics.

A complex function is a function in which the independent variable and the dependent variable are both complex numbers. More precisely, a complex function is a function whose domain Ω is a subset of the complex plane and whose range is also a subset of the complex plane.

For any complex function, both the independent variable and the dependent variable may be separated into real and imaginary parts:

$$z = x + iy \tag{8.34a}$$

$$w = f(z) = u(z) + iv(z) \tag{8.34b}$$

where $x, y \in \mathbf{R}$ and $u(z)$ and $v(z)$ are real-valued functions. In other words, the components of the function $f(z)$

$$u = u(x, y) \tag{8.35a}$$

$$v = v(x, y) \tag{8.35b}$$

can be interpreted as real valued functions of the two real variables, x and y. The basic concepts of complex analysis are often introduced by extending the elementary real functions (e.g., exponentials, logarithms, and trigonometric functions) into the complex domain.

Just as in real analysis, a "smooth" complex function $w = f(z)$ may have a derivative at a particular point in its domain Ω. In fact, the definition of the derivative

$$f'(z) = \lim_{h \to 0} \frac{f(z+h) - f(z)}{h} \tag{8.36}$$

is analogous to the real case but with one very important difference. In real analysis, the limit can only be approached by moving along the one-dimensional number line. In complex analysis, the limit can be approached from any direction in the two-dimensional complex plane. (The claim that "in real analysis, the limit can only be approached by moving along the one dimensional number line" should not be confused with directional derivatives. It may be explained that in directional derivatives, one still moves along the one dimensional x line but it can be in "discrete" units; that is, if one follows $y = x^2$ curve, that does not mean that one is moving on the plane (instead of the one dimensional x line) but means that one is approaching in steps of discrete units.)

If this limit, the derivative, exists for every point$z$in Ω, then$f(z)$ is said to be differentiable on Ω. It can be shown that any differentiable $f(z)$ is analytic. This is a much more powerful result than the analogous theorem that can be proved for real-valued functions of real numbers. In the calculus of real numbers, we can construct a function $f(x)$ that has a first derivative everywhere, but for which the second derivative does not exist at one or more points in the function's domain. But in the complex plane, if a function$f(z)$ is differentiable in a neighborhood it must also be infinitely differentiable in that neighborhood.

By applying the methods of vector calculus to compute the partial derivatives of the two real functions $u(x, y)$ and $v(x, y)$ into which $f(z)$ can be decomposed, and by considering two paths leading to a point z in Ω, it can be shown that the existence of derivative implies

$$f'(z) = \frac{\partial u}{\partial x} + i\frac{\partial v}{\partial x} = \frac{\partial v}{\partial y} - i\frac{\partial u}{\partial y} \tag{8.37}$$

Equating the real and imaginary parts of these two expressions we obtain the traditional formulation of the Cauchy-Riemann Equations:

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \text{and} \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x} \tag{8.38}$$

or, in another common notation

$$u_x = v_y, \text{and} \quad u_{\mathrm{y}} = -v_{\mathrm{x}} \tag{8.39}$$

By differentiating this system of two partial differential equations first with respect to x, and then with respect to y, we can easily show that

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0, \text{and} \quad \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} = 0 \tag{8.40}$$

In other words, the real and imaginary parts of a differentiable function of a complex variable are harmonic functions because they satisfy Laplace's equation.

8.5.2 Holomorphic functions

Holomorphic functions are complex functions defined on an open subset of the complex plane which are differentiable. Complex differentiability has much stronger consequences than usual (real) differentiability. For instance, holomorphic functions are infinitely differentiable, a fact that is far from true for real differentiable functions. Most elementary functions, including the exponential function, the trigonometric functions, and all polynomial functions, are holomorphic.

8.5.3 Meromorphic functions

A meromorphic function on an open subset D of the complex plane is a function that is holomorphic on all D except a set of isolated points, which are poles for the function.

Every meromorphic function on D can be expressed as the ratio between two holomorphic functions (with the denominator not constant 0) defined on D: the poles then occur at the zeroes of the denominator. The Gamma function is meromorphic in the whole complex plane.

Intuitively then, a meromorphic function is a ratio of two nice (holomorphic) functions. Such a function will still be "nice", except at the points where the denominator of the fraction is zero, when the value of the function will be infinite.

From an algebraic point of view, if D is connected, then the set of meromorphic functions is the field of fractions of the integral domain of the set of holomorphic functions. This is analogous to the relationship between **Q**, the rational numbers, and **Z**, the integers.

As this particle moves about, its state properties will be understood to be the same as the local state properties of the continuum.

1.3 INERTIAL COORDINATE FRAMES

It is sufficient to consider Euclidean space to describe the laws of fluid motion. A Euclidean space is a curvature-free space in which a set of rectangular Cartesian coordinates can always be introduced on a global scale. One can introduce any other system of coordinates in this space without altering the basic nature of the space itself. These ideas form a logical environment for understanding coordinate transformation in Newtonian mechanics.

In fluid dynamics, the speeds encountered are far smaller than the speed of light, so that the relativistic effects are negligibly small. Time is considered an absolute entity irrespective of the state of motion, and Newton's laws of motion are assumed to be exact. The concept of an inertial frame of reference is very important. It is precisely defined by Newton's first law of motion. It is a coordinate frame with respect to which bodies, under the absence of external forces, move with zero acceleration. (For transformation between reference frames, refer to ME9.)

In this regard, the idea of a Galilean frame is also important. A coordinate frame that has only uniform translation with respect to a primitive intertial frame embedded in the nearby "fixed stars" is called Galilean:

$$\bar{\mathbf{r}} = \mathbf{r} - \mathbf{V}\mathrm{t} \quad \text{or,} \quad \bar{\mathrm{x}}_{\mathrm{i}} = \mathrm{x}_{\mathrm{i}} - \mathrm{V}_{\mathrm{i}}\mathrm{t}$$

$$\bar{t} = t$$

or

$$\mathbf{r} = \bar{\mathbf{r}} + \mathbf{V}\bar{\mathrm{t}} \quad \text{or,} \quad x_i = \bar{x}_i + V_i\bar{t}$$

where **V** is a constant velocity.

Thus,

$$\bar{\mathbf{u}} = \mathbf{u} - \mathbf{V}$$

$$\mathbf{u} = \bar{\mathbf{u}} + \mathbf{V}$$

$$\bar{\mathbf{a}} = \mathbf{a}$$

The quantities that remain invariant between Galilean frames are called Galilean invariants. Examples are acceleration, stress, vorticity, pressure, temperature, and heat flux. Some Galilean noninvariants are velocity, kinetic energy, and molecular mean free path.

1.4 MOTION OF A CONTINUUM

The continuum hypothesis postulates fluid particles or the material points distributed continuously. To describe any kind of motion, a reference coordinate system is needed. Because fluid motion does not require any relativistic considerations, we take time as an absolute quantity common to

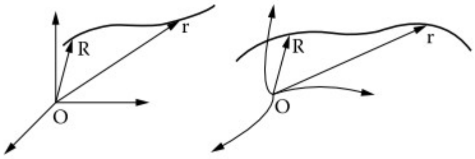

Figure 1.1 Inertial Cartesian or curvilinear reference frame.

any reference frame at rest or in motion. For simplicity, choose a reference frame at rest and refer the motion of all particles with respect to it. This coordinate system can be a curvilinear coordinate system. In what follows, we shall consider an inertial frame for the description of fluid motion, as shown in Figure 1.1.

The material points at the fixed reference time t_0 or at any time t can now be located with respect to this inertial coordinate system by drawing position vectors from point o. Let **R** and **r** denote the position vectors of the fluid particles at time t_0 and t, respectively.* The vectors **R** and **r** can be denoted as an ordered triple of numbers in any of the following forms (refer to ME1 for details):

$$\mathbf{R} = (X, Y, Z) = (X_i) = (X^i),$$

$$\mathbf{r} = (x, y, z) = (x_i) = (x^i)$$

where **R** is the reference configuration at t_0, the reference time.

In this text subscripted variables X_i, x_i denote rectangular Cartesian coordinates, whereas X^i, x^i denote any general nonrectangular coordinates. Thus, **r** referred to a rectangular Cartesian system is

$$\mathbf{r} = x_1\mathbf{i}_1 + x_2\mathbf{i}_2 + x_3\mathbf{i}_3 = x_k\mathbf{i}_k \tag{1.1a}$$

where any two repeated indices imply summation, and $\mathbf{i}_k$ for $k = 1, 2, 3$ are the constant unit vectors along x_1, x_2, and x_3 axes, respectively. For general curvilinear coordinates (x^1, x^2, x^3) the position vector **r** is a function of these coordinates, i.e., $\mathbf{r} = \mathbf{r}(x^i)$, and it is not possible to write **r** linearly in terms of x^i as in Equation 1.1a. It must, however, be noted that the first differential $d\mathbf{r}$ is expressible linearly in dx^i for all coordinates as

$$\begin{aligned} d\mathbf{r} &= \frac{\partial \mathbf{r}}{\partial x^m}\, dx^m \,(\text{sum on } m) \\ &= \mathbf{a}_m\, dx^m \end{aligned} \tag{1.1b}$$

and $\mathbf{a}_m$'s are called the *covariant base vectors*. If x^m's are the rectangular Cartesian coordinates, i.e.,

$$x^1 = x_1, \qquad x^2 = x_2, \qquad x^3 = x_3$$

then from Equation 1.1a we find that

$$\mathbf{a}_m = \mathbf{i}_m, \qquad m = 1, 2, 3 \tag{1.1c}$$

where $\mathbf{i}_m$'s are the constant unit vectors. (Refer to ME1.)

---

* At some places we have also used the symbol **x** in lieu of **r**.

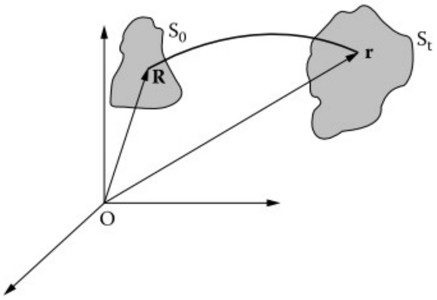

Figure 1.2 Motion of an imaginary volume in a continuum.

In this text, we will use both rectangular Cartesian and general curvilinear coordinates. From this discussion, the reader should have no difficulty in identifying the implied coordinate system. Functions of the coordinates will be written as $F(\mathbf{R})$ or $F(\mathbf{r})$, etc.

Suppose at time $t = t_0$ we isolate a portion of the continuum and denote its bounding surface by S_0, as shown in Figure 1.2. A specific particle in the region enclosed by S_0 can be named $X_1 = a$, $X_2 = b$, $X_3 = c$, where (a, b, c) are the Cartesian coordinates of a particle at $t = t_0$. As this particle moves, its position at some other time $t > t_0$ can be located with respect to the reference system by (x_1, x_2, x_3), where

$$x_i = \phi_i(a,b,c,t), \qquad i = 1, 2, 3 \tag{1.2}$$

The functions ϕ_i are to be determined by the laws of fluid motion. (The determination of ϕ_i is actually the "ultimate problem" of fluid dynamics, and the functions are not known *a priori*.) In the same manner any other particle labeled by its coordinates can be followed to a time $t > t_0$. Collectively, all these particles at time $t > t_0$ will be enclosed by a surface S_t.

This notion of mapping points at $t = t_0$ enclosed by an imaginary surface S_0 onto the points of the region enclosed by S_t at $t > t_0$ is of great help. This mapping should be one-to-one for distinct points to remain distinct. That is, two or more points enclosed by S_0 should not map onto a single point of the region enclosed by S_t.

Collectively, consider all the points at time $t = t_0$ and follow their motion in time $t > t_0$. The law of fluid motion should then be written as

$$x_i = \phi_i(X_1, X_2, X_3, t), \qquad i = 1, 2, 3 \tag{1.3}$$

so that (X_1, X_2, X_3) can be any fluid particle at $t = t_0$. In vector form Equation 1.3 is written as

$$\mathbf{r} = \boldsymbol{\phi}(\mathbf{R}, t) \tag{1.4}$$

where the vector-valued function $\boldsymbol{\phi}$ must be such that at the time $t = t_0$, the position vectors $\mathbf{r}$ and $\mathbf{R}$ coincide. Thus,

$$\mathbf{r}(\mathbf{R}, t_0) = \boldsymbol{\phi}(\mathbf{R}, t_0) = \mathbf{R} \tag{1.5}$$

The coordinates (X^i or X_i) are usually called the material or *Lagrangian coordinates*, and (x^i or x_i) are called the spatial or *Eulerian coordinates*. The following interpretation is in order:

1. If **R** is kept fixed and t varies, then Equation 1.4 represents the path or the trajectory followed by the chosen particle through time.
2. If t is kept fixed, then Equation 1.4 represents the transformation of coordinates occupied by the fluid particles at $t = t_0$ to the coordinates at time t. This transformation is generally nonlinear. Because the space remains Euclidean at $t = t_0$ and $t > t_0$, Equation 1.4 transforms an Euclidean space into itself. In essence, the map **F** defined as $\mathbf{F} : \mathbf{R} \rightarrow \boldsymbol{\phi}\,(\mathbf{R}, t)$ is the fluid flow map.

Besides $\boldsymbol{\phi}$ being a one-to-one mapping of points, the function $\boldsymbol{\phi}$ in Equation 1.4 must be spatially differentiable to some specified order. We will consider $\boldsymbol{\phi}$ to be single valued and at least first-order differentiable in the spatial variables. Let the inverse of Equation 1.4 be written as

$$\mathbf{R} = \psi(\mathbf{r}, t) \tag{1.6}$$

For Equation 1.6 to exist, the Jacobian J of the map **F** defined below must not vanish at any point of the flow field:

$$J(\mathbf{R}, t) = \det\left(\frac{\partial x_i}{\partial X_j}\right) \neq 0 \tag{1.7a}$$

Another way of defining J is to introduce the gradient operator "Grad" in the reference configuration **R** and then a second-order tensor or matrix **G** is obtained as

$$\mathbf{G} = \text{Grad } \mathbf{r}$$

Thus,

$$J = \det(\mathbf{G})$$

In fully expanded form Equation 1.7a is

$$\begin{vmatrix} \dfrac{\partial x_1}{\partial X_1} & \dfrac{\partial x_1}{\partial X_2} & \dfrac{\partial x_1}{\partial X_3} \\ \dfrac{\partial x_2}{\partial X_1} & \dfrac{\partial x_2}{\partial X_2} & \dfrac{\partial x_2}{\partial X_3} \\ \dfrac{\partial x_3}{\partial X_1} & \dfrac{\partial \boldsymbol{x}_3}{\partial X_2} & \dfrac{\partial x_3}{\partial X_3} \end{vmatrix} \neq 0 \tag{1.7b}$$

The condition $J \neq 0$ is known as the *smoothness condition* of fluid motion. Because of the continuity and differentiability of $\boldsymbol{\phi}$ and $\boldsymbol{\psi}$ in Equation 1.4 and Equation 1.6, we have

$$\boldsymbol{\phi}[\boldsymbol{\psi}(\mathbf{r}, t), t] = \mathbf{r} \tag{1.8a}$$

$$\boldsymbol{\psi}[\boldsymbol{\phi}(\mathbf{R}, t), t] = \mathbf{R} \tag{1.8b}$$

$$J(\mathbf{R}, t_0) = 1 \tag{1.8c}$$

The preceding can formally be stated using the implicit function theorem. According to the implicit function theorem, if the vector-valued function $\boldsymbol{r} = \boldsymbol{\varphi}(\boldsymbol{R}, \mathrm{t})$ for a fixed time t is continuous and possesses continuous first-order partial derivatives with respect to $\boldsymbol{R}$ in a neighborhood of the point $\boldsymbol{R}$, and if $J \neq 0$ there, then a unique inverse $\boldsymbol{R} = \boldsymbol{\psi}(\boldsymbol{r}, \mathrm{t})$ exists at a point $\boldsymbol{r}$ at time t.

1.5 THE TIME DERIVATIVES

Suppose F to be either a scalar, vector, or tensor function of position and time representing some physical property of the flow. We can write it as $F(\mathbf{r}, t)$ or $F(\mathbf{R}, t)$ because the inverse of the transformation from $\mathbf{r}$ to $\mathbf{R}$ or $\mathbf{R}$ to $\mathbf{r}$ is assumed to exist. Physically, $F(\mathbf{R}, t)$ is the value of F experienced by a fluid particle at time t that at time t_0 was at $\mathbf{R}$, and $F(\mathbf{r}, t)$ is the value experienced by an observer at the fixed position $\mathbf{r}$ at time t. There are two possible time derivatives:

$$(i) \quad \frac{\partial F}{\partial t} = \left.\frac{\partial F(\mathbf{r}, t)}{\partial t}\right|_{\mathbf{r}\ \text{fixed}} \tag{1.9a}$$

$$(i) \quad \frac{dF}{dt} = \left.\frac{\partial F(\mathbf{R}, t)}{\partial t}\right|_{\mathbf{R}\ \text{fixed}} \tag{1.9b}$$

Here, $\partial F/\partial t$ is the rate of change of F measured by an observer stationed at the fixed point $\mathbf{r}$ and is a local time variation of F. On the other hand, dF/dt is the rate of change of F measured by an observer moving with the fluid particle. The time derivative dF/dt is called the *material* or *substantive derivative*, or the *derivative following the motion*. The reason for these names is based on the fact that $F(\mathbf{R}, t)$ is purely a function of time and its derivative is a total derivative.

1.6 VELOCITY AND ACCELERATION

Any description of fluid motion using the Lagrangian coordinates $\mathbf{R} = (X_i)$ and time t is called a description in the *sense of Lagrange*. From an intuitive viewpoint, one should start describing velocity and acceleration in the sense of Lagrange, as is done in classical particle dynamics. It must be noted in this context that the $\mathbf{r}$ defined in Equation 1.4 represents the changing coordinates of a moving fluid particle. The velocity of a fluid particle at time t, which was at the position $\mathbf{R}$ at time $t = t_0$, is obtained by differentiating Equation 1.4, i.e.,

$$\frac{d\mathbf{r}}{dt} = \frac{\partial \boldsymbol{\phi}(\mathbf{R}, t)}{\partial t} = \mathbf{U}(\mathbf{R}, t) \tag{1.10}$$

and is called the *Lagrangian velocity*. Also,

$$d\mathbf{r} = \mathbf{U}(\mathbf{R}, t)dt$$

which on integration and using Equation 1.5 yields the particle trajectory:

$$\mathbf{r} = \mathbf{R} + \int_{t_0}^{t} \mathbf{U}(\mathbf{R}, t)\, dt \tag{1.11}$$

Problema 3.21 Demonstre que os operadores de projeção são **idempotentes:** $\hat{P}^2 = \hat{P}$. Determine os autovalores de $\hat{P}$ e caracterize seus autovetores.

Problema 3.22 Considere um espaço vetorial tridimensional gerado por uma base ortonormal $|1\rangle$, $|2\rangle$, $|3\rangle$. *Kets* $|\alpha\rangle$ e $|\beta\rangle$ são dados por

$$|\alpha\rangle = i|1\rangle - 2|2\rangle - i|3\rangle, \quad |\beta\rangle = i|1\rangle + 2|3\rangle.$$

(a) Monte $\langle\alpha|$ e $\langle\beta|$ (nos termos da base dual $\langle 1|$, $\langle 2|$, $\langle 3|$).

(b) Calcule $\langle\alpha|\beta\rangle$ e $\langle\beta|\alpha\rangle$ e confirme que $\langle\beta|\alpha\rangle = \langle\alpha|\beta\rangle^*$.

(c) Calcule os nove elementos da matriz do operador $\hat{A} \equiv |\alpha\rangle\langle\beta|$ nos termos dessa base e monte a matriz **A**. Ela é hermitiana?

Problema 3.23 O Hamiltoniano para determinado sistema de dois níveis é

$$\hat{H} = \epsilon(|1\rangle\langle 1| - |2\rangle\langle 2| + |1\rangle\langle 2| + |2\rangle\langle 1|),$$

em que $|1\rangle$, $|2\rangle$ é uma base ortonormal e ϵ é um número com as dimensões da energia. Encontre seus autovalores e autovetores (como combinações lineares de $|1\rangle$ e $|2\rangle$). Qual é a matriz **H** que representa $\hat{H}$ em relação a essa base?

Problema 3.24 Seja $\hat{Q}$ um operador com um conjunto completo de autovetores ortonormais:

$$\hat{Q}|e_n\rangle = q_n|e_n\rangle \quad (n = 1, 2, 3, \ldots).$$

Demonstre que $\hat{Q}$ pode ser escrito em termos de sua **decomposição espectral:**

$$\hat{Q} = \sum_n q_n |e_n\rangle\langle e_n|.$$

Dica: um operador é caracterizado por sua ação em todos os vetores possíveis, portanto, o que você deve mostrar é que

$$\hat{Q}|\alpha\rangle = \left\{\sum_n q_n |e_n\rangle\langle e_n|\right\}|\alpha\rangle,$$

para qualquer vetor $|\alpha\rangle$.

Problema 3.27 **Medições sequenciais.** Um operador $\hat{A}$ representando o observável A tem dois autoestados normalizados, Ψ_1 e Ψ_2, com autovalores a_1 e a_2, respectivamente. O operador $\hat{B}$, representando o observável B, tem dois autoestados normalizados, ϕ_1 e ϕ_2, com autovalores b_1 e b_2. Os autoestados estão relacionados por

---

[30] Legendre não sabia qual seria a melhor convenção; ele escolheu o fator global para que todas as suas funções fossem 1 em $x = 1$, e agora estamos presos a essa escolha infeliz.

$$\psi_1 = (3\phi_1 = 4\phi_2)/5, \quad \psi_2 = (4\phi_1 - 3\phi_2) \ /5.$$

(a) O observável A é medido e o valor a_1 é obtido. Qual é o estado do sistema (imediatamente) após a medida?

(b) Se a medição de B já foi feita, quais são os resultados possíveis, e quais são as probabilidades para cada um deles?

(c) Logo após a medição de B, A é medido novamente. Qual é a probabilidade de se obter a_1? (Observe que a resposta seria bem diferente se eu tivesse informado o resultado das medições de B.)

****Problema 3.28** Calcule a função de onda para o espaço de momento $\Phi_n(p, t)$ para o n-ésimo estado estacionário do poço quadrado infinito. Esboce $|\Phi_1(p, t)|^2$ e $|\Phi_2(p, t)|^2$, como funções de p (preste atenção aos pontos $p = \pm n\pi\hbar/a$). Use $\Phi_n(p, t)$ para calcular o valor esperado de p^2. Compare sua resposta à do Problema 2.4.

Problema 3.29 Considere a função de onda

$$\Psi(x,0) = \begin{cases} \dfrac{1}{\sqrt{2n\lambda}} e^{i2\pi x/\lambda}, & -n\lambda < x < n\lambda, \\ 0, & \text{caso contrário,} \end{cases}$$

em que n é um número positivo inteiro. Essa função é puramente sinusoidal (com comprimentos de onda λ) no intervalo $-n\lambda < x < n\lambda$, mas ainda carrega uma *faixa* de momentos, pois as oscilações não seguem até o infinito. Descubra a função de onda para o espaço de momento $\Phi(p, 0)$. Faça o gráfico de $|\Psi(x, 0)|^2$ e $|\Phi(p, 0)|^2$ e determine suas larguras, w_x e w_p (a distância entre os zeros de cada lado do ponto principal). Observe o que acontece com cada largura quando $n \Rightarrow \infty$. Usando w_x e w_p como estimativas de Δx e Δp, verifique se o princípio da incerteza é satisfeito. *Atenção:* se você tentar calcular σ_p, terá uma desagradável surpresa. Você consegue diagnosticar o problema?

Problema 3.30 Suponha que

$$\Psi(x,0) = \frac{A}{x^2 + a^2}, \quad (-\infty < x < \infty)$$

para constantes A e a.

(a) Determine A, normalizando $\Psi_1(x, 0)$.

(b) Calcule $\langle x \rangle$, $\langle x^2 \rangle$ e σ_x (em tempo $t = 0$).

(c) Calcule a função de onda para o espaço de momento $\Phi(p, 0)$ e certifique-se de que ela esteja normalizada.

(d) Use $\Phi(p, 0)$ para calcular $\langle p \rangle$, $\langle p \rangle^2$ e σ_p (em tempo $t = 0$).

(e) Verifique o princípio da incerteza de Heisenberg para esse estado.

***Problema 3.31 Teorema do virial.** Use a Equação 3.71 para mostrar que

$$\frac{d}{dt}\langle xp \rangle = 2\langle T \rangle - \left\langle x\frac{dV}{dx} \right\rangle, \qquad [3.96]$$

em que T é a energia cinética ($H = T + V$). Em um estado *estacionário*, o lado esquerdo é zero (por quê?) assim que

$$2\langle T \rangle - \left\langle x\frac{dV}{dx} \right\rangle. \qquad [3.97]$$

Isso é chamado de **teorema do virial**. Use-o para provar que $\langle T \rangle = \langle V \rangle$ para estados estacionários do oscilador harmônico e verifique se isso é compatível com os resultados obtidos nos problemas 2.11 e 2.12.

Problema 3.32 Em uma versão interessante do princípio da incerteza para a energia-tempo[31] $\Delta t = \tau/\pi$, em que τ é o tempo que $\Psi(x, t)$ leva para evoluir a um estado ortogonal $\Psi(x, 0)$. Faça um teste usando uma função de onda que é uma mistura equivalente de dois estados estacionários (ortonormais) de um potencial (arbitrário): $\Psi(x, 0) = (1\sqrt{2})[\Psi_1(x) + \Psi_2(x)]$.

****Problema 3.33** Calcule os elementos da matriz $\langle n|x|n'\rangle$ e $\langle n|p|n'\rangle$ na base (ortonormal) de estados estacionários para o oscilador harmônico (Equação 2.67). Você já calculou os elementos 'diagonais' ($n = n'$) no Problema 2.12; use a mesma técnica para o caso geral. Construa as matrizes (infinitas) correspondentes, **X** e **P**. Mostre que $(1/2m)\mathbf{P}^2 + (m\omega^2/2)\mathbf{X}^2 = \mathbf{H}$ é *diagonal* nessa base. Os elementos diagonais que você encontrou são o que você esperava? *Resposta parcial:*

$$\langle n|x|n'\rangle = \sqrt{\frac{\hbar}{2m\omega}}\left(\sqrt{n'}\delta_{n,n'-1} + \sqrt{n}\delta_{n',n-1}\right). \qquad [3.98]$$

Problema 3.34 O oscilador harmônico está em tal estado que a medida da energia produziria tanto $(1/2)\hbar\omega$ quanto $(3/2)\ \hbar\omega$, com igual probabilidade. Qual é o maior valor possível de $\langle p \rangle$ nesse caso? Se esse valor máximo for aceito no tempo $t = 0$, qual é o $\Psi(x, t)$?

*****Problema 3.35 Estados coerentes para o oscilador harmônico.** Entre os estados estacionários do oscilador harmônico ($|n\rangle = \Psi_n(x)$, Equação 2.67), somente $n = 0$ atinge o limite da incerteza ($\sigma_x\sigma_p = \hbar/2$); em geral, $\sigma_x\sigma_p = (2n + 1)\hbar/2$, conforme você viu no Problema 2.12. Porém, certas *combinações lineares* (conhecidas como **estados coerentes**) também minimizam o produto da incerteza. Acontece que eles são *autofunções do operador de abaixamento*:[32]

$$a_-|\alpha\rangle = \alpha|\alpha\rangle$$

(O autovalor α pode ser qualquer número complexo.)

(a) Calcule $\langle x \rangle$, $\langle x^2 \rangle$, $\langle p \rangle$, $\langle p^2 \rangle$ no estado $|\alpha\rangle$. *Dica:* use a técnica do Exemplo 2.5 e lembre-se de que a_+ é o conjugado hermitiano de a_-. *Não* suponha que α seja real.

---

[31] Veja Lev Vaidman, *Am. J. Phys.* 60, 182 (1992) para uma prova disso.

[32] Não há autofunções normalizáveis do operador de *levantamento*.

(b) Calcule σ_x e σ_p; demonstre que $\sigma_x\sigma_p = \hbar/2$.

(c) Assim como qualquer outra função de onda, um estado coerente pode ser expandido em termos dos autoestados das energias:

$$|\alpha\rangle = \sum_{n=0}^{\infty} c_n\,|n\rangle.$$

Demonstre que os coeficientes de expansão são

$$c_n = \frac{\alpha^n}{\sqrt{n!}}c_0.$$

(d) Determine c_0 por meio da normalização de $|\alpha\rangle$. *Resposta:* $\exp(-|\alpha|^2/2)$.

(e) Agora coloque a dependência do tempo:

$$|n\rangle \to e^{-iE_n t/\hbar}\,|n\rangle,$$

e demonstre que $|\alpha(t)\rangle$ continua sendo um autoestado de a_-, porém, o *autovalor* evolui com o tempo:

$$\alpha(t) = e^{-i\omega t}\alpha.$$

Portanto, um estado coerente *permanece* coerente e continua a minimizar o produto da incerteza.

(f) O estado fundamental ($|n=0\rangle$) é um estado coerente? Se sim, qual é o autovalor?

Problema 3.36 Princípio da incerteza expandido.[33] O princípio da incerteza generalizado (Equação 3.62) afirma que

$$\sigma_A^2\sigma_B^2 \geq \frac{1}{4}\langle C\rangle^2,$$

em que $\hat{C} \equiv -i[\hat{A}, \hat{B}]$.

(a) Demonstre que a equação pode ser reforçada para dizer

$$\sigma_A^2\sigma_B^2 \geq \frac{1}{4}(\langle C\rangle^2 + \langle D\rangle^2), \qquad [3.99]$$

em que $\hat{D} \equiv \hat{A}\hat{B} + \hat{B}\hat{A} - 2\langle A\rangle\langle B\rangle$. *Dica:* mantenha o termo $\mathrm{Re}(z)$ na Equação 3.60.

(b) Verifique a Equação 3.99 para o caso $B = A$ (nesse caso, o princípio da incerteza padrão é trivial, sendo que $\hat{C} = 0$; infelizmente, o princípio da incerteza expandido não ajuda muito).

Problema 3.37 O Hamiltoniano para um determinado sistema de três níveis está representado pela seguinte matriz:

$$\mathbf{H} = \begin{pmatrix} a & 0 & b \\ 0 & c & 0 \\ b & 0 & a \end{pmatrix},$$

em que a, b e c são números reais (suponha $a - c \neq \pm b$).

(a) Se o sistema se inicia no estado

$$|\mathcal{S}(0)\rangle = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix},$$

qual é a $|\mathcal{S}(t)\rangle$?

(b) Se o sistema se inicia no estado

$$|\mathcal{S}(0)\rangle = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix},$$

qual é a $|\mathcal{S}(t)\rangle$?

Problema 3.38 O Hamiltoniano para um determinado sistema de três níveis está representado pela seguinte matriz:

$$\mathbf{H} = \hbar\omega\begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 2 \end{pmatrix}.$$

Dois outros observáveis, A e B, estão representados pelas matrizes

$$\mathbf{A} = \lambda\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 2 \end{pmatrix}, \quad \mathbf{B} = \mu\begin{pmatrix} 2 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix},$$

em que ω, λ e μ são números reais positivos.

(a) Calcule os autovalores e autovetores normalizados de **H**, **A** e **B**.

(b) Suponha que o sistema seja iniciado no estado genérico

$$|\mathcal{S}(0)\rangle = \begin{pmatrix} c_1 \\ c_2 \\ c_3 \end{pmatrix},$$

com $|c_1|^2 + |c_2|^2 + |c_3|^2 = 1$. Descubra os valores esperados de H, A e B (em $t = 0$).

(c) Qual é a $|\mathcal{S}(t)\rangle$? Se você medir a energia desse estado (em tempo t), quais valores você obterá, e quais as probabilidades de cada um? Responda a essas mesmas perguntas para A e B.

****Problema 3.39**

(a) Para uma função $f(x)$, que pode ser expandida em uma série de Taylor, demonstre que

$$f(x + x_0) = e^{i\hat{p}x_0/\hbar}f(x)$$

(em que x_0 é qualquer distância constante). Por essa razão, $\hat{p}/\hbar$ é chamado de **gerador de translações no**

---

[33] Para comentários e referências interessantes, veja R. R. Puri, *Phys. Rev. A* **49**, 2178 (1994).

espaço. *Nota:* o exponencial de um *operador* é definido pela expansão em série de potências: $e^{\hat{Q}} \equiv 1 + \hat{Q} + (1/2)\hat{Q}^2 + (1/3!)\hat{Q}^3 + \ldots$.

(b) Se $\Psi(x, t)$ satisfaz a equação de Schrödinger (dependente do tempo), demonstre que

$$\Psi(x, t + t_0) = e^{-i\hat{H}t_0/\hbar}\Psi(x, t)$$

(em que t_0 é qualquer tempo constante); $-\hat{H}/\hbar$ é chamado de **gerador de translações no tempo**.

(c) Demonstre que o valor esperado de uma variável dinâmica $Q(x, p, t)$ em tempo $t + t_0$ pode ser escrito[34]

$$\langle Q \rangle_{t=t_0} = \langle \Psi(x, t) | e^{i\hat{H}t_0/\hbar}\hat{Q}(\hat{x}, \hat{p}, t = t_0)e^{-i\hat{H}t_0/\hbar} | \Psi(x, t) \rangle.$$

Use isso para recuperar a Equação 3.71. *Dica:* faça $t_0 = dt$, e expanda para primeira ordem em dt.

****Problema 3.40**

(a) Escreva a 'equação de Schrödinger' dependente do tempo no espaço de momento para uma partícula livre e obtenha o resultado. *Resposta:* $\exp(-ip^2t/2m\hbar)\Phi(p, 0)$.

(b) Calcule $\Phi(p, 0)$ para o pacote de onda gaussiano móvel (Problema 2.43) e monte $\Phi(p, t)$ para esse caso. Monte também $|\Phi(p, t)|^2$, e note que é independente do tempo.

(c) Calcule $\langle p \rangle$ e $\langle p^2 \rangle$ por meio de avaliação das integrais apropriadas que envolvem Φ e compare suas respostas ao Problema 2.43.

(d) Demonstre que $\langle H \rangle \equiv \langle p \rangle^2/2m + \langle H \rangle_0$ (em que o índice 0 representa o *estacionário* gaussiano) e comente esse resultado.

---

[34] Especialmente se estabelecermos $t = 0$ e descartarmos o índice em t_0,

$$\langle Q(t) \rangle = \langle \Psi(x, t) | \hat{Q} | \Psi(x, t) \rangle = \langle \Psi(x, 0) | \hat{U}^{-1}\hat{Q}\hat{U} | \Psi(x, 0) \rangle,$$

em que $\hat{U} \equiv \exp(-i\hat{H}t/\hbar)$. Isso significa que você pode calcular os valores esperados de Q tanto imprensando $\hat{Q}$ entre $\Psi(x, t)^*$ e $\Psi(x, t)$ quanto como sempre fazemos (deixando as funções de onda carregar a dependência de tempo), ou, ainda, imprensando $\hat{U}^{-1}\hat{Q}\hat{U}$ entre $\Psi(x, 0)^*$ e $\Psi(x, 0)$, deixando assim que o *operador* carregue a dependência do tempo. O primeiro é chamado de **representação de Schrödinger**, e o último é chamado de **representação de Heisenberg**.

where

$$\text{}\mathscr{r}^2 = z^2 + R^2 - 2zR\cos\theta,$$

so

$$\begin{aligned} V_{\text{ave}} &= \frac{1}{4\pi R^2}\frac{q}{4\pi\epsilon_0}\int [z^2 + R^2 - 2zR\cos\theta]^{-1/2} R^2 \,\sin\theta\, d\theta\, d\phi \\ &= \frac{q}{4\pi\epsilon_0}\frac{1}{2zR}\sqrt{z^2 + R^2 - 2zR\cos\theta}\,\Big|_0^{\pi} \\ &= \frac{q}{4\pi\epsilon_0}\frac{1}{2zR}[(z+R) - (z-R)] = \frac{1}{4\pi\epsilon_0}\frac{q}{z}. \end{aligned}$$

But this is precisely the potential due to q at the *center* of the sphere! By the superposition principle, the same goes for any *collection* of charges outside the sphere: their average potential over the sphere is equal to the net potential they produce at the center. □

Problem 3.1 Find the average potential over a spherical surface of radius R due to a point charge q located *inside* (same as above, in other words, only with $z < R$). (In this case, of course, Laplace's equation does not hold within the sphere.) Show that, in general,

$$V_{\text{ave}} = V_{\text{center}} + \frac{Q_{\text{enc}}}{4\pi\epsilon_0 R},$$

where V_{center} is the potential at the center due to all the *external* charges, and Q_{enc} is the total enclosed charge.

Problem 3.2 In one sentence, justify **Earnshaw's Theorem:** *A charged particle cannot be held in a stable equilibrium by electrostatic forces alone.* As an example, consider the cubical arrangement of fixed charges in Fig. 3.4. It *looks,* off hand, as though a positive charge at the center would be suspended in midair, since it is repelled away from each corner. Where is the leak in this "electrostatic bottle"? [To harness nuclear fusion as a practical energy source it is necessary to heat a plasma (soup of charged particles) to fantastic temperatures—so hot that contact would vaporize any ordinary pot. Earnshaw's theorem says that electrostatic containment is also out of the question. Fortunately, it *is* possible to confine a hot plasma magnetically.]

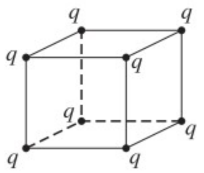

FIGURE 3.4

Problem 3.3 Find the general solution to Laplace's equation in spherical coordinates, for the case where V depends only on r. Do the same for cylindrical coordinates, assuming V depends only on s.

Problem 3.4

(a) Show that the average electric *field* over a spherical surface, due to charges outside the sphere, is the same as the field at the center.

(b) What is the average due to charges *inside* the sphere?

3.1.5 ■ Boundary Conditions and Uniqueness Theorems

Laplace's equation does not by itself determine V; in addition, suitable boundary conditions must be supplied. This raises a delicate question: What are appropriate boundary conditions, sufficient to determine the answer and yet not so strong as to generate inconsistencies? The one-dimensional case is easy, for here the general solution $V = mx + b$ contains two arbitrary constants, and we therefore require two boundary conditions. We might, for instance, specify the value of the function at each end, or we might give the value of the function and its derivative at one end, or the value at one end and the derivative at the other, and so on. But we cannot get away with *just* the value or *just* the derivative at *one* end—this is insufficient information. Nor would it do to specify the derivatives at both ends—this would either be redundant (if the two are equal) or inconsistent (if they are not).

In two or three dimensions we are confronted by a *partial* differential equation, and it is not so obvious what would constitute acceptable boundary conditions. Is the shape of a taut rubber membrane, for instance, uniquely determined by the frame over which it is stretched, or, like a canning jar lid, can it snap from one stable configuration to another? The answer, as I think your intuition would suggest, is that V *is* uniquely determined by its value at the boundary (canning jars evidently do not obey Laplace's equation). However, other boundary conditions can also be used (see Prob. 3.5). The *proof* that a proposed set of boundary conditions will suffice is usually presented in the form of a **uniqueness theorem.** There are many such theorems for electrostatics, all sharing the same basic format—I'll show you the two most useful ones.[4]

> **First uniqueness theorem:** The solution to Laplace's equation in some volume $\mathcal{V}$ is uniquely determined if V is specified on the boundary surface $\mathcal{S}$.

Proof. In Fig. 3.5 I have drawn such a region and its boundary. (There could also be "islands" inside, so long as V is given on all their surfaces; also, the outer

---

[4] I do not intend to prove the *existence* of solutions here—that's a much more difficult job. In context, the existence is generally clear on physical grounds.

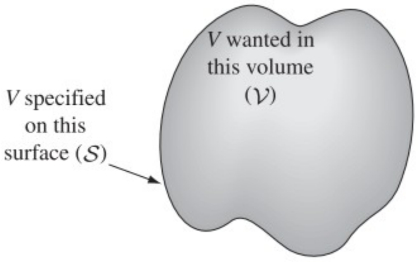

FIGURE 3.5

boundary could be at infinity, where V is ordinarily taken to be zero.) Suppose there were *two* solutions to Laplace's equation:

$$\nabla^2 V_1 = 0 \quad \text{and} \quad \nabla^2 V_2 = 0,$$

both of which assume the specified value on the surface. I want to prove that they must be equal. The trick is look at their *difference:*

$$V_3 \equiv V_1 - V_2.$$

This obeys Laplace's equation,

$$\nabla^2 V_3 = \nabla^2 V_1 - \nabla^2 V_2 = 0,$$

and it takes the value *zero* on all boundaries (since V_1 and V_2 are equal there). But Laplace's equation allows no local maxima or minima—all extrema occur on the boundaries. So the maximum and minimum of V_3 are both zero. Therefore V_3 must be zero everywhere, and hence

$$V_1 = V_2. \qquad \square$$

Example 3.1. Show that the potential is *constant* inside an enclosure completely surrounded by conducting material, provided there is no charge within the enclosure.

Solution

The potential on the cavity wall is some constant, V_0 (that's item (iv), in Sect. 2.5.1), so the potential inside is a function that satisfies Laplace's equation and has the constant value V_0 at the boundary. It doesn't take a genius to think of *one* solution to this problem: $V = V_0$ everywhere. The uniqueness theorem guarantees that this is the *only* solution. (It follows that the *field* inside an empty cavity is zero—the same result we found in Sect. 2.5.2 on rather different grounds.)

The uniqueness theorem is a license to your imagination. It doesn't matter *how* you come by your solution; if (a) it satisfies Laplace's equation and (b) it has the correct value on the boundaries, then it's *right.* You'll see the power of this argument when we come to the method of images.

Incidentally, it is easy to improve on the first uniqueness theorem: I assumed there was no charge inside the region in question, so the potential obeyed Laplace's equation, but we may as well throw in some charge (in which case V obeys Poisson's equation). The argument is the same, only this time

$$\nabla^2 V_1 = -\frac{1}{\epsilon_0}\rho, \qquad \nabla^2 V_2 = -\frac{1}{\epsilon_0}\rho,$$

so

$$\nabla^2 V_3 = \nabla^2 V_1 - \nabla^2 V_2 = -\frac{1}{\epsilon_0}\rho + \frac{1}{\epsilon_0}\rho = 0.$$

Once again the *difference* ($V_3 \equiv V_1 - V_2$) satisfies Laplace's equation and has the value zero on all boundaries, so $V_3 = 0$ and hence $V_1 = V_2$.

Corollary: The potential in a volume $\mathcal{V}$ is uniquely determined if (a) the charge density throughout the region, and (b) the value of V on all boundaries, are specified.

3.1.6 ■ Conductors and the Second Uniqueness Theorem

The *simplest* way to set the boundary conditions for an electrostatic problem is to specify the value of V on all surfaces surrounding the region of interest. And this situation often occurs in practice: In the laboratory, we have conductors connected to batteries, which maintain a given potential, or to **ground**, which is the experimentalist's word for $V = 0$. However, there are other circumstances in which we do not know the *potential* at the boundary, but rather the *charges* on various conducting surfaces. Suppose I put charge Q_a on the first conductor, Q_b on the second, and so on—I'm not telling you how the charge distributes itself over each conducting surface, because as soon as I put it on, it moves around in a way I do not control. And for good measure, let's say there is some specified charge density ρ in the region between the conductors. Is the electric field now uniquely determined? Or are there perhaps a number of different ways the charges could arrange themselves on their respective conductors, each leading to a different field?

Second uniqueness theorem: In a volume $\mathcal{V}$ surrounded by conductors and containing a specified charge density ρ, the electric field is uniquely determined if the *total charge* on each conductor is given (Fig. 3.6). (The region as a whole can be bounded by another conductor, or else unbounded.)

Proof. Suppose there are *two* fields satisfying the conditions of the problem. Both obey Gauss's law in differential form in the space between the conductors:

$$\nabla \cdot \mathbf{E}_1 = \frac{1}{\epsilon_0}\rho, \qquad \nabla \cdot \mathbf{E}_2 = \frac{1}{\epsilon_0}\rho.$$

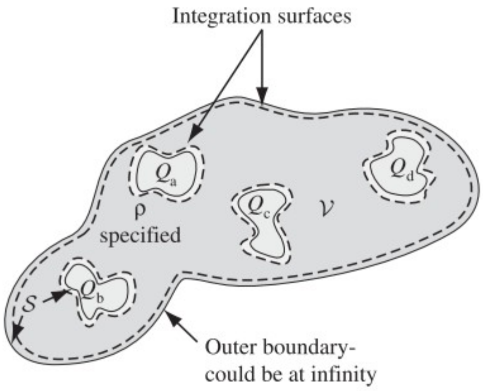

FIGURE 3.6

And both obey Gauss's law in integral form for a Gaussian surface enclosing each conductor:

$$\oint\limits_{\substack{i\text{th conducting}\\ \text{surface}}} \mathbf{E}_1 \cdot d\mathbf{a} = \frac{1}{\epsilon_0} Q_i, \qquad \oint\limits_{\substack{i\text{th conducting}\\ \text{surface}}} \mathbf{E}_2 \cdot d\mathbf{a} = \frac{1}{\epsilon_0} Q_i.$$

Likewise, for the outer boundary (whether this is just inside an enclosing conductor or at infinity),

$$\oint\limits_{\substack{\text{outer}\\ \text{boundary}}} \mathbf{E}_1 \cdot d\mathbf{a} = \frac{1}{\epsilon_0} Q_{\text{tot}}, \qquad \oint\limits_{\substack{\text{outer}\\ \text{boundary}}} \mathbf{E}_2 \cdot d\mathbf{a} = \frac{1}{\epsilon_0} Q_{\text{tot}}.$$

As before, we examine the difference

$$\mathbf{E}_3 \equiv \mathbf{E}_1 - \mathbf{E}_2,$$

which obeys

$$\nabla \cdot \mathbf{E}_3 = 0 \tag{3.7}$$

in the region between the conductors, and

$$\oint \mathbf{E}_3 \cdot d\mathbf{a} = 0 \tag{3.8}$$

over each boundary surface.

Now there is one final piece of information we must exploit: Although we do not know how the charge Q_i distributes itself over the ith conductor, we *do* know that each conductor is an equipotential, and hence V_3 is a *constant* (not necessarily the *same* constant) over each conducting surface. (It need not be *zero,* for the potentials V_1 and V_2 may not be equal—all we know for sure is that *both* are *constant* over any given conductor.) Next comes a trick. Invoking product rule number 5 (inside front cover), we find that

$$\nabla \cdot (V_3 \mathbf{E}_3) = V_3(\nabla \cdot \mathbf{E}_3) + \mathbf{E}_3 \cdot (\nabla V_3) = -(E_3)^2.$$

Here I have used Eq. 3.7, and $\mathbf{E}_3 = -\nabla V_3$. Integrating this over $\mathcal{V}$, and applying the divergence theorem to the left side:

$$\int_{\mathcal{V}} \nabla \cdot (V_3 \mathbf{E}_3)\, d\tau = \oint_{\mathcal{S}} V_3 \mathbf{E}_3 \cdot d\mathbf{a} = -\int_{\mathcal{V}} (E_3)^2\, d\tau.$$

The surface integral covers all boundaries of the region in question—the conductors and outer boundary. Now V_3 is a constant over each surface (if the outer boundary is infinity, $V_3 = 0$ there), so it comes outside each integral, and what remains is zero, according to Eq. 3.8. Therefore,

$$\int_{\mathcal{V}} (E_3)^2\, d\tau = 0.$$

But this integrand is never negative; the only way the integral can vanish is if $E_3 = 0$ everywhere. Consequently, $\mathbf{E}_1 = \mathbf{E}_2$, and the theorem is proved. □

This proof was not easy, and there is a real danger that the theorem itself will seem more plausible to you than the proof. In case you think the second uniqueness theorem is "obvious," consider this example of Purcell's: Figure 3.7 shows a simple electrostatic configuration, consisting of four conductors with charges $\pm Q$, situated so that the plusses are near the minuses. It all looks very comfortable. Now, what happens if we join them in pairs, by tiny wires, as indicated in Fig. 3.8? Since the positive charges are very near negative charges (which is where they *like* to be) you might well guess that *nothing* will happen—the configuration looks stable.

Well, that sounds reasonable, but it's wrong. The configuration in Fig. 3.8 is *impossible.* For there are now effectively *two* conductors, and the total charge on each is *zero*. *One* possible way to distribute zero charge over these conductors is to have no accumulation of charge anywhere, and hence zero field

FIGURE 3.7

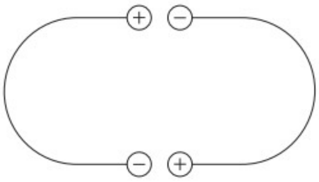

FIGURE 3.8

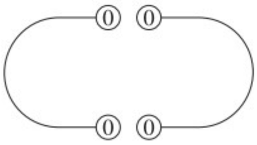

FIGURE 3.9

everywhere (Fig. 3.9). By the second uniqueness theorem, this must be *the* solution: The charge will flow down the tiny wires, canceling itself off.

Problem 3.5 Prove that the field is uniquely determined when the charge density ρ is given and *either* V *or* the normal derivative $\partial V/\partial n$ is specified on each boundary surface. Do not assume the boundaries are conductors, or that V is constant over any given surface.

Problem 3.6 A more elegant proof of the second uniqueness theorem uses Green's identity (Prob. 1.61c), with $T = U = V_3$. Supply the details.

3.2 ■ THE METHOD OF IMAGES

3.2.1 ■ The Classic Image Problem

Suppose a point charge q is held a distance d above an infinite grounded conducting plane (Fig. 3.10). *Question:* What is the potential in the region above the plane? It's not just $(1/4\pi\epsilon_0)q/\mathscr{r}$, for q will induce a certain amount of negative charge on the nearby surface of the conductor; the total potential is due in part to q directly, and in part to this induced charge. But how can we possibly calculate the potential, when we don't know how much charge is induced or how it is distributed?

From a mathematical point of view, our problem is to solve Poisson's equation in the region $z > 0$, with a single point charge q at $(0, 0, d)$, subject to the boundary conditions:

1. $V = 0$ when $z = 0$ (since the conducting plane is grounded), and
2. $V \to 0$ far from the charge $\big($that is, for $x^2 + y^2 + z^2 \gg d^2\big)$.

The first uniqueness theorem (actually, its corollary) guarantees that there is only one function that meets these requirements. If by trick or clever guess we can discover such a function, it's got to be the answer.

Trick: Forget about the actual problem; we're going to study a *completely different* situation. This new configuration consists of *two* point charges, $+q$ at

1.7 Further exercises and problems

Here is a collection of problems relating to the calculus of variations. Some date back to the sixteenth century, others are quite recent in origin.

Exercise 1.1: A smooth path in the xy-plane is given by $\mathbf{r}(t) = (x(t), y(t))$ with $\mathbf{r}(0) = \mathbf{a}$, and $\mathbf{r}(1) = \mathbf{b}$. The length of the path from $\mathbf{a}$ to $\mathbf{b}$ is therefore

$$S[\mathbf{r}] = \int_0^1 \sqrt{\dot{x}^2 + \dot{y}^2}\, dt,$$

where $\dot{x} \equiv dx/dt$, $\dot{y} \equiv dy/dt$. Write down the Euler–Lagrange conditions for $S[\mathbf{r}]$ to be stationary under small variations of the path that keep the endpoints fixed, and hence show that the shortest path between two points is a straight line.

Exercise 1.2: *Fermat's principle*. A medium is characterized optically by its *refractive index n*, such that the speed of light in the medium is c/n. According to Fermat (1657), the path taken by a ray of light between any two points makes the travel time stationary between those points. Assume that the ray propagates in the xy-plane in a layered medium with refractive index $n(x)$. Use Fermat's principle to establish Snell's law in its general form $n(x) \sin\psi = \text{constant}$, by finding the equation giving the stationary paths $y(x)$ for

$$F_1[y] = \int n(x)\sqrt{1 + y'^2}\, dx.$$

(Here the prime denotes differentiation with respect to x.) Repeat this exercise for the case that n depends only on y and find a similar equation for the stationary paths of

$$F_2[y] = \int n(y)\sqrt{1 + y'^2}\, dx.$$

By using suitable definitions of the angle of incidence ψ in each case, show that the two formulations of the problem give physically equivalent answers. In the second formulation you will find it easiest to use the first integral of Euler's equation.

How are we to make sense of this expression? We begin in the next chapter where we explain what it means to differentiate $\delta(x)$, and show that (1.186) does indeed correspond to the differential operator L. In subsequent chapters we explore the manner in which differential operators and matrices are related. We will learn that just as some matrices can be diagonalized so can some differential operators, and that the class of diagonalizable operators includes (1.182).

If all the eigenvalues of L are positive, our stationary point was a minimum. For each negative eigenvalue, there is direction in function space in which $J[y]$ decreases as we move away from the stationary point.

1.7 Further exercises and problems

Here is a collection of problems relating to the calculus of variations. Some date back to the sixteenth century, others are quite recent in origin.

Exercise 1.1: A smooth path in the xy-plane is given by $\mathbf{r}(t) = (x(t), y(t))$ with $\mathbf{r}(0) = \mathbf{a}$, and $\mathbf{r}(1) = \mathbf{b}$. The length of the path from $\mathbf{a}$ to $\mathbf{b}$ is therefore

$$S[\mathbf{r}] = \int_0^1 \sqrt{\dot{x}^2 + \dot{y}^2}\, dt,$$

where $\dot{x} \equiv dx/dt$, $\dot{y} \equiv dy/dt$. Write down the Euler–Lagrange conditions for $S[\mathbf{r}]$ to be stationary under small variations of the path that keep the endpoints fixed, and hence show that the shortest path between two points is a straight line.

Exercise 1.2: *Fermat's principle*. A medium is characterized optically by its *refractive index n*, such that the speed of light in the medium is c/n. According to Fermat (1657), the path taken by a ray of light between any two points makes the travel time stationary between those points. Assume that the ray propagates in the xy-plane in a layered medium with refractive index $n(x)$. Use Fermat's principle to establish Snell's law in its general form $n(x)\sin\psi = \text{constant}$, by finding the equation giving the stationary paths $y(x)$ for

$$F_1[y] = \int n(x)\sqrt{1 + y'^2}\, dx.$$

(Here the prime denotes differentiation with respect to x.) Repeat this exercise for the case that n depends only on y and find a similar equation for the stationary paths of

$$F_2[y] = \int n(y)\sqrt{1 + y'^2}\, dx.$$

By using suitable definitions of the angle of incidence ψ in each case, show that the two formulations of the problem give physically equivalent answers. In the second formulation you will find it easiest to use the first integral of Euler's equation.

.6 9 J /

Problem 1.3: *Hyperbolic geometry*. This problem introduces a version of the Poincaré model for the non-Euclidean geometry of Lobachevski.

(a) Show that the stationary paths for the functional

$$F_3[y] = \int \frac{1}{y}\sqrt{1+y'^2}dx,$$

with $y(x)$ restricted to lying in the upper half-plane, are semicircles of arbitrary radius and with centres on the x-axis. These paths are the *geodesics*, or minimum length paths, in a space with Riemann metric

$$ds^2 = \frac{1}{y^2}(dx^2 + dy^2), \qquad y > 0.$$

(b) Show that if we call these geodesics "lines", then one and only one line can be drawn though two given points.

(c) Two lines are said to be *parallel* if, and only if, they meet at "infinity", i.e. on the x-axis. (Verify that the x-axis is indeed infinitely far from any point with $y > 0$.) Show that given a line q and a point A not lying on that line, there are *two* lines passing through A that are parallel to q, and that between these two lines lies a pencil of lines passing through A that never meet q.

Problem 1.4: *Elastic rods.* The elastic energy per unit length of a bent steel rod is given by $\frac{1}{2}YI/R^2$. Here R is the radius of curvature due to the bending, Y is the Young's modulus of the steel and $I = \iint y^2 dxdy$ is the moment of inertia of the rod's cross-section about an axis through its centroid and perpendicular to the plane in which the rod is bent. If the rod is only slightly bent into the yz-plane and lies close to the z-axis, show that this elastic energy can be approximated as

$$U[y] = \int_0^L \frac{1}{2} YI \left(y''\right)^2 \, dz,$$

where the prime denotes differentiation with respect to z and L is the length of the rod. We will use this approximate energy functional to discuss two practical problems.

(a) *Euler's problem: The buckling of a slender column*. The rod is used as a column which supports a compressive load Mg directed along the z-axis (which is vertical; see Figure (1.14a)). Show that when the rod buckles slightly (i.e. deforms with both ends remaining on the z-axis) the total energy, including the gravitational potential energy of the loading mass M, can be approximated by

$$U[y] = \int_0^L \left\{ \frac{YI}{2} \left(y''\right)^2 - \frac{Mg}{2} \left(y'\right)^2 \right\} dz.$$

.6 7:/ 6 8 : "D J 6

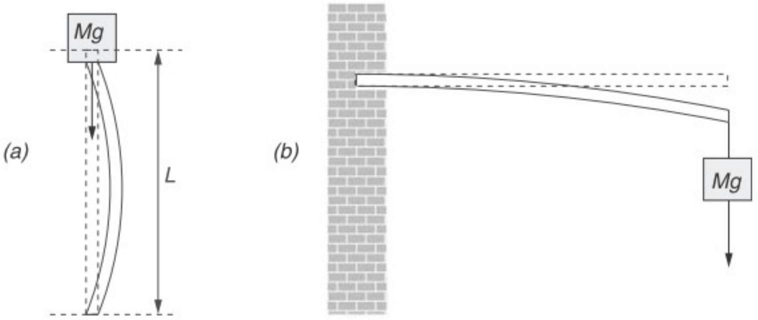

Figure 1.14 A rod used as: (a) a column, (b) a cantilever.

By considering small deformations of the form

$$y(z) = \sum_{n=1}^{\infty} a_n \sin \frac{n\pi z}{L}$$

show that the column is unstable to buckling and collapse if $Mg \geq \pi^2 YI/L^2$.

(b) *Leonardo da Vinci's problem: The light cantilever.* Here we take the z-axis as horizontal and the y-axis as being vertical (Figure 1.14b). The rod is used as a beam or cantilever and is fixed into a wall so that $y(0) = 0 = y'(0)$. A weight Mg is hung from the end $z = L$ and the beam sags in the $(-y)$-direction. We wish to find $y(z)$ for $0 < z < L$. We will ignore the weight of the beam itself.

- Write down the complete expression for the energy, including the gravitational potential energy of the weight.
- Find the differential equation and boundary conditions at $z = 0, L$ that arise from minimizing the total energy. In doing this take care not to throw away any term arising from the integration by parts. You may find the following identity to be of use:

$$\frac{d}{dz}(f'g'' - fg''') = f''g'' - fg''''.$$

- Solve the equation. You should find that the displacement of the end of the beam is $y(L) = -\frac{1}{3}MgL^3/YI$.

Exercise 1.5: Suppose that an elastic body Ω of density ρ is slightly deformed so that the point that was at cartesian coordinate x_i is moved to $x_i + \eta_i(x)$. We define the resulting *strain tensor* e_{ij} by

$$e_{ij} = \frac{1}{2}\left(\frac{\partial \eta_j}{\partial x_i} + \frac{\partial \eta_i}{\partial x_j}\right).$$

It is automatically symmetric in its indices. The Lagrangian for small-amplitude elastic motion of the body is

$$L[\boldsymbol{\eta}] = \int_\Omega \left\{ \frac{1}{2}\rho\dot{\eta}_i^2 - \frac{1}{2}e_{ij}c_{ijkl}e_{kl} \right\} d^3x.$$

Here, c_{ijkl} is the tensor of *elastic constants*, which has the symmetries

$$c_{ijkl} = c_{klij} = c_{jikl} = c_{ijlk}.$$

By varying the η_i, show that the equation of motion for the body is

$$\rho\frac{\partial^2\eta_i}{\partial t^2} - \frac{\partial}{\partial x_j}\sigma_{ji} = 0,$$

where

$$\sigma_{ij} = c_{ijkl}e_{kl}$$

is the *stress tensor*. Show that variations of η_i on the boundary $\partial\Omega$ give as boundary conditions

$$\sigma_{ij}n_j = 0,$$

where n_i are the components of the outward normal on $\partial\Omega$.

Problem 1.6: *The catenary revisited.* We can describe a catenary curve in parametric form as $x(s)$, $y(s)$, where s is the arc-length. The potential energy is then simply $\int_0^L \rho g y(s) ds$ where ρ is the mass per unit length of the hanging chain. The x, y are not independent functions of s, however, because $\dot{x}^2 + \dot{y}^2 = 1$ at every point on the curve. Here a dot denotes a derivative with respect to s.

(a) Introduce infinitely many Lagrange multipliers $\lambda(s)$ to enforce the $\dot{x}^2 + \dot{y}^2$ constraint, one for each point s on the curve. From the resulting functional derive two coupled equations describing the catenary, one for $x(s)$ and one for $y(s)$. By thinking about the forces acting on a small section of the cable, and perhaps by introducing the angle ψ where $\dot{x} = \cos\psi$ and $\dot{y} = \sin\psi$, so that s and ψ are *intrinsic coordinates* for the curve, interpret these equations and show that $\lambda(s)$ is proportional to the position-dependent tension $T(s)$ in the chain.

(b) You are provided with a lightweight line of length $\pi a/2$ and some lead shot of total mass M. By using equations from the previous part (suitably modified to take into account the position dependent $\rho(s)$) or otherwise, determine how the lead should be distributed along the line if the loaded line is to hang in an arc of a circle of radius a (see Figure 1.15) when its ends are attached to two points at the same height.

.6 ? " : 2 "

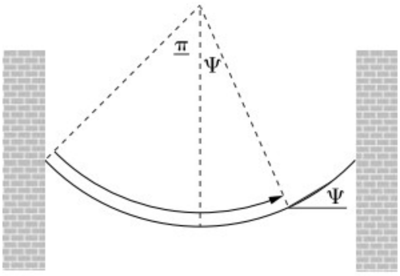

Figure 1.15 Weighted line.

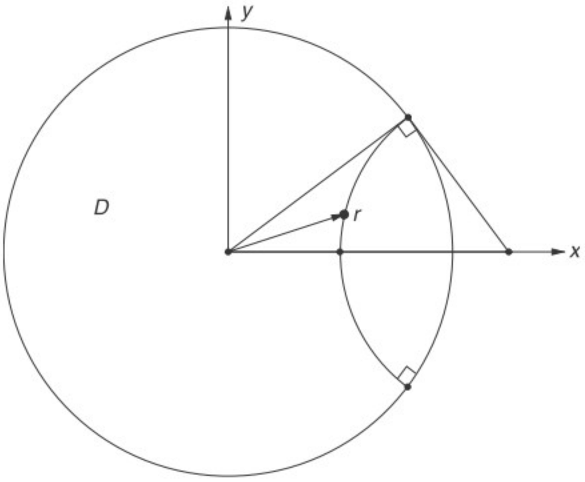

Figure 1.16 The Poincaré disc of Exercise 1.7. The radius OP of the Poincaré disc is unity, while the radius of the geodesic arc PQR is PX = QX = RX = R. The distance between the centres of the disc and arc is OX = x_0. Your task in part (c) is to show that ∠OPX = ∠ORX = 90°.

Problem 1.7: Another model for Lobachevski geometry (see Exercise 1.3) is the *Poincaré disc* (Figure 1.16). This space consists of the interior of the unit disc $D^2 = \{(x,y) \in \mathbb{R}^2 : x^2 + y^2 \leq 1\}$ equipped with the Riemann metric

$$ds^2 = \frac{dx^2 + dy^2}{(1 - x^2 - y^2)^2}.$$

The geodesic paths are found by minimizing the arc-length functional

$$s[\mathbf{r}] \equiv \int ds = \int \left\{ \frac{1}{1 - x^2 - y^2} \sqrt{\dot{x}^2 + \dot{y}^2} \right\} dt,$$

where $\mathbf{r}(t) = (x(t), y(t))$ and a dot indicates a derivative with respect to the parameter t.

(a) Either by manipulating the two Euler–Lagrange equations that give the conditions for $s[\mathbf{r}]$ to be stationary under variations in $\mathbf{r}(t)$, or, more efficiently, by observing that $s[\mathbf{r}]$ is invariant under the infinitesimal rotation

$$\begin{aligned} \delta x &= \varepsilon y \\ \delta y &= -\varepsilon x \end{aligned}$$

and applying Noether's theorem, show that the parametrized geodesics obey

$$\frac{d}{dt}\left(\frac{1}{1-x^2-y^2}\frac{x\dot{y}-y\dot{x}}{\sqrt{\dot{x}^2+\dot{y}^2}}\right)=0.$$

(b) Given a point (a, b) within D^2, and a direction through it, show that the equation you derived in part (a) determines a unique geodesic curve passing through (a, b) in the given direction, but does not determine the parametrization of the curve.

(c) Show that there exists a solution to the equation in part (a) in the form

$$\begin{aligned} x(t) &= R\cos t + x_0 \\ y(t) &= R\sin t. \end{aligned}$$

Find a relation between x_0 and R, and from it deduce that the geodesics are circular arcs that cut the bounding unit circle (which plays the role of the line at infinity in the Lobachevski plane) at right angles.

Exercise 1.8: The Lagrangian for a particle of charge q is

$$L[\mathbf{x}, \dot{\mathbf{x}}] = \frac{1}{2}m\dot{\mathbf{x}}^2 - q\phi(\mathbf{x}) + q\dot{\mathbf{x}}\cdot\mathbf{A}(\mathbf{x}).$$

Show that Lagrange's equation leads to

$$m\ddot{\mathbf{x}} = q(\mathbf{E} + \dot{\mathbf{x}}\times\mathbf{B}),$$

where

$$\mathbf{E} = -\nabla\phi - \frac{\partial\mathbf{A}}{\partial t}, \quad \mathbf{B} = \operatorname{curl}\mathbf{A}.$$

Exercise 1.9: Consider the action functional

$$S[\boldsymbol{\omega}, \mathbf{p}, \mathbf{r}] = \int\left(\frac{1}{2}I_1\omega_1^2 + \frac{1}{2}I_2\omega_2^2 + \frac{1}{2}I_3\omega_3^2 + \mathbf{p}\cdot(\dot{\mathbf{r}} + \boldsymbol{\omega}\times\mathbf{r})\right\}\,dt,$$

where $\mathbf{r}$ and $\mathbf{p}$ are time-dependent 3-vectors, as is $\boldsymbol{\omega} = (\omega_1, \omega_2, \omega_3)$. Apply the action principle to obtain the equations of motion for $\mathbf{r}, \mathbf{p}, \boldsymbol{\omega}$ and show that they lead to Euler's

.6 D ? DG

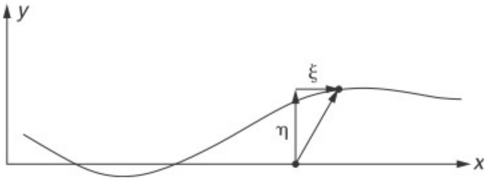

Figure 1.17 Vibrating piano string.

equations

$$\begin{aligned} I_1\dot{\omega}_1 - (I_2 - I_3)\omega_2\omega_3 &= 0, \\ I_2\dot{\omega}_2 - (I_3 - I_1)\omega_3\omega_1 &= 0, \\ I_3\dot{\omega}_3 - (I_1 - I_2)\omega_1\omega_2 &= 0, \end{aligned}$$

governing the angular velocity of a freely rotating rigid body.

Problem 1.10: *Piano string*. An elastic piano string can vibrate both transversely and longitudinally, and the two vibrations influence one another (Figure 1.17). A Lagrangian that takes into account the lowest-order effect of stretching on the local string tension, and can therefore model this coupled motion, is

$$L[\xi, \eta] = \int dx \left\{ \frac{1}{2}\rho_0 \left[\left(\frac{\partial \xi}{\partial t}\right)^2 + \left(\frac{\partial \eta}{\partial t}\right)^2 \right] - \frac{\lambda}{2} \left[\frac{\tau_0}{\lambda} + \frac{\partial \xi}{\partial x} + \frac{1}{2}\left(\frac{\partial \eta}{\partial x}\right)^2 \right]^2 \right\}.$$

Here $\xi(x,t)$ is the longitudinal displacement and $\eta(x,t)$ the transverse displacement of the string. Thus, the point that in the undisturbed string had coordinates $[x, 0]$ is moved to the point with coordinates $[x+\xi(x,t), \eta(x,t)]$. The parameter τ_0 represents the tension in the undisturbed string, λ is the product of Young's modulus and the cross-sectional area of the string and ρ_0 is the mass per unit length.

(a) Use the action principle to derive the two coupled equations of motion, one involving $\dfrac{\partial^2 \xi}{\partial t^2}$ and one involving $\dfrac{\partial^2 \eta}{\partial t^2}$.

(b) Show that when we linearize these two equations of motion, the longitudinal and transverse motions decouple. Find expressions for the longitudinal (c_{L}) and transverse (c_{T}) wave velocities in terms of τ_0, ρ_0 and λ.

(c) Assume that a given transverse pulse $\eta(x,t) = \eta_0(x - c_{\mathrm{T}}t)$ propagates along the string. Show that this induces a concurrent longitudinal pulse of the form $\xi(x - c_{\mathrm{T}}t)$. Show further that the longitudinal Newtonian momentum density in this concurrent pulse is given by

$$\rho_0 \frac{\partial \xi}{\partial t} = \frac{1}{2} \frac{c_{\mathrm{L}}^2}{c_{\mathrm{L}}^2 - c_{\mathrm{T}}^2} T^0{}_1$$

.6

where

$$T^0{}_1 \equiv -\rho_0 \frac{\partial \eta}{\partial x}\frac{\partial \eta}{\partial t}$$

is the associated pseudo-momentum density.

The forces that created the transverse pulse will also have created other longitudinal waves that travel at c_L. Consequently the Newtonian x-momentum moving at c_T is not the only x-momentum on the string, and the total "true" longitudinal momentum density is not simply proportional to the pseudo-momentum density.

Exercise 1.11: Obtain the canonical energy–momentum tensor $T^\nu{}_\mu$ for the barotropic fluid described by (1.119). Show that its conservation leads to both the momentum conservation equation (1.128), and the energy conservation equation

$$\partial_t \mathcal{E} + \partial_i \{v_i(\mathcal{E} + P)\},$$

where the energy density is

$$\mathcal{E} = \frac{1}{2}\rho(\nabla\phi)^2 + u(\rho).$$

Interpret the energy flux as being the sum of the convective transport of energy together with the rate of working by an element of fluid on its neighbours.

Problem 1.12: Consider the action functional[3]

$$S[\mathbf{v}, \rho, \phi, \beta, \gamma] = \int d^4x \left\{ -\frac{1}{2}\rho\mathbf{v}^2 - \phi\left(\frac{\partial \rho}{\partial t} + \mathrm{div}\,(\rho\mathbf{v})\right) + \rho\beta\left(\frac{\partial \gamma}{\partial t} + (\mathbf{v}\cdot\nabla)\gamma\right) + u(\rho)\right\},$$

which is a generalization of (1.177) to include two new scalar fields β and γ. Show that varying $\mathbf{v}$ leads to

$$\mathbf{v} = \nabla\phi + \beta\nabla\gamma.$$

This is the *Clebsch representation* of the velocity field. It allows for flows with non-zero vorticity

$$\boldsymbol{\omega} \equiv \mathrm{curl}\,\mathbf{v} = \nabla\beta \times \nabla\gamma.$$

[3] H. Bateman, *Proc. Roy. Soc. Lond.* A, **125** (1929) 598; C. C. Lin, *Liquid Helium* in *Proc. Int. Sch. Phys. "Enrico Fermi", Course XXI* (Academic Press, 1965).

.6 6 / 2 : "

Show that the equations that arise from varying the remaining fields $\rho, \phi, \beta, \gamma$ together imply the mass conservation equation

$$\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho \mathbf{v}) = 0,$$

and Bernoulli's equation in the form

$$\frac{\partial \mathbf{v}}{\partial t} + \boldsymbol{\omega} \times \mathbf{v} = -\nabla \left(\frac{1}{2}\mathbf{v}^2 + h \right).$$

(Recall that $h = du/d\rho$.) Show that this form of Bernoulli's equation is equivalent to Euler's equation

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} = -\nabla h.$$

Consequently S provides an action principle for a general inviscid barotropic flow.

Exercise 1.13: *Drums and membranes*. The shape of a distorted drumskin is described by the function $h(x, y)$, which gives the height to which the point (x, y) of the flat undistorted drumskin is displaced.

(a) Show that the area of the distorted drumskin is equal to

$$\text{Area}[h] = \int dx\, dy \sqrt{1 + \left(\frac{\partial h}{\partial x}\right)^2 + \left(\frac{\partial h}{\partial y}\right)^2},$$

where the integral is taken over the area of the flat drumskin.

(b) Show that for small distortions, the area reduces to

$$\mathcal{A}[h] = \text{const.} + \frac{1}{2}\int dx\, dy\, |\nabla h|^2.$$

(c) Show that if h satisfies the two-dimensional Laplace equation then $\mathcal{A}$ is stationary with respect to variations that vanish at the boundary.

(d) Suppose the drumskin has mass ρ_0 per unit area, and surface tension T. Write down the Lagrangian controlling the motion of the drumskin, and derive the equation of motion that follows from it.

Problem 1.14: *The Wulff construction.* The surface-area functional of the previous exercise can be generalized so as to find the equilibrium shape of a crystal. We describe the crystal surface by giving its height $z(x, y)$ above the xy-plane, and introduce the direction-dependent surface tension (the surface free-energy per unit area) $\alpha(p, q)$, where

$$p = \frac{\partial z}{\partial x}, \quad q = \frac{\partial z}{\partial y}. \qquad (\star)$$

.6 ; L

We seek to minimize the total surface free energy

$$F[z] = \int dxdy \left\{ \alpha(p,q)\sqrt{1+p^2+q^2} \right\},$$

subject to the constraint that the volume of the crystal

$$V[z] = \int z\, dxdy$$

remains constant.

(a) Enforce the volume constraint by introducing a Lagrange multiplier $2\lambda^{-1}$, and so obtain the Euler–Lagrange equation

$$\frac{\partial}{\partial x}\left(\frac{\partial f}{\partial p}\right) + \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial q}\right) = 2\lambda^{-1}.$$

Here

$$f(p,q) = \alpha(p.q)\sqrt{1+p^2+q^2}.$$

(b) Show in the isotropic case, where α is constant, that

$$z(x,y) = \sqrt{(\alpha\lambda)^2 - (x-a)^2 - (y-b)^2} + \text{const.}$$

is a solution of the Euler–Lagrange equation. In this case, therefore, the equilibrium shape is a sphere.

An obvious way to satisfy the Euler–Lagrange equation in the general anisotropic case would be to arrange things so that

$$x = \lambda\frac{\partial f}{\partial p}, \quad y = \lambda\frac{\partial f}{\partial q}. \tag{$\star\star$}$$

(c) Show that ($\star\star$) is exactly the relationship we would have if $z(x,y)$ and $\lambda f(p,q)$ were Legendre transforms of each other, i.e. if

$$\lambda f(p,q) = px + qy - z(x,y),$$

where the x and y on the right-hand side are functions of p, q obtained by solving ($\star$). Do this by showing that the inverse relation is

$$z(x,y) = px + qy - \lambda f(p,q)$$

where now the p, q on the right-hand side become functions of x and y, and are obtained by solving ($\star\star$).

.6 D ? G /

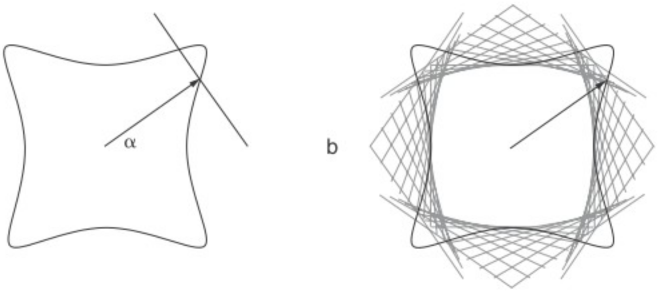

Figure 1.18 Two-dimensional Wulff crystal. (a) Polar plot of surface tension α as a function of the normal **n** to a crystal face, together with a line perpendicular to **n** at distance α from the origin. (b) Wulff's construction of the corresponding crystal surface as the envelope of the family of perpendicular lines. In this case, the minimum-energy crystal has curved faces, but sharp corners. The envelope continues beyond the corners, but these parts are unphysical.

For real crystals, $\alpha(p,q)$ can have the property of being a continuous-but-nowhere-differentiable function, and so the differential calculus used in deriving the Euler–Lagrange equation is inapplicable. The Legendre transformation, however, has a geometric interpretation that is more robust than its calculus-based derivation.

Recall that if we have a two-parameter family of surfaces in $\mathbb{R}^3$ given by $F(x,y,z;p,q) = 0$, then the equation of the *envelope* of the surfaces is found by solving the equations

$$0 = F = \frac{\partial F}{\partial p} = \frac{\partial F}{\partial q}$$

so as to eliminate the parameters p, q.

(d) Show that the equation

$$F(x,y,z;p,q) \equiv px + qy - z - \lambda\alpha(p,q)\sqrt{1+p^2+q^2} = 0$$

describes a family of planes perpendicular to the unit vectors

$$\mathbf{n} = \frac{(p,q,-1)}{\sqrt{1+p^2+q^2}}$$

and at a distance $\lambda\alpha(p,q)$ away from the origin.

(e) Show that the equations to be solved for the envelope of this family of planes are exactly those that determine $z(x,y)$. Deduce that, for smooth $\alpha(p,q)$, the profile $z(x,y)$ is this envelope.

Wulff conjectured[4] that, even for non-smooth $\alpha(p,q)$, the minimum-energy shape is given by an equivalent geometric construction: erect the planes from part (d) and, for each plane, discard the half-space of $\mathbb{R}^3$ that lies on the far side of the plane from the origin. The convex region consisting of the intersection of the retained half-spaces is the crystal. When $\alpha(p, q)$ is smooth this "Wulff body" is bounded by part of the envelope of the planes. (The parts of the envelope not bounding the convex body – the "swallowtails" visible in Figure 1.18 – are unphysical.) When $\alpha(p, q)$ has cusps, these singularities can give rise to flat facets which are often joined by rounded edges. A proof of Wulff's claim had to wait 43 years until 1944, when it was established by use of the Brunn–Minkowski inequality.[5]

Chapter 4
Evolution of the Curvature

The Ricci flow is introduced in this chapter as a geometric heat-type equation for the metric. In Sect. 4.4 we derive evolution equations for the curvature, and its various contractions, whenever the metric evolves by Ricci flow. These equations, particularly that of Theorem 4.14, are pivotal to our analysis throughout the coming chapters. In Sect. 4.5.3 we discuss a historical result concerning the convergence theory for the Ricci flow in n-dimensions. This will motivational much of the Böhm and Wilking analysis discussed in Chap. 11.

4.1 Introducing the Ricci Flow

The Ricci flow was first introduced by Richard Hamilton in the early 1980s. Inspired by Eells and Sampson's work on Harmonic map heat flow [ES64] (where they take maps between manifolds and try to 'make them better'), Hamilton speculated that it should be possible to take other geometric objects, for instance the metric g_{ij}, and try to 'improve it' by means of a heat-type equation.

In looking for a suitable parabolic equation, one would like $\frac{\partial g_{ij}}{\partial t}$ to equal a Laplacian-type expression involving second-order derivatives of the metric. Computing derivatives of the metric with the Levi–Civita connection is of no help, as they vanish in normal coordinates. However, computing derivatives with respect to a fixed background connection does give something non-trivial. In particular, the Ricci tensor in Lemma 2.47 has an expression which involves second derivatives the components of the metric, thus it is a natural candidate for such a $(2,0)$-tensor (specifically, the last term in the bracket in Lemma 2.47 is $-\frac{1}{2}$ times a 'Laplacian' of the metric computed using coordinate second derivatives). Taking this factor into account, we are led to the evolution equation

$$\frac{\partial}{\partial t} g_{ij} = -2\,\mathrm{Ric}_{ij} \tag{4.1}$$

B. Andrews and C. Hopper, *The Ricci Flow in Riemannian Geometry*,
Lecture Notes in Mathematics 2011, DOI 10.1007/978-3-642-16286-2_4,
© Springer-Verlag Berlin Heidelberg 2011

known simply as the Ricci flow. Further motivation comes from the expression for the metric in exponential coordinates given in Theorem 2.65, as it implies that the Laplacian of the metric computed at the origin in exponential coordinates is equal to $-\frac{2}{3}\mathrm{Ric}_{ij}$.

In contrast to other natural geometric equations (such as the minimal surface equation and its parabolic analogue the mean curvature flow; the harmonic map equation and the associated flow; and many other examples), the Ricci flow was not initially derived as the gradient flow of a geometric functional. However despite this, Perelman's work [Per02] shows there is a natural energy functional lying behind the Ricci flow. We discuss this in Chap. 10.

In light of (4.1), it is clear that we are no longer interested in just a single manifold (M, g), but rather – assuming a suitable local existence theory – a manifold with a one-parameter family of metrics $t \mapsto g(t)$ parametrised by a 'time' t. We adopt this point of view here, taking the metrics $g(t)$ as sections of the fixed bundle $\mathrm{Sym}^2 T^*M$. The rate of change in time of the metric makes sense since at each point $p \in M$ we are simply differentiating $g(t)$ in the vector space given by the fibre of this bundle at p. Later (in Chap. 6) we will see that there are advantages in instead working with bundles defined over $M \times \mathbb{R}$, where a more geometrically meaningful notion of the time derivative can be used.

4.1.1 Exact Solutions

In order to get a feel for the evolution equation, we present some simple solutions of the Ricci flow.

4.1.1.1 Einstein Metrics

If the initial metric is Ricci flat, that is Ric=0, then clearly the metric remains stationary for all subsequent times. Concrete examples of this are the Euclidean space $\mathbb{R}^n$ and the flat torus $\mathbb{T}^n = S^1 \times \cdots \times S^1$.

If the initial metric is Einstein, that is $\mathrm{Ric}(g_0) = \lambda g_0$ for some $\lambda \in \mathbb{R}$, then a solution $g(t)$ with $g(0) = g_0$ is given by $g(t) = (1 - 2\lambda t)g_0$. The cases $\lambda > 0$, $\lambda = 0$ and $\lambda < 0$ correspond to shrinking, steady and expanding solutions. The simplest shrinking solution is that of the unit sphere (S^n, g_0). Here $\mathrm{Ric}(g_0) = (n-1)g_0$, so $g(t) = (1 - 2(n-1)t)g_0$. Thus the sphere will collapse to a point in finite time $T = 1/2(n-1)$. By contrast, if the initial metric g_0 were hyperbolic, $\mathrm{Ric}(g_0) = -(n-1)g_0$ so the evolution $g(t) = (1 + 2(n-1)t)g_0$ will expand the manifold homothetically for all time. In this case, the solution only goes back to $T = -1/2(n-1)$ upon which the metric explodes out of a single point.

4.1.1.2 Quotient Metrics

If the initial Riemannian manifold $N = M/\mathcal{G}$ is a quotient of a Riemannian manifold M by a discrete group of isometries $\mathcal{G}$, it will remain so under the Ricci flow – as the flow on M preserves the isometry group. For example, the projective space $\mathbb{R}P^n = S^n/\mathbb{Z}_2$ of constant curvature shrinks to a point, as does its cover S^n.

4.1.1.3 Product Metrics

If we take the product metric (cf. Sect. 2.4.2) on a product manifold $M \times N$ initially, the metric will remain a product metric under the Ricci flow. Hence the metric on each factor evolves by the Ricci flow independently of the other.

For example, on $S^2 \times S^1$ the S^2 shrinks to a point while S^1 stays fixed so that the manifold collapses to a circle. Moreover, if we take any Riemannian manifold (M, g) and evolve the metric g by the Ricci flow, then it will also evolve on the product manifold $M \times \mathbb{R}^n$, $n \geq 1$, with product metric $g \oplus (dx_1^2 + \cdots + dx_n^2)$ – since the flow is stationary on the $\mathbb{R}^n$ part.

4.1.2 Diffeomorphism Invariance

The curvature of a manifold M can be thought of as the obstruction to being locally isometric to Euclidean space. Indeed, a Riemannian manifold is flat if and only if its curvature tensor vanishes identically. Moreover, recall that:

Theorem 4.1. *The Riemann curvature tensor R is invariant under local isometries: If $\varphi : (M, g) \to (\widetilde{M}, \widetilde{g})$ is a local isometry, then $\varphi^* \widetilde{R} = R$.*

So if $\varphi : M \to \widetilde{M}$ is a time-*independent* diffeomorphism such that $g(t) = \varphi^* \widetilde{g}(t)$ and $\widetilde{g}$ is a solution of the Ricci flow, we see that

$$\begin{aligned} \frac{\partial}{\partial t} g &= \varphi^* \Big(\frac{\partial}{\partial t} \widetilde{g} \Big) \\ &= \varphi^* \big(-2 \operatorname{Ric}(\widetilde{g}) \big) \\ &= -2 \operatorname{Ric}(\varphi^* \widetilde{g}) \\ &= -2 \operatorname{Ric}(g), \end{aligned}$$

where the second last equality is due to Theorem 4.1. Hence g is also a solution to the Ricci flow. Therefore we conclude that (4.1) is invariant under the full diffeomorphism group.[1]

---

[1] Note that if φ is time-*dependent*, an extra Lie derivative term is introduced into the equation (cf. Sect. 5.4).

4.1.2.1 Preservation of Symmetries

The Ricci flow preserves any symmetries that are present in the initial metric. To see this, note that each symmetry is an isometric diffeomorphism of the initial metric; so the pullback of a solution of the Ricci flow by this diffeomorphism gives a solution of Ricci flow. Since the symmetry is an isometry of the initial metric, these are solutions of Ricci flow with the same initial data, and so are identical (assuming the uniqueness result proved in Chap. 5). Therefore the symmetry is an isometry of the metric at any positive time.

4.1.3 Parabolic Rescaling of the Ricci Flow

Aside from the geometric symmetries of diffeomorphism invariance, the Ricci flow has additional scaling properties that are essential for blow-up analysis of singularities. The time-independent diffeomorphism invariance allows for changes in the spatial coordinates. We can also translate in the time coordinates: If $g(x,t)$ satisfies Ricci flow, then so does $g(x,t-t_0)$ for any $t_0 \in \mathbb{R}$. Further, the Ricci flow has a *scale invariance*: If g is a solution of Ricci flow, and $\lambda > 0$, then g_λ is also a solution, where

$$g_\lambda(x,t) = \lambda^2 g\Big(x, \frac{t}{\lambda^2}\Big).$$

The main use of this rescaling will be to analyse singularities that develop under the Ricci flow. In such a case the curvature tends to infinity, so we perform a rescaling to produce metrics with bounded curvature and try to produce a smooth limit of these. We will discuss the machinery required for this in Chap. 9, and return to the blow-up procedure in Sect. 9.5.

4.2 The Laplacian of Curvature

We devote this section to the derivation of an expression for the Laplacian of $R_{ijk\ell}$. This will be used to derive an evolution equation for the curvature in Sect. 4.4, where the Ricci flow (4.1) implies a heat-type equation for the Riemannian curvature R. In order to do this, we need to introduce quadratic $B_{ijk\ell}$ terms which will help simplify our computation.

4.2.1 Quadratic Curvature Tensor

Various second order derivatives of the curvature tensor are likely to differ by terms quadratic in the curvature tensor. To this end we introduce the $(4,0)$-tensor $B \in \mathscr{T}_0^4(M)$ defined by

$$B(X,Y,W,Z) = \langle R(X,\cdot,Y,\star), R(W,\cdot,Z,\star)\rangle\,,$$

where the inner product $\langle,\rangle$ is given by (2.3). In components this becomes

$$B_{ijk\ell} = g^{pr}g^{qs}R_{piqj}R_{rks\ell} = R^{p\ q}_{\ i\ j}R_{pkq\ell}. \tag{4.2}$$

This tensor has some of the symmetries of the curvature tensor, namely

$$B_{ijk\ell} = B_{ji\ell k} = B_{k\ell ij}.$$

However other symmetries of the curvature tensor may fail to hold for $B_{ijk\ell}$.

4.2.2 Calculating the Connection Laplacian $\Delta R_{ijk\ell}$

Using the definition of the Laplacian explicated in Sect. 2.6, we compute the connection Laplacian acting on the $\mathscr{T}_0^4(M)$ tensor bundle.

Proposition 4.2. *On a Riemannian manifold (M,g), the Laplacian of the curvature tensor R satisfies*

$$\begin{aligned}\Delta R_{ijk\ell} &= \nabla_i\nabla_k R_{j\ell} - \nabla_j\nabla_k R_{i\ell} + \nabla_j\nabla_\ell R_{ik} - \nabla_i\nabla_\ell R_{jk}\\ &\quad - 2\big(B_{ijk\ell} - B_{ij\ell k} - B_{i\ell jk} + B_{ikj\ell}\big) + g^{pq}\big(R_{qjk\ell}R_{pi} + R_{iqk\ell}R_{pj}\big).\end{aligned}$$

Proof. Using the second Bianchi identity – together with the linearity of ∇ over the space of tensor fields – we find that

$$\begin{aligned}0 &= (\nabla_p\nabla_q R)(\partial_i,\partial_j,\partial_k,\partial_\ell)\\ &\quad + (\nabla_p\nabla_i R)(\partial_j,\partial_q,\partial_k,\partial_\ell) + (\nabla_p\nabla_j R)(\partial_q,\partial_i,\partial_k,\partial_\ell).\end{aligned}$$

Combining this identity with (2.10) implies that the Laplacian of R takes the form

$$\begin{aligned}\Delta R_{ijk\ell} &= (\mathrm{tr}_g\nabla^2 R)_{ijk\ell}\\ &= g^{pq}(\nabla_{\partial_p}\nabla_{\partial_q}R)(\partial_i,\partial_j,\partial_k,\partial_\ell)\\ &= g^{pq}\left(-(\nabla_p\nabla_i R)(\partial_j,\partial_q,\partial_k,\partial_\ell) - (\nabla_p\nabla_j R)(\partial_q,\partial_i,\partial_k,\partial_\ell)\right)\\ &= g^{pq}\big(\nabla_p\nabla_i R_{qjk\ell} - \nabla_p\nabla_j R_{qik\ell}\big).\end{aligned}$$

From this it suffices to express $g^{pq}\nabla_p\nabla_i R_{qjk\ell}$ in terms of lower order terms by commuting derivatives and contracting with the metric.

Firstly, Proposition 2.44 implies that

$$\nabla_p\nabla_i R_{qjk\ell} = \nabla_i\nabla_p R_{qjk\ell} + \big(R(\partial_i,\partial_p)R\big)(\partial_q,\partial_j,\partial_k,\partial_\ell). \tag{4.3}$$

From the second Bianchi identity, the first term on the right-hand side of (4.3) becomes

$$\nabla_i\nabla_p R_{qjk\ell} = \nabla_i\nabla_k R_{jq\ell p} - \nabla_i\nabla_\ell R_{jqkp}.$$

Contracting with the metric and invoking Proposition 2.48, (2.15), gives

$$\begin{aligned} g^{pq}\nabla_i\nabla_p R_{qjk\ell} &= g^{pq}\nabla_i\nabla_k R_{jq\ell p} - g^{pq}\nabla_i\nabla_\ell R_{jqkp} \\ &= \nabla_i\nabla_k R_{j\ell} - \nabla_i\nabla_\ell R_{jk}. \end{aligned} \tag{4.4}$$

Turning our attention to the second term on the right-hand side of (4.3), we find by Proposition 2.43 that

$$\begin{aligned} &\big(R(\partial_i,\partial_p)R\big)(\partial_q,\partial_j,\partial_k,\partial_\ell) \\ &\quad= \cancel{R(\partial_i,\partial_p)(R_{qjk\ell})} \\ &\qquad - R(R(\partial_i,\partial_p)\partial_q,\partial_j,\partial_k,\partial_\ell) - \cdots - R(\partial_q,\partial_j,\partial_k,R(\partial_i,\partial_p)\partial_\ell) \\ &\quad= -R_{ipq}{}^{n}R_{njk\ell} - R_{ipq}{}^{n}R_{qnk\ell} - R_{ipq}{}^{n}R_{qjn\ell} - R_{ipq}{}^{n}R_{qjkn} \\ &\quad= g^{mn}\big(R_{piqm}R_{njk\ell} + R_{pijm}R_{qnk\ell} + R_{pikm}R_{qjn\ell} + R_{pi\ell m}R_{qjkn}\big). \end{aligned}$$

Therefore

$$\begin{aligned} &g^{pq}\big(R(\partial_i,\partial_p)R\big)(\partial_q,\partial_j,\partial_k,\partial_\ell) \\ &\quad= g^{pq}g^{mn}\big(R_{piqm}R_{njk\ell} + R_{pijm}R_{qnk\ell} + R_{pikm}R_{qjn\ell} + R_{pi\ell m}R_{qjkn}\big). \end{aligned}$$

We now look to simplify this expression by observing that the first term contracts to

$$g^{pq}g^{mn}R_{piqm}R_{njk\ell} = g^{mn}R_{ipm}{}^{p}R_{njk\ell} = g^{mn}R_{njk\ell}R_{im} = g^{pq}R_{pjk\ell}R_{iq},$$

the second term contracts to

$$\begin{aligned} g^{pq}g^{mn}R_{pijm}R_{qnk\ell} &= g^{pq}g^{mn}R_{pijm}(-R_{nkq\ell} - R_{kqn\ell}) \\ &= g^{pq}g^{mn}(R_{pimj}R_{q\ell nk} - R_{pimj}R_{qkn\ell}) \\ &= R^{q}{}_{i}{}^{n}{}_{j}R_{q\ell nk} - R^{q}{}_{i}{}^{n}{}_{j}R_{qkn\ell} \\ &= B_{ij\ell k} - B_{ijk\ell}, \end{aligned}$$

and the third and forth terms contract to

$$\begin{aligned} g^{pq}g^{mn}(R_{pikm}R_{qjn\ell} + R_{pi\ell m}R_{qjkn}) &= g^{pq}g^{mn}(-R_{pimk}R_{qjn\ell} + R_{pim\ell}R_{qjnk}) \\ &= -R^{q\ n}_{\ i\ k}R_{qjn\ell} + R^{q\ n}_{\ i\ \ell}R_{qjnk} \\ &= -B_{ikj\ell} + B_{i\ell jk}. \end{aligned}$$

Combining these results gives

$$\begin{aligned} &g^{pq}\big(R(\partial_i, \partial_p)R\big)(\partial_q, \partial_j, \partial_k, \partial_\ell) \\ &\qquad = g^{pq}R_{pjk\ell}R_{iq} - (B_{ijk\ell} - B_{ij\ell k} - B_{i\ell jk} + B_{ikj\ell}). \end{aligned} \tag{4.5}$$

Finally, by putting (4.4) and (4.5) together we get

$$\begin{aligned} g^{pq}\nabla_p\nabla_i R_{qjk\ell} &= \nabla_i\nabla_k R_{j\ell} - \nabla_i\nabla_\ell R_{jk} \\ &\quad - \ (B_{ijk\ell} - B_{ij\ell k} - B_{i\ell jk} + B_{ikj\ell}) + g^{pq}R_{pjk\ell}R_{iq}. \end{aligned}$$

Since $\Delta R_{ijk\ell} = g^{pq}\nabla_p\nabla_i R_{qjk\ell} - (i \leftrightarrow j)$ the desired formula now follows. □

4.3 Metric Variation Formulas

In this section we establish how one can formally take the time derivative of a metric and the associated Levi–Civita connection. Thereafter we derive various variational equations for the Levi–Civita connection, curvature tensor and various traces thereof.

4.3.1 *Interpreting the Time Derivative*

Consider a one-parameter family of smooth metrics $g = g(t) \in \Gamma(\mathrm{Sym}^2\, T^*M)$ parametrised by 'time' t. We define the time derivative $\frac{\partial}{\partial t}g : \mathscr{X}(M) \times \mathscr{X}(M) \to C^\infty(M)$ of the metric g by letting

$$\Big(\frac{\partial}{\partial t}g\Big)(X, Y) := \frac{\partial}{\partial t}g(X, Y) \tag{4.6}$$

for any time *independent* vector fields $X, Y \in \mathscr{X}(M)$ (where $\frac{\partial}{\partial t}g(X, Y)$ is the time derivative of the smooth function $g(X, Y) \in C^\infty(M)$ given by the standard difference quotient). The metric in local coordinates can be expressed as $g(t) = g_{ij}(t)dx^i \otimes dx^j$, in which case (4.6) implies that

$$\frac{\partial}{\partial t}g = \dot{g}_{ij}(t)\, dx^i \otimes dx^j.$$

Therefore we regard the time derivative of the metric as the derivative of its the component functions with respect to a fixed basis.

Since the Levi–Civita connection ∇ can be written locally in terms of the metric (2.9), it too will be time dependent. So in a similar fashion, we define the time derivative of $\nabla = \nabla^{(t)}$ by letting

$$\Big(\frac{\partial}{\partial t}\nabla\Big)(X,Y) := \frac{\partial}{\partial t}\nabla_X Y \tag{4.7}$$

for time-independent vector fields X and Y. As ∇ satisfies the product rule by definition, it is not tensorial. However, we observe the following special properties of its time derivative:

Lemma 4.3. *The time derivative* $\frac{\partial}{\partial t}\nabla$ *of the Levi–Civita connection* ∇ *is tensorial.*

Proof. For $f \in C^\infty(M)$ and any time independent vector fields $X, Y \in \mathscr{X}(M)$, we see that

$$\Big(\frac{\partial}{\partial t}\nabla\Big)(X, fY) = \frac{\partial}{\partial t}\Big((Xf)Y + f\nabla_X Y\Big) = f\,\frac{\partial}{\partial t}\nabla_X Y = f\Big(\frac{\partial}{\partial t}\nabla\Big)(X,Y).$$

Thus $\frac{\partial}{\partial t}\nabla$ is a tensor by Proposition 2.19. □

Lemma 4.4. *If X is a time independent vector field and $V = V(t)$ is a time dependent vector field, then*

$$\frac{\partial}{\partial t}\nabla_X V = \Big(\frac{\partial}{\partial t}\nabla\Big)(X,V) + \nabla_X\frac{\partial V}{\partial t}.$$

Proof. Fix a time independent vector field X. As $\nabla_X = \nabla_X^{(t)} : \mathscr{X}(M) \to \mathscr{X}(M)$ we see that

$$\frac{\partial}{\partial t}\nabla_X V \lim_{\delta\to 0}\frac{\nabla^{(t+\delta)}(X, V(t+\delta)) - \nabla^{(t)}(X, V(t))}{\delta}.$$

Since

$$\begin{aligned}
\nabla^{(t+\delta)}&(X, V(t+\delta)) - \nabla^{(t)}(X, V(t)) \\
&= \nabla^{(t+\delta)}(X, V(t+\delta)) - \nabla^{(t+\delta)}(X, V(t)) \\
&\quad + \Big(\nabla^{(t+\delta)} - \nabla^{(t)}\Big)(X, V(t)) \\
&= \nabla^{(t+\delta)}(X, V(t+\delta) - V(t)) + \big(\nabla^{(t+\delta)} - \nabla^{(t)}\big)(X, V(t)),
\end{aligned}$$

we conclude that

$$\begin{aligned}\frac{\partial}{\partial t}\nabla_X V &= \lim_{\delta\to 0}\frac{1}{\delta}\nabla^{(t+\delta)}(X, V(t+\delta)-V(t))\\ &\quad+\lim_{\delta\to 0}\frac{1}{\delta}\Big(\nabla^{(t+\delta)}-\nabla^{(t)}\Big)(X, V(t))\\ &= \nabla^{(t)}_X\Big(\lim_{\delta\to 0}\frac{V(t+\delta)-V(t)}{\delta}\Big)+\Big(\frac{\partial}{\partial t}\nabla\Big)(X,V). \qquad \square\end{aligned}$$

Furthermore, we would like to differentiate the Christoffel symbols $\Gamma^k_{ij} = dx^k(\nabla_{\partial_i}\partial_j)$ of the Levi–Civita connection ∇. To do this, we consider them as a map $\Gamma : \mathscr{X}(M)\times\mathscr{X}(M)\times\mathscr{T}^1_0(M)\to C^\infty(M)$ defined by $\Gamma(X,Y,\omega) := \omega(\nabla_X Y)$. With this we proceed in a similar fashion by defining $\frac{\partial}{\partial t}\Gamma$ to be

$$\Big(\frac{\partial}{\partial t}\Gamma\Big)(X,Y,\omega) := \frac{\partial}{\partial t}\Gamma(X,Y,\omega). \tag{4.8}$$

It is easy so see that $\frac{\partial}{\partial t}\Gamma$ is tensorial since $(\frac{\partial}{\partial t}\Gamma)(X,Y,\omega) = \frac{\partial}{\partial t}\omega(\nabla_X Y) = \omega(\frac{\partial}{\partial t}\nabla_X Y)$ and $\frac{\partial}{\partial t}\nabla$ is a tensor by Lemma 4.3.

4.3.2 Variation Formulas of the Curvature

We now derive evolution equations for geometric quantities under arbitrary metric variations. Note that $\frac{\partial}{\partial t}T = (\delta_{\dot g}T)(g) = (\delta_h T)(g)$ for a (k,ℓ)-tensor T, whenever the direction $h = \frac{\partial}{\partial t}g$ (where the first variation δ_h is taken in the sense of Appendix A).

Lemma 4.5. *Suppose $g(t)$ is a smooth one-parameter family of metrics on a manifold M such that $\frac{\partial}{\partial t}g = h$. Then*

$$\frac{\partial}{\partial t}g^{ij} = -g^{ik}g^{j\ell}h_{k\ell}. \tag{4.9}$$

Proof. As $g^{ik}g_{k\ell} = \delta^i_\ell$ we find that $0 = (\frac{\partial}{\partial t}g^{ik})\,g_{k\ell} + g^{ik}h_{k\ell}$. In which case $\frac{\partial}{\partial t}g^{ij} = -g^{ik}g^{j\ell}h_{k\ell} = -h^{ij}$. $\square$

Proposition 4.6. *Suppose $g(t)$ is a smooth one-parameter family of metrics on a manifold M such that $\frac{\partial}{\partial t}g = h$. Then the Levi–Civita connection Γ^k_{ij} of g evolves by*

$$\frac{\partial}{\partial t}\Gamma^k_{ij} = \frac{1}{2}g^{k\ell}\Big((\nabla_j h)(\partial_i,\partial_\ell)+(\nabla_i h)(\partial_j,\partial_\ell)-(\nabla_\ell h)(\partial_i,\partial_j)\Big).$$

Proof. As $\frac{\partial}{\partial t}\Gamma$ and ∇h are tensorial, we are free to work in any local coordinate chart (x^i). In particular, by choosing normal coordinates about a point p (and evaluating the computation at that point), (2.9) implies that

$$\frac{\partial}{\partial t}\Gamma_{ij}^{k} = \frac{1}{2}\Big(\frac{\partial}{\partial t}g^{k\ell}\Big)\cancel{(\partial_j g_{i\ell} + \partial_i g_{j\ell} - \partial_\ell g_{ij})} + \frac{1}{2}g^{k\ell}\frac{\partial}{\partial t}\Big(\partial_j g_{i\ell} + \partial_i g_{j\ell} - \partial_\ell g_{ij}\Big).$$

Using Proposition 2.29 we observe that

$$\frac{\partial}{\partial t}\partial_j g_{i\ell} = \partial_j\big(h(\partial_i, \partial_\ell)\big) = (\nabla_j h)(\partial_i, \partial_\ell) + h(\cancel{\nabla_j \partial_i}, \partial_\ell) + h(\partial_i, \cancel{\nabla_j \partial_\ell}),$$

from which the result now follows. ☐

Proposition 4.7. *Suppose $g(t)$ is a smooth one-parameter family of metrics on a manifold M such that $\frac{\partial}{\partial t}g = h$. Then the Riemannian curvature tensor evolves by*

$$\begin{aligned}\frac{\partial}{\partial t}R_{ijk}{}^{\ell} = \frac{1}{2}g^{\ell p}\Big(&\nabla_i\nabla_p h_{jk} + \nabla_j\nabla_k h_{ip} - \nabla_i\nabla_k h_{jp} - \nabla_j\nabla_p h_{ik}\\ &- R_{ijk}{}^{q}h_{qp} - R_{ijp}{}^{q}h_{qk}\Big).\end{aligned}$$

Proof. As the expression is tensorial, we are free to work in normal coordinates in a neighbourhood about a point p (and evaluating the expression at that point). Using Lemma 2.46 in these coordinates, we find that

$$\begin{aligned}\frac{\partial}{\partial t}R_{ijk}{}^{\ell} &= \frac{\partial}{\partial t}\big(\partial_j\Gamma_{ik}^{\ell} - \partial_i\Gamma_{jk}^{\ell}\big)\\ &\quad + \Big(\Big(\frac{\partial}{\partial t}\Gamma_{ik}^{m}\Big)\cancel{\Gamma_{jm}^{\ell}} + \cancel{\Gamma_{ik}^{m}}\Big(\frac{\partial}{\partial t}\Gamma_{jm}^{\ell}\Big)\Big) - \cancel{(i \leftrightarrow j)}\\ &= \partial_j\Big(\frac{\partial}{\partial t}\Gamma_{ik}^{\ell}\Big) - \partial_i\Big(\frac{\partial}{\partial t}\Gamma_{jk}^{\ell}\Big).\end{aligned}$$

From this, together with Proposition 4.6, we have that

$$\begin{aligned}\partial_j\Big(\frac{\partial}{\partial t}\Gamma_{ik}^{\ell}\Big) &= \frac{1}{2}\cancel{\partial_j g^{\ell p}}\Big(\nabla_k h_{ip} + \nabla_i h_{kp} - \nabla_p h_{ik}\Big)\\ &\quad + \frac{1}{2}g^{\ell p}\Big(\partial_j\big(\nabla_k h_{ip} + \nabla_i h_{kp} - \nabla_p h_{ik}\big)\Big)\\ &= \frac{1}{2}g^{\ell p}\Big(\nabla_j\nabla_k h_{ip} + \nabla_j\nabla_i h_{kp} - \nabla_j\nabla_p h_{ik}\Big),\end{aligned}$$

where the last equality – using Proposition 2.29 – is due to

$$\begin{aligned}\partial_j\big((\nabla h)(\partial_i, \partial_k, \partial_\ell)\big) &= \big(\nabla_j(\nabla h)\big)(\partial_i, \partial_k, \partial_\ell)\\ &\quad + (\nabla h)(\cancel{\nabla_j\partial_i}, \ldots) + \cdots + (\nabla h)(\ldots, \cancel{\nabla_j\partial_\ell})\\ &= (\nabla_j\nabla_i h)(\partial_k, \partial_\ell).\end{aligned}$$

Therefore,

$$
\begin{aligned}
\frac{\partial}{\partial t} R_{ijk}{}^{\ell} &= \frac{1}{2} g^{\ell p}\big(\nabla_j \nabla_k h_{ip} + \nabla_j \nabla_i h_{kp} - \nabla_j \nabla_p h_{ik}\big) \\
&\quad - \frac{1}{2} g^{\ell p}\big(\nabla_i \nabla_k h_{jp} + \nabla_i \nabla_j h_{kp} - \nabla_i \nabla_p h_{jk}\big) \qquad (4.10) \\
&= \frac{1}{2} g^{\ell p}\Big(\nabla_i \nabla_p h_{jk} + \nabla_j \nabla_k h_{ip} - \nabla_i \nabla_k h_{jp} - \nabla_j \nabla_p h_{ik} \\
&\qquad + \big(R(\partial_i, \partial_j) h\big)(\partial_k, \partial_p)\Big) \qquad (4.11)
\end{aligned}
$$

since $\nabla_j \nabla_i h_{kp} - \nabla_i \nabla_j h_{kp} = (R(\partial_i, \partial_j)h)(\partial_k, \partial_p)$ by Proposition 2.44. The desired equation now follows since we find, by Proposition 2.43, that

$$
\begin{aligned}
\big(R(\partial_i, \partial_j)h\big)(\partial_k, \partial_p) &= \cancel{R(\partial_i, \partial_j) h_{kp}} - h(R(\partial_i, \partial_j)\partial_k, \partial_p) - h(\partial_k, R(\partial_i, \partial_j)\partial_p) \\
&= -R_{ijk}{}^{q} h_{qp} - R_{ijp}{}^{q} h_{qk}. \qquad \square
\end{aligned}
$$

Proposition 4.8. *Suppose $g(t)$ is a smooth family of metrics on a manifold M with $\frac{\partial}{\partial t} g = h$. Then the $(4,0)$-Riemann curvature tensor R evolves by*

$$
\begin{aligned}
\frac{\partial}{\partial t} R_{ijk\ell} &= \frac{1}{2}\big(\nabla^2_{i,\ell} h_{jk} + \nabla^2_{j,k} h_{i\ell} - \nabla^2_{i,k} h_{j\ell} - \nabla^2_{j,\ell} h_{ik}\big) \\
&\quad + \frac{1}{2} g^{pq}\big(R_{ijkp} h_{q\ell} + R_{ijp\ell} h_{qk}\big).
\end{aligned}
$$

Proof. As $R_{ijk\ell} = R_{ijk}{}^{m} g_{m\ell}$, we have

$$
\frac{\partial}{\partial t} R_{ijk\ell} = R_{ijk}{}^{q} \frac{\partial}{\partial t} g_{q\ell} + g_{a\ell} \frac{\partial}{\partial t} R_{ijk}{}^{a}.
$$

Now since

$$
R_{ijk}{}^{q} \frac{\partial}{\partial t} g_{q\ell} = g^{pq} R_{ijkp} h_{q\ell},
$$

and (by Proposition 4.7)

$$
\begin{aligned}
g_{a\ell} \frac{\partial}{\partial t} R_{ijk}{}^{a} &= \frac{1}{2}\big(\nabla^2_{i,\ell} h_{jk} + \nabla^2_{j,k} h_{i\ell} - \nabla^2_{i,k} h_{j\ell} - \nabla^2_{j,\ell} h_{ik}\big) \\
&\quad - \frac{1}{2} g^{pq}\big(R_{ijkp} h_{q\ell} + R_{ij\ell p} h_{qk}\big)
\end{aligned}
$$

the result naturally follows. $\square$

Proposition 4.9. *Suppose $g(t)$ is a smooth one-parameter family of metrics on a manifold M such that $\frac{\partial}{\partial t} g = h$. Then the Ricci tensor* Ric *evolves by*

$$
\frac{\partial}{\partial t} R_{ik} = \frac{1}{2} g^{pq}\big(\nabla^2_{q,k} h_{ip} - \nabla^2_{i,k} h_{qp} + \nabla^2_{q,i} h_{kp} - \nabla^2_{q,p} h_{ik}\big).
$$

Proof. Recall from (4.10) that

$$\begin{aligned}\frac{\partial}{\partial t}R_{ijk}{}^{\ell} = \frac{1}{2}g^{\ell p}\big(&\nabla^2_{j,k}h_{ip} + \nabla^2_{j,i}h_{kp} - \nabla^2_{j,p}h_{ik}\\ &- \nabla^2_{i,k}h_{jp} - \nabla^2_{i,j}h_{kp} + \nabla^2_{i,p}h_{jk}\big).\end{aligned}$$

From which we find that

$$\begin{aligned}\frac{\partial}{\partial t}R_{ik} = \frac{\partial}{\partial t}R_{ijk}{}^{j} &= \frac{1}{2}g^{jp}\big(\nabla^2_{j,k}h_{ip} - \nabla^2_{i,k}h_{jp} + \nabla^2_{j,i}h_{kp} - \nabla^2_{j,p}h_{ik}\big)\\ &\quad + \frac{1}{2}\cancel{g^{qp}\big(-\nabla^2_{i,q}h_{kp} + \nabla^2_{i,p}h_{qk}\big)}. \qquad \square\end{aligned}$$

Proposition 4.10. *Suppose $g(t)$ is a smooth one-parameter family of metrics on a manifold M with $\frac{\partial}{\partial t}g = h$. Then the scalar curvature* Scal *evolves by*

$$\frac{\partial}{\partial t}\mathrm{Scal} = -\Delta \mathrm{tr}_g h + \delta^2 h - \langle h, \mathrm{Ric}\rangle\,,$$

where $\delta^2 h = g^{ij}g^{pq}\nabla^2_{q,j}h_{pi}$ is the 'divergence term'.

Proof. Using (4.9) and Proposition 4.9 we find that

$$\begin{aligned}\frac{\partial}{\partial t}\mathrm{Scal} &= R_{ik}\frac{\partial}{\partial t}g^{ik} + g^{ik}\frac{\partial}{\partial t}R_{ik}\\ &= -g^{ij}g^{k\ell}h_{j\ell}R_{ik} + \frac{1}{2}g^{ik}g^{pq}\Big(\nabla^2_{q,k}h_{ip} - \nabla^2_{i,k}h_{qp} + \nabla^2_{q,i}h_{kp} - \nabla^2_{q,p}h_{ik}\Big)\\ &= -g^{ij}g^{pq}h_{jq}R_{ip} + g^{ij}g^{pq}\nabla^2_{q,j}h_{ip} - g^{ij}g^{pq}\nabla^2_{i,j}h_{pq}\\ &= -h_{jq}R^{jq} + g^{ij}g^{pq}\nabla^2_{q,j}h_{pi} - \Delta\mathrm{tr}_g h. \qquad \square\end{aligned}$$

Proposition 4.11. *Suppose $g(t)$ is a smooth one-parameter family of metrics on a manifold M with $\frac{\partial}{\partial t}g = h$. Then the volume form $d\mu(g(t))$ evolves by*

$$\frac{\partial}{\partial t}d\mu = \frac{1}{2}\mathrm{tr}\,h\,d\mu.$$

To prove this, recall that:

Definition 4.12. The *adjunct* of a square matrix A is defined as the transpose of the cofactor matrix of A, that is

$$\mathrm{adj}\,A = \begin{pmatrix} \det A_{11} & -\det A_{21} & \dots \\ -\det A_{12} & \det A_{22} & \dots \\ \vdots & \vdots & \ddots \end{pmatrix}$$

where A_{ij} is obtained from A by striking out the i-th row and the j-th column.

Also recall that:

Lemma 4.13. *If A is a square matrix then* $A \operatorname{adj} A = \operatorname{adj} A\, A = \det A\, I_{n\times n}$. *Moreover, if* $\det A \neq 0$ *then* $A^{-1} = \frac{1}{\det A} \operatorname{adj} A$.

So if A is a square matrix with (i, j)-th entry a_{ij}, we can expand $\det A$ along the i-th row to get: $\det A = \sum_{k=1}^{n} (-1)^{i+k} \det A_{ik}$. Therefore by Lemma 4.13, the partial derivative of $\det A$ with respect to the (i, j)-th entry are

$$\begin{aligned}\frac{\partial}{\partial a_{ij}} \det A &= (-1)^{i+j} \det A_{ij} \\ &= (\operatorname{adj} A)_{ji} = \det A\, (A^{-1})_{ji}.\end{aligned} \tag{4.12}$$

Proof (Proposition 4.11). In local coordinates (x^i) the volume form can be written as $d\mu = \sqrt{\det g}\, dx^1 \wedge \ldots \wedge x^n$. So by (4.12) and the chain rule,

$$\begin{aligned}\frac{\partial}{\partial t}\sqrt{\det g} &= \frac{1}{2}\frac{1}{\sqrt{\det g}}\frac{\partial}{\partial t}\det g \\ &= \frac{1}{2}\frac{1}{\sqrt{\det g}}\frac{\partial \det g}{\partial g_{ij}}\frac{\partial g_{ij}}{\partial t} \\ &= \frac{1}{2}\sqrt{\det g}\,(g^{-1})_{ji} h_{ij} \\ &= \frac{1}{2} g^{ij} h_{ij}\,\sqrt{\det g} = \frac{1}{2}\operatorname{tr} h\,\sqrt{\det g}.\end{aligned}$$

Thus,

$$\frac{\partial}{\partial t} d\mu = \frac{\partial\sqrt{\det g}}{\partial t} dx^1 \wedge \ldots \wedge x^n = \frac{1}{2}\operatorname{tr} h\, d\mu. \qquad \square$$

4.4 Evolution of the Curvature Under the Ricci Flow

Using the results of the previous sections, it is now a relatively easy task to derive the evolution equations of the curvature, and its various traces, under the Ricci flow.

Theorem 4.14. *Suppose $g(t)$ is a solution of the Ricci flow, the $(4, 0)$-Riemannian tensor R evolves by*

$$\begin{aligned}\frac{\partial}{\partial t} R_{ijk\ell} &= \Delta R_{ijk\ell} + 2(B_{ijk\ell} - B_{ij\ell k} - B_{i\ell jk} + B_{ikj\ell}) \\ &\quad - g^{pq}(R_{pjk\ell} R_{qi} + R_{ipk\ell} R_{qj} + R_{ijkp} R_{q\ell} + R_{ijp\ell} R_{qk}).\end{aligned}$$

Proof. By Proposition 4.8, with $\frac{\partial}{\partial t} g_{ij} = -2R_{ij}$, the time derivative of $R_{ijk\ell}$ satisfies

$$\begin{aligned}&\nabla^2_{i,\ell}R_{jk}+\nabla^2_{j,k}R_{i\ell}-\nabla^2_{i,k}R_{j\ell}-\nabla^2_{j,\ell}R_{ik}\\&\quad=-\frac{\partial}{\partial t}R_{ijk\ell}-g^{pq}\big(R_{ijkp}R_{q\ell}+R_{ijp\ell}R_{qk}\big).\end{aligned}$$

By Proposition 4.2, with indices k and ℓ switched, the Laplacian of R satisfies

$$\begin{aligned}&\nabla^2_{i,\ell}R_{jk}-\nabla^2_{j,\ell}R_{ik}+\nabla^2_{j,k}R_{i\ell}-\nabla^2_{i,k}R_{j\ell}\\&\quad=\Delta R_{ij\ell k}+2(B_{ij\ell k}-B_{ijk\ell}-B_{ikj\ell}+B_{i\ell jk})\\&\qquad-g^{pq}(R_{qj\ell k}R_{pi}+R_{iq\ell k}R_{pj}).\end{aligned}$$

Combining these equations gives

$$\begin{aligned}-\Delta R_{ijk\ell}=\Delta R_{ij\ell k}=&-\frac{\partial}{\partial t}R_{ijk\ell}-2(B_{ij\ell k}-B_{ijk\ell}-B_{ikj\ell}+B_{i\ell jk})\\&+g^{pq}(R_{qj\ell k}R_{pi}+R_{iq\ell k}R_{pj})\\&-g^{pq}(R_{ijkp}R_{q\ell}+R_{ijp\ell}R_{qk}).\end{aligned}$$ □

We can also derive, without too much effort, the evolution of the following quantities under the Ricci flow.

Corollary 4.15. *Under the Ricci flow, the connection coefficients evolve by*

$$\frac{\partial}{\partial t}\Gamma^k_{ij}=-g^{k\ell}\Big((\nabla_j\mathrm{Ric})(\partial_i,\partial_\ell)+(\nabla_i\mathrm{Ric})(\partial_j,\partial_\ell)-(\nabla_\ell\mathrm{Ric})(\partial_i,\partial_j)\Big).$$

Corollary 4.16. *Under the Ricci flow, the volume form of g evolves by*

$$\frac{\partial}{\partial t}d\mu=-\mathrm{Scal}\,d\mu.$$

Corollary 4.17. *Under the Ricci flow,*

$$\begin{aligned}\frac{\partial}{\partial t}R_{ik}&=\Delta R_{ik}+\nabla^2_{ik}\mathrm{Scal}-g^{pq}(\nabla^2_{q,i}R_{kp}+\nabla^2_{q,k}R_{ip}),\\\frac{\partial}{\partial t}\mathrm{Scal}&=2\Delta\mathrm{Scal}-2g^{ij}g^{pq}\nabla^2_{q,j}R_{pi}+2|\mathrm{Ric}|^2.\end{aligned}$$

The proof of these corollaries follow easily by substituting $\frac{\partial}{\partial t}g_{ij}=-2R_{ij}$ into Propositions 4.6, 4.11, 4.9 and 4.10 respectively.

We note that the formulas in the last corollary can be simplified as follows.

Corollary 4.18. *Under the Ricci flow,*

$$\frac{\partial}{\partial t}R_{ik}=\Delta R_{ik}+2g^{pq}g^{rs}R_{pikr}R_{qs}-2g^{pq}R_{ip}R_{qk}.$$

Proof. By (4.9) the time derivative of $R_{ik} = g^{j\ell} R_{ijk\ell}$ is $\frac{\partial}{\partial t} R_{ik} = g^{j\ell} \frac{\partial}{\partial t} R_{ijk\ell} - 2g^{jp} g^{\ell q} R_{pq} R_{ijk\ell}$. Substituting the expression for $\frac{\partial}{\partial t} R_{ijk\ell}$ in Theorem 4.14 (with $g^{j\ell} \Delta R_{ijk\ell} = \Delta R_{ik}$ from (2.15)) results in

$$\begin{aligned}\frac{\partial}{\partial t} R_{ik} &= \Delta R_{ik} + 2g^{j\ell}(B_{ijk\ell} - B_{ij\ell k} - B_{i\ell jk} + B_{ikj\ell}) \\ &\quad - g^{j\ell} g^{pq}(R_{pjk\ell} R_{qi} + R_{ipk\ell} R_{qj} + R_{ijp\ell} R_{qk} + R_{ijkp} R_{q\ell}).\end{aligned}$$

As we find that

$$\begin{aligned}&2g^{j\ell}(B_{ijk\ell} - B_{ij\ell k} - B_{i\ell jk} + B_{ikj\ell}) \\ &\quad = 2g^{j\ell} B_{ijk\ell} - 2g^{j\ell}(B_{i\ell jk} + B_{ij\ell k}) + 2g^{pr} g^{qs} R_{piqk} R_{rs} \\ &\quad = 2g^{j\ell} B_{ijk\ell} - 4g^{j\ell} B_{ij\ell k} + 2g^{pr} g^{qs} R_{piqk} R_{rs} \\ &\quad = 2g^{j\ell}(B_{ijk\ell} - 2B_{ij\ell k}) + 2g^{pr} g^{qs} R_{piqk} R_{rs}\end{aligned}$$

and

$$\begin{aligned}&g^{j\ell} g^{pq}(R_{pjk\ell} R_{qi} + R_{ipk\ell} R_{qj} + R_{ijp\ell} R_{qk} + R_{ijkp} R_{q\ell}) \\ &\quad = 2g^{pq} R_{pi} R_{qk} + g^{j\ell} g^{pq} R_{ipk\ell} R_{qj} + g^{j\ell} g^{pq} R_{ijkp} R_{q\ell} \\ &\quad = 2g^{pq} R_{pi} R_{qk} + 2g^{pr} g^{qs} R_{piqk} R_{rs},\end{aligned}$$

it follows that

$$\frac{\partial}{\partial t} R_{ik} = \Delta R_{ik} + 2g^{j\ell}(B_{ijk\ell} - 2B_{ij\ell k}) + 2g^{pr} g^{qs} R_{piqk} R_{rs} - 2g^{pq} R_{pi} R_{qk}.$$

The desired result now follows from the following claim.

Claim 4.19. For any metric g_{ij}, the tensor $B_{ijk\ell}$ satisfies the identity

$$g^{j\ell}(B_{ijk\ell} - 2B_{ij\ell k}) = 0.$$

Proof of Claim. Using the Bianchi identities,

$$\begin{aligned}g^{j\ell} B_{ijk\ell} &= g^{j\ell} g^{pr} g^{qs} R_{piqj} R_{rks\ell} \\ &= g^{j\ell} g^{pr} g^{qs} R_{pqij} R_{rsk\ell} \\ &= g^{j\ell} g^{pr} g^{qs}(R_{piqj} - R_{pjqi})(R_{rks\ell} - R_{r\ell sk}) \\ &= 2g^{j\ell}(B_{ijk\ell} - B_{ij\ell k}).\end{aligned}$$

□

Corollary 4.20. *Under the Ricci flow,*

$$\frac{\partial}{\partial t} \mathrm{Scal} = \Delta \mathrm{Scal} + 2|\mathrm{Ric}|^2.$$

Proof. From Corollary 4.17 it suffices to show that

$$2g^{ij}g^{pq}\nabla^2_{q,j}R_{pi} = g^{pq}\nabla_q\nabla_p\mathrm{Scal} = \Delta\mathrm{Scal}.$$

To do this we claim:

Claim 4.21. The identity

$$\frac{1}{2}\nabla_q\nabla_p\mathrm{Scal} = g^{ij}\nabla_q\nabla_j R_{pi}$$

holds true.

Proof of Claim. By the contracted second Bianchi identity (2.16),

$$\begin{aligned}\frac{1}{2}(\nabla\mathrm{Scal})(\partial_p) = \frac{1}{2}\nabla_p\mathrm{Scal} = g^{ij}\nabla_j R_{pi} &= (g^{-1}\otimes\nabla\mathrm{Ric})(\partial_i,\partial_j,\partial_j,\partial_p,\partial_i)\\ &= (\mathrm{tr}_{14}\,\mathrm{tr}_{23}\,g^{-1}\otimes\nabla\mathrm{Ric})(\partial_p)\\ &= (\mathrm{tr}\,g^{-1}\otimes\nabla\mathrm{Ric})(\partial_p).\end{aligned}$$

As $\nabla_q(\mathrm{tr}\,g^{-1}\otimes\nabla\mathrm{Ric}) = \mathrm{tr}\,g^{-1}\otimes\nabla_q(\nabla\mathrm{Ric})$ we find that

$$\begin{aligned}\frac{1}{2}\nabla_q\nabla_p\mathrm{Scal} &= \frac{1}{2}(\nabla_q(\nabla\mathrm{Scal}))(\partial_p)\\ &= (\mathrm{tr}\,g^{-1}\otimes\nabla_q(\nabla\mathrm{Ric}))(\partial_p)\\ &= g^{ij}\nabla_q\nabla_j R_{pi}.\end{aligned}$$ □

Remark 4.22. The evolution of the scalar curvature by Corollary 4.20 provides a simple illustration of the fact that the Ricci flow 'prefers' positive curvature. In this case the two components $\Delta\mathrm{Scal}$ and $2|\mathrm{Ric}|^2$ can be interpreted in the following way: The dissipative term $\Delta\mathrm{Scal}$ reflects the fact that a point in M with a higher average curvature than its neighbours will tend to revert to the mean. The nonlinear term $2|\mathrm{Ric}|^2$ reflects the fact that if one is in a positive curvature region (e.g. a region behaving like a sphere), then the metric will contract, thus increasing the curvature to be even more positive. Conversely, if one is in a negative curvature region (such as a region behaving like a saddle), then the metric will expand, thus weakening the negativity of curvature. In both cases the curvature is trending upwards, consistent with the non-negativity of $2|\mathrm{Ric}|^2$.

4.5 A Closer Look at the Curvature Tensor

So far we have managed to derive, in Theorem 4.14, a heat-type evolution equation for the curvature tensor under the Ricci flow. As we seek to deform the metric so it has constant sectional curvature, we need to look at the relationship between the algebraic properties of the curvature tensor and the global topological and geometry of the manifold.

In three dimensions the curvature is relatively simple algebraically, and in four dimensions still somewhat tractable, but in higher dimensions the curvature becomes very complicated and hard to study. To get a glimpse of this we will look closely at the algebraic structure, in particular that of the Weyl curvature tensor. To do this though, we first need to define the following product.

4.5.1 Kulkarni–Nomizu Product

Given two $(2,0)$-tensors we want to build a $(4,0)$-tensor that has the same symmetries as that of the algebraic Riemannian curvature tensor (that is, a $(4,0)$-tensor that satisfies symmetry properties (i)–(iv) in Sect. 2.7.4.1). To do this we need a map, called the Kulkarni–Nomizu product, of the form

$$\owedge : \mathrm{Sym}^2(M) \times \mathrm{Sym}^2(M) \to \mathrm{Curv}(M),$$

where $\mathrm{Sym}^2(M)$ is the bundle of symmetric $(2,0)$-tensors and $\mathrm{Curv}(M)$ is the bundle of curvature tensors. Thus given $\alpha, \beta \in \mathrm{Sym}^2(M)$ we require the product $\alpha \owedge \beta$ to satisfy the following symmetries:

(a) Antisymmetric in the first two arguments: $(\alpha \owedge \beta)_{ijk\ell} = -(\alpha \odot \beta)_{jik\ell}$
(b) Antisymmetric in the last two arguments: $(\alpha \owedge \beta)_{ijk\ell} = -(\alpha \owedge \beta)_{ij\ell k}$
(c) Symmetric paired arguments: $(\alpha \owedge \beta)_{ijk\ell} = (\alpha \owedge \beta)_{k\ell ij}$
(d) Satisfy the Bianchi identity: $(\alpha \owedge \beta)_{ijk\ell} + (\alpha \owedge \beta)_{jki\ell} + (\alpha \owedge \beta)_{kij\ell} = 0$

A natural way to build $\alpha \owedge \beta$ is to use the tensor product. By linearity we expect $\alpha \owedge \beta$ to be a sum of $\alpha \otimes \beta$ with components permuted in such a way that the symmetries matches that of the algebraic Riemann curvature tensor. Hence all that is needed is to find the correct permutations.

Now as α and β are symmetric, terms of the form $\alpha_{ij}\beta_{k\ell}$ are disallowed since this would contradict (a) and (b). So we need to mix i, j with k, ℓ across the tensors α and β. If we naïvely suppose one of the terms is $\alpha_{ik}\beta_{j\ell}$, then (c) implies we will also need $\alpha_{j\ell}\beta_{ik}$ and by (a), (b) we will also need $-\alpha_{jk}\beta_{i\ell}$ and $-\alpha_{i\ell}\beta_{jk}$. Therefore by defining

$$(\alpha \owedge \beta)_{ijk\ell} := \alpha_{ik}\beta_{j\ell} + \alpha_{j\ell}\beta_{ik} - \alpha_{jk}\beta_{i\ell} - \alpha_{i\ell}\beta_{jk} \tag{4.13}$$

or alternatively

$$\begin{aligned}(\alpha \owedge \beta)(v_1, v_2, v_3, v_4) &= (\alpha \otimes \beta)(v_1, v_3, v_2, v_4) + (\alpha \otimes \beta)(v_2, v_4, v_1, v_3) \\ &\quad - (\alpha \otimes \beta)(v_1, v_4, v_2, v_3) - (\alpha \otimes \beta)(v_2, v_3, v_1, v_4),\end{aligned}$$

properties (a)–(c) are immediately satisfied; inspection also shows that the Bianchi identity holds as well. Thus we have constructed a $(4,0)$-tensor that has all of the symmetries of that of the algebraic curvature tensor.

4.5.2 Weyl Curvature Tensor

The Weyl curvature tensor is defined to be the *traceless component* of the Riemann curvature tensor. It can be obtained from the full curvature tensor R by subtracting out various traces. To find an exact expression, we seek to subtract a tensor C which is the sum of the scalar and traceless Ricci[2] parts of R, with the additional conditions that C must have the same traces and algebraic structures as that of R. By using the Kulkarni–Nomizu product, we consider the tensor C as taking the form

$$C = c_1 \mathrm{Scal}\, g \owedge g + c_2 \overset{\circ}{\mathrm{Ric}} \owedge g,$$

where c_1 and c_2 are scalars. As $\operatorname{tr} R = \operatorname{tr} C$, where the trace is taken over *any* pair of indices, we must have

$$\mathrm{Ric}_{ik} = g^{j\ell} R_{ijk\ell} = g^{j\ell} C_{ijk\ell}.$$

Now since

$$\begin{aligned} C_{ijk\ell} &= 2c_1 \mathrm{Scal}(g_{ik} g_{j\ell} - g_{i\ell} g_{jk}) \\ &\quad + c_2(\overset{\circ}{\mathrm{Ric}}_{ik} g_{j\ell} + \overset{\circ}{\mathrm{Ric}}_{j\ell} g_{ik} - \overset{\circ}{\mathrm{Ric}}_{i\ell} g_{jk} - \overset{\circ}{\mathrm{Ric}}_{jk} g_{i\ell}), \end{aligned}$$

it follows that

$$\begin{aligned} \frac{1}{n} \mathrm{Scal}\, g_{ik} + \overset{\circ}{\mathrm{Ric}}_{ik} = \mathrm{Ric}_{ik} &= g^{j\ell} C_{ijk\ell} \\ &= 2c_1(n-1) \mathrm{Scal}\, g_{ik} + c_2(n-2)\, \overset{\circ}{\mathrm{Ric}}_{ik}. \end{aligned}$$

In which case the scalars $c_1 = \frac{1}{2n(n-1)}$ and $c_2 = \frac{1}{n-2}$.

Therefore the Weyl tensor W must be of the form

$$\mathrm{Weyl} = R - \frac{1}{n-2} \overset{\circ}{\mathrm{Ric}} \owedge g - \frac{\mathrm{Scal}}{2n(n-1)} g \owedge g. \tag{4.14}$$

---

[2] Where the traceless Ricci tensor $\overset{\circ}{\mathrm{Ric}} := \mathrm{Ric} - \frac{\mathrm{Scal}}{n} g$, since $g^{ik} \overset{\circ}{\mathrm{Ric}}_{ik} = \mathrm{Scal} - \frac{\mathrm{Scal}}{n} g^{ik} \mathrm{Ric}_{ik} = \mathrm{Scal} - \frac{\mathrm{Scal}}{n} \delta^i_i = 0$.

Alternatively, by using $\overset{\circ}{\mathrm{Ric}} = \mathrm{Ric} - \frac{\mathrm{Scal}}{n} g$, we could also write

$$\mathrm{Weyl} = R - \frac{1}{n-2}\mathrm{Ric} \owedge g + \frac{\mathrm{Scal}}{2(n-1)(n-2)} g \owedge g. \tag{4.15}$$

Since W is defined using the Kulkarni–Nomizu product it has the same symmetries as the curvature tensor, but by definition all of its traces vanish. Indeed, one can check by hand that ${W_{ijk}}^{j} = 0$, or indeed any other trace, as per definition. Also note that

$$\left|R\right|^2 = \left|\frac{\mathrm{Scal}}{2n(n-1)} g \owedge g\right|^2 + \left|\frac{1}{n-2}\overset{\circ}{\mathrm{Ric}} \owedge g\right|^2 + \left|\mathrm{Weyl}\right|^2$$

as the decomposition is orthogonal and that the metric g has constant sectional curvature if and only if $\overset{\circ}{\mathrm{Ric}} = 0$ and $\mathrm{Weyl} = 0$ (cf. Sect. 12.3.1).

4.5.3 Sphere Theorem of Huisken–Margerin–Nishikawa

In three dimensions the Weyl tensor vanishes, and the curvature can be understood solely in terms of the Ricci tensor (see Sect. 7.5.3 for one way of doing this). One of the first insights into the differentiable pinching problem, for dimensions $n \geq 4$, was made independently by Huisken [Hui85], Nishikawa [Nis86] and Margerin [Mar86]. By using the Ricci flow, they were able show that a manifold is diffeomorphic to a spherical space form, provided the norm of the Weyl curvature tensor and the norm of the traceless Ricci tensor are not too large compared to the scalar curvature at each point.

Theorem 4.23. *Let $n \geq 4$. If the curvature tensor of a smooth compact n-dimensional Riemannian manifold M of positive scalar curvature satisfies*

$$\left|\mathrm{Weyl}\right|^2 + \left|\frac{1}{n-2}\overset{\circ}{\mathrm{Ric}} \owedge g\right|^2 \leq \delta_n \frac{2}{n(n-1)}\mathrm{Scal}^2 \tag{4.16}$$

with $\delta_4 = \frac{1}{5}$, $\delta_5 = \frac{1}{10}$, and $\delta_n = \frac{2}{(n-2)(n+1)}$ for $n \geq 6$, then the Ricci flow has a solution $g(t)$ on a maximal finite time interval $[0, T)$, and $\frac{g(t)}{2(n-1)(T-t)}$ converges in C^∞ to a metric of constant curvature 1 as $t \to \infty$. In particular, M is diffeomorphic to a spherical space form.

Remark 4.24. The Riemann curvature tensor can be considered as an element of the vector space of symmetric bilinear forms acting on the space $\bigwedge^2 TM$ (see Sect. 12.2). The inequality (4.16) defines a cone in this vector space around the line of constant curvature tensors, in which the Riemann tensor must lie. In Chaps. 12 and 13 we will return to this idea of constructing cones in the space of curvature tensors.

The technique of the proof follows Hamilton's original paper [Ham82b]. The approach is to show that if the scalar-free part of the curvature is small compared to the scalar curvature initially, then it must remain so for all time. In which case we need to show, under the hypothesis (4.16) with an appropriate δ_n, there exists $\varepsilon > 0$ such that

$$\left|\mathrm{Weyl}\right|^2 + \left|\frac{1}{n-2}\mathring{\mathrm{Ric}} \owedge g\right|^2 \leq \delta_n \, (1-\varepsilon)^2 \, \frac{2}{n(n-1)}\mathrm{Scal}^2 \tag{4.17}$$

remains valid as long as the solution to the Ricci flow exists for times $t \in [0, T)$. This is achieved by working with

$$\mathring{R} := R - \frac{2\,\mathrm{Scal}}{n(n-1)} g \owedge g,$$

which measures the failure of g to have (pointwise) constant positive sectional curvature (cf. Sect. 12.3.1). It is proved using the maximum principle (which we discuss in Chap. 7) that a bound can be obtained on a function of the form

$$F_\sigma = \frac{|\mathring{R}|^2}{\mathrm{Scal}^{2-\sigma}},$$

for $\sigma \geq 0$, yielding the following result.[3]

Proposition 4.25 ([Hui85, Sect. 3])**.** *If the inequality (4.17), that is*

$$|\mathring{R}|^2 \leq \delta_n \, (1-\varepsilon)^2 \, \frac{2}{n(n-1)}\mathrm{Scal}^2,$$

holds at time $t = 0$, then it remains so on $0 \leq t < T$. Moreover, there are constants $C < \infty$ and $\sigma > 0$, depending on n and the initial metric, such that

$$|\mathring{R}|^2 \leq C\,\mathrm{Scal}^{2-\sigma}$$

holds for $0 \leq t < T$.

Remark 4.26. From this analysis we see that the main obstacle to obtaining similar sphere-type theorem, under weaker pinching conditions than that of Theorem 4.23, is the Weyl curvature tensor W. Controlling the behaviour of W under the Ricci flow, for dimensions $n \geq 4$, has proved to be a major technical hurdle, which was finally overcome by the efforts of Böhm and Wilking [BW08]. We discuss their method in Chap. 12.

---

[3] The quantity $|\mathring{R}|^2$ is a higher dimensional analogue of the quantity $|\mathring{\mathrm{Ric}}|^2 = |\mathrm{Ric}|^2 - \frac{1}{3}\mathrm{Scal}^2$ used by Hamilton [Ham82b] in the $n = 3$ case, which measures how far the eigenvalues of the Ricci tensor diverge from each other.

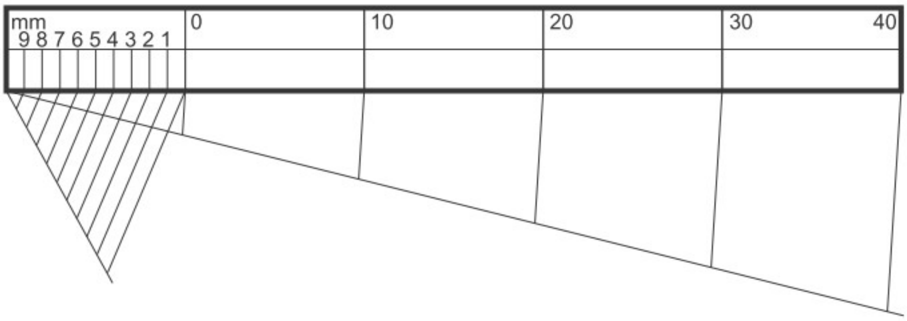

Figure 1.2 Plain scale 30 mm = 10 mm (RF = $\frac{3}{1}$).

Diagonal Scales

There is a limit to the number of divisions that can be constructed on a plain scale. Try to divide 10 mm into 50 parts; you will find that it is almost impossible. The architect, cartographer and surveyor all have the problem of having to subdivide into smaller units than a plain scale allows. A diagonal scale allows you to divide into smaller units.

Before looking at any particular diagonal scale, let us first look at the underlying principle.

Figure 1.3 shows a triangle ABC. Suppose that AB is 10 mm long and BC is divided into 10 equal parts. Lines from these equal parts have been drawn parallel to AB and numbered from 1 to 10.

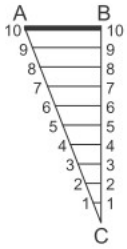

Figure 1.3 Showing how to divide a line AB into 10 equal parts.

It should be obvious that the line 5–5 is half the length of AB. Similarly, the line 1–1 is $\frac{1}{10}$ the length of AB and line 7–7 is $\frac{7}{10}$ the length of AB. (If you wish to prove this mathematically use similar triangles.)

You can see that the lengths of the lines 1–1 to 10–10 increase by 1 mm each time you go up a line. If the length of AB had been 1 mm to begin with, the increases would have been $\frac{1}{10}$ mm each time. In this way small lengths can be divided into very much smaller lengths, and can be easily picked out.

Three examples of diagonal scales follow.

This scale would be used where the drawing is twice the size of the natural object and the draughtsperson has to be able to measure on a scale accurate to 0.1 mm.

The longest natural dimension is 60 mm. This length is first divided into six 10 mm intervals. The first 10 mm is then divided into 10 parts, each 1 mm wide (scaled). Each of these 1 mm intervals is divided with a diagonal into 10 more equal parts (Fig. 1.4).

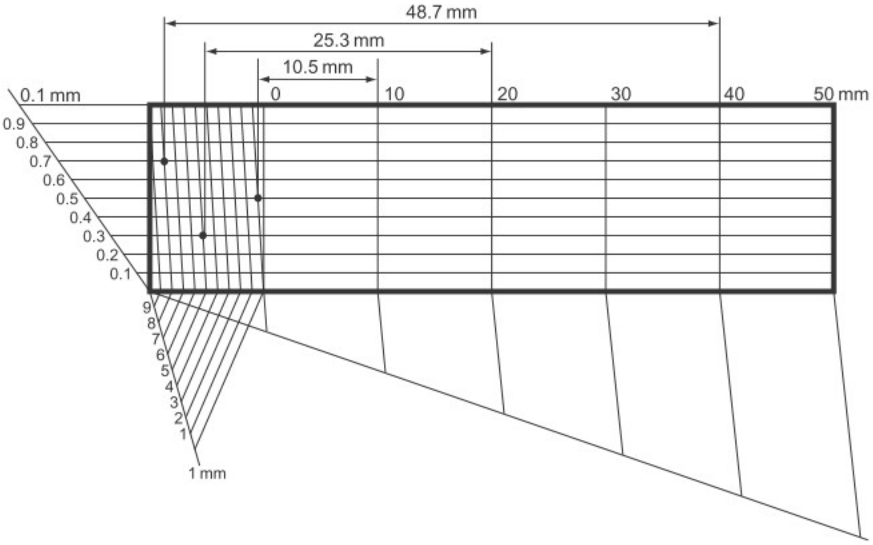

Figure 1.4 Diagonal scale 20 mm = 10 mm to read to 0.1 mm (RF = $\frac{2}{1}$).

To construct a diagonal scale, 30 mm = 1 mm, 4 m long to read to 10 mm (Fig. 1.5).

Proportional Scales

It is possible to construct one plain scale directly from another, so that the new scale is proportional to the original one. An example of this is given in Fig. 1.7. The new scale is a copy of the original one but is $\frac{7}{4}$ times larger. The proportions of the scales can be varied by changing the ratios of the lines AB to BC.

(b) Construct a plain scale with an RF of $\frac{5}{4}$ suitable for use in the making of an enlarged drawing of this key. Do *not* draw this key again.

Southern Regional Examinations Board (question originally set in imperial units).

2. Construct a plain scale of 50 mm = 300 mm to read to 10 mm up to 1200 mm. Using this scale, draw to scale a triangle having a perimeter of 1200 mm and having sides in the ratio 3:4:6. Print neatly along each side the length to the nearest 10 mm.

Oxford Local Examinations (question originally set in imperial units; see Chapter 2 for information not in Chapter 1).

3. Construct the plain figure shown in Fig. 2 and then, by means of a proportional scale, draw a similar figure standing on the base AG. All angles must be constructed geometrically in the first figure. Measure and state the length of the side corresponding with CD.

Oxford Local Examinations (question originally set in imperial units; see Chapter 2 for information not in Chapter 1).

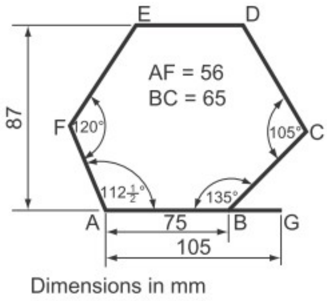

Figure 2

4. Construct a diagonal scale in which 40 mm represents 1 m. The scale is to read down to 10 mm and is to cover a range of 5 m. Mark off a distance of 4 m 780 mm.

5. Construct a diagonal scale of 25 mm to represent 1 m which can be used to measure m and 10 mm up to 8 m. Using this scale construct a quadrilateral ABCD which stands on a base AB of length 4 m 720 mm and having BC = 3 m 530 mm, AD = 4 m 170 mm, $\angle ABC = 120°$ and $\angle ADC = 90°$. Measure and state the lengths of the two diagonals and the perpendicular height, all correct to the nearest 10 mm. Angles must be constructed geometrically.

Oxford Local Examinations (question originally set in imperial units; see Chapter 2 for information not in Chapter 1).

6. Construct a diagonal scale, 10 times full size, to show mm and tenths of a mm and to read to a maximum of 20 mm. Using the scale, construct a triangle ABC with AB 17.4 mm, BC 13.8 mm and AC 11 mm.

Oxford and Cambridge Schools Examinations Board.

2 The Construction of Geometric Figures from Given Data

This chapter is concerned with the construction of plane geometric figures. Plane geometry is the geometry of figures that are two-dimensional, i.e. figures that have only length and breadth. Solid geometry is the geometry of three-dimensional figures.

There are an endless number of plane figures but we will concern ourselves only with the more common ones – the triangle, the quadrilateral and the better known polygons.

Before we look at any particular figure, there are a few constructions that must be revised (Figs. 2.1–2.13).

The Triangle

Definitions

The triangle is a plane figure bounded by three straight sides.

A *scalene* triangle is a triangle with three unequal sides and three unequal angles.
An *isosceles* triangle is a triangle with two sides, and hence two angles, equal.
An *equilateral* triangle is a triangle with all the sides, and hence all the angles, equal.
A *right-angled* triangle is a triangle containing one right angle. The side opposite the right angle is called the 'hypotenuse'.

Constructions

To construct an equilateral triangle, given one of the sides (Fig. 2.14).

1. Draw a line AB, equal to the length of the side.
2. With compass point on A and radius AB, draw an arc as shown.
3. With compass point on B, and with the same radius, draw another arc to cut the first arc at C.

Triangle ABC is equilateral.

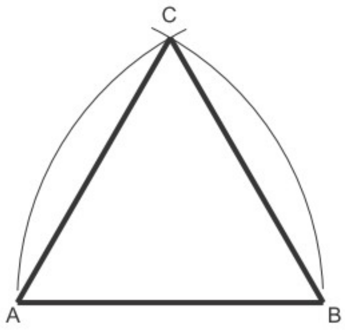

Figure 2.14

To construct an isosceles triangle given the perimeter and the altitude (Fig. 2.15).

1. Draw line AB equal to half the perimeter.
2. From B erect a perpendicular and make BC equal to the altitude.
3. Join AC and bisect it to cut AB in D.
4. Produce DB so that BE = BD. CDE is the required triangle.

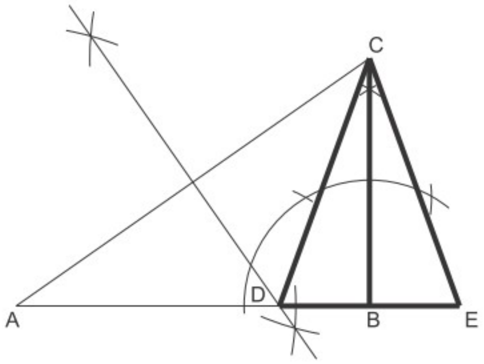

Figure 2.15

To construct a triangle, given the base angles and the altitude (Fig. 2.16).

1. Draw a line AB.
2. Construct CD parallel to AB so that the distance between them is equal to the altitude.
3. From any point E, on CD, draw CÊF and DÊG so that they cut AB in F and G, respectively.

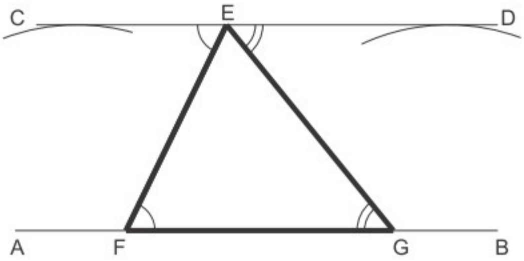

Figure 2.16

Since CÊF = EF̂G and DÊG = EĜF (alternate angles), then EFG is the required triangle.

To construct a triangle given the base, the altitude and the vertical angle (Fig. 2.17).

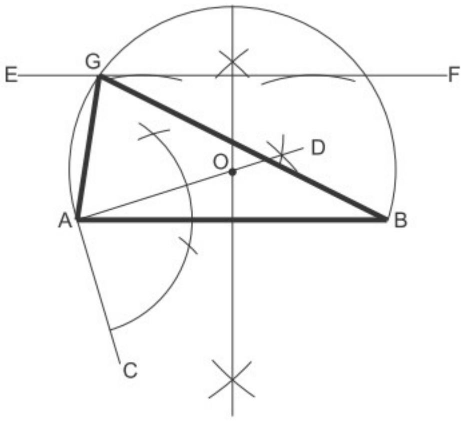

Figure 2.17

1. Draw the base AB.
2. Construct BÂC equal to the vertical angle.
3. Erect AD perpendicular to AC.
4. Bisect AB to meet AD in O.
5. With centre O and radius OA (= OB), draw a circle.
6. Construct EF parallel to AB so that the distance between them is equal to the altitude.

Let EF intersect the circle in G.

ABG is the required triangle.

To construct a triangle given the perimeter and the ratio of the sides (Fig. 2.18).

1. Draw the line AB equal in length to the perimeter.
2. Divide AB into the required ratio (e.g. 4:3:6).
3. With centre C and radius CA, draw an arc.
4. With centre D and radius DB, draw an arc to intersect the first arc in E.

ECD is the required triangle.

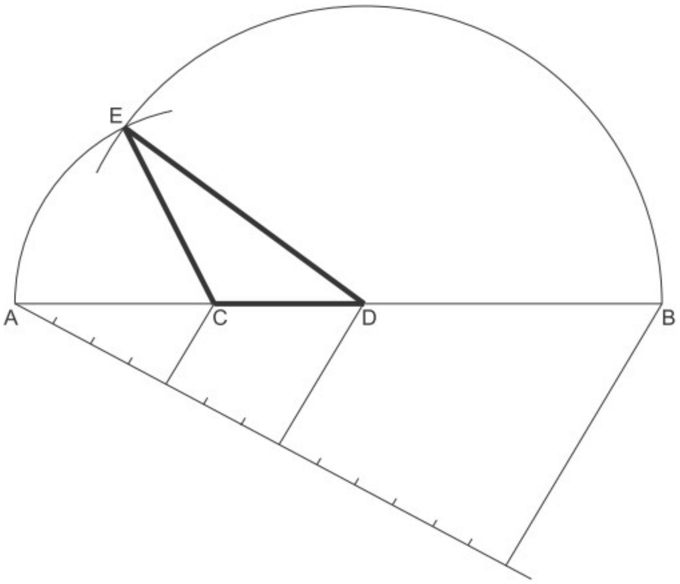

Figure 2.18

To construct a triangle given the perimeter, the altitude and the vertical angle (Fig. 2.19).

1. Draw AB and AC each equal to half the perimeter, so that CAB is the vertical angle.
2. From B and C erect perpendiculars to meet in D.
3. With centre D, draw a circle, radius DB (= DC).
4. With centre A and radius equal to the altitude, draw an arc.
5. Construct the common tangent between the circle and the arc. Let this tangent intersect AC in F and AB in E. (For tangent construction see Chapter 4.)

FEA is the required triangle.

A
Common tangent

Figure 2.19

To construct a triangle similar to another triangle but with a different perimeter (Fig. 2.20).

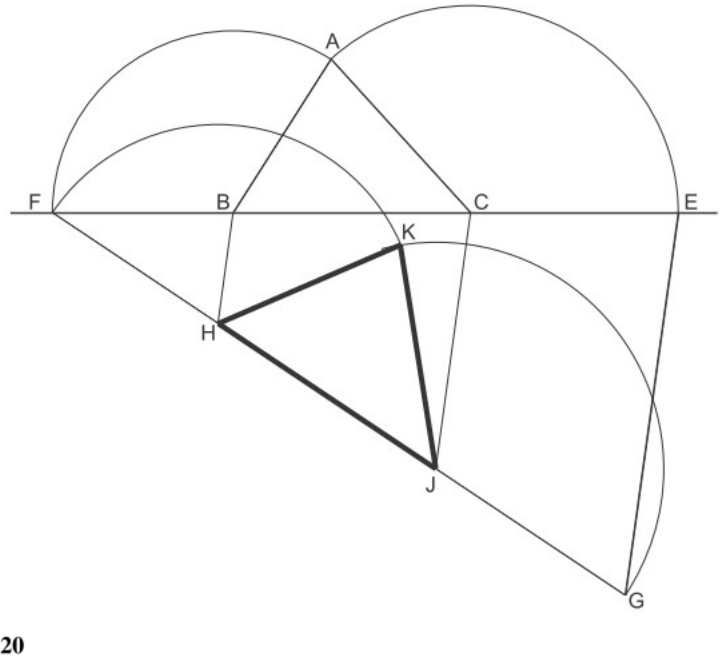

Figure 2.20

1. Draw the given triangle ABC.
2. Produce BC in both directions.
3. With compass point on B and radius BA, draw an arc to cut CB produced in F.
4. With compass point on C and radius CA, draw an arc to cut BC produced in E.
5. Draw a line FG equal in length to the required perimeter.
6. Join EG and draw CJ and BH parallel to it.
7. With centre H and radius HF, draw an arc.
8. With centre J and radius JG, draw another arc to intersect the first arc in K.

HKJ is the required triangle.

The Quadrilateral

Definitions

The quadrilateral is a plane figure bounded by four straight sides.

A *square* is a quadrilateral with all four sides of equal length and one of its angles (and hence the other three) a right angle.
A *rectangle* is a quadrilateral with its opposite sides of equal length and one of its angles (and hence the other three) a right angle.
A *parallelogram* is a quadrilateral with opposite sides equal and therefore parallel.
A *rhombus* is a quadrilateral with all four sides equal.
A *trapezium* is a quadrilateral with one pair of opposite sides parallel.
A *trapezoid* is a quadrilateral with all four sides and angles unequal.

Constructions

To construct a square given the length of the side (Fig. 2.21).

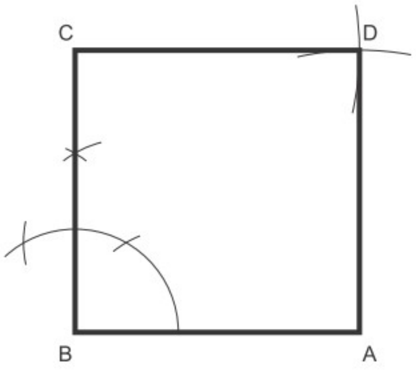

Figure 2.21

1. Draw the side AB.
2. From B erect a perpendicular.
3. Mark off the length of side BC.
4. With centres A and C draw arcs, radius equal to the length of the side of the square, to intersect at D.

ABCD is the required square.

To construct a square given the diagonal (Fig. 2.22).

1. Draw the diagonal AC.
2. Bisect AC.
3. With centre O and radius OA (= OC), draw a circle to cut the bisecting line in B and D.

ABCD is the required square.

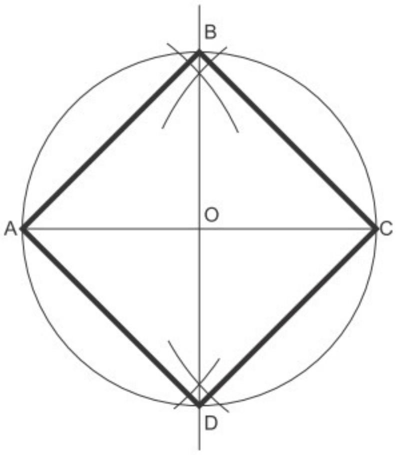

Figure 2.22

To construct a rectangle given the length of the diagonal and one of the sides (Fig. 2.23).

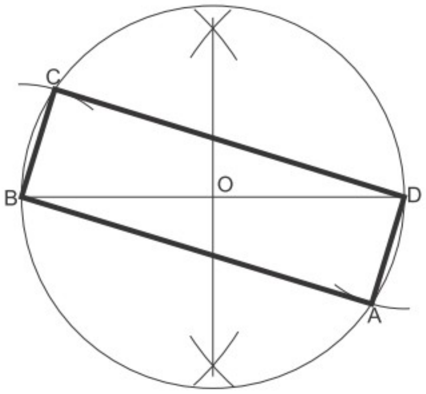

Figure 2.23

1. Draw the diagonal BD.
2. Bisect BD.
3. With centre O and radius OB (= OD), draw a circle.
4. With centre B and radius equal to the length of the known side, draw an arc to cut the circle in C.
5. Repeat step 4 with centre D to cut at A.

ABCD is the required rectangle.

To construct a parallelogram given two sides and an angle (Fig. 2.24).

1. Draw AD equal to the length of one of the sides.
2. From A construct the known angle.
3. Mark off AB equal in length to the other known side.
4. With compass point at B, draw an arc equal in radius to AD.
5. With compass point at D, draw an arc equal in radius to AB.

ABCD is the required parallelogram.

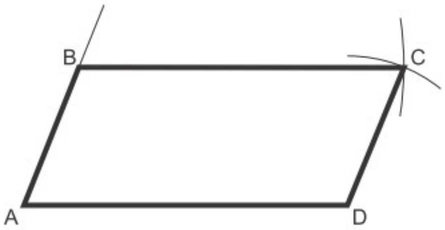

Figure 2.24

To construct a rhombus given the diagonal and the length of the sides (Fig. 2.25).

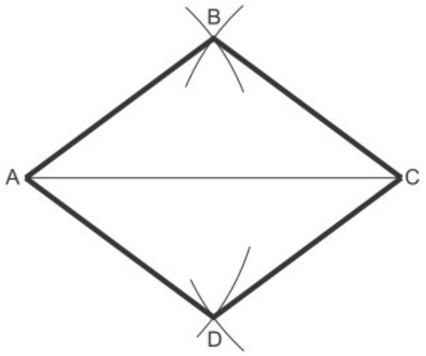

Figure 2.25

1. Draw the diagonal AC.
2. From A and C draw intersecting arcs, equal in length to the sides, to meet at B and D.

ABCD is the required rhombus.

To construct a trapezium given the lengths of the parallel sides, the perpendicular distance between them and one angle (Fig. 2.26).

1. Draw one of the parallels AB.
2. Construct the parallel line.
3. Construct the known angle from B to intersect the parallel line in C.
4. Mark off the known length CD.

ABCD is the required trapezium.

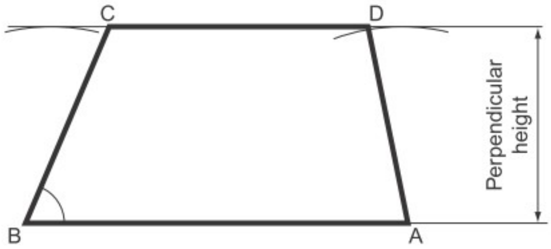

Figure 2.26

Polygons

Definitions

A polygon is a plane figure bounded by more than four straight sides. Polygons that are frequently referred to have particular names. Some of these are listed below.

A *pentagon* is a plane figure bounded by five sides.
A *hexagon* is a plane figure bounded by six sides.
A *heptagon* is a plane figure bounded by seven sides.
An *octagon* is a plane figure bounded by eight sides.
A *nonagon* is a plane figure bounded by nine sides.
A *decagon* is a plane figure bounded by ten sides.

A regular polygon is one that has all its sides equal and therefore all its exterior angles equal and all its interior angles equal.

It is possible to construct a circle within a regular polygon so that all the sides of the polygon are tangential to that circle. The diameter of that circle is called the 'diameter of the polygon'. If the polygon has an even number of sides, the diameter is the distance between two diametrically opposed faces. This dimension is often called the 'across-flats' dimension.

The diagonal of a polygon is the distance from one corner to the corner furthest away from it. If the polygon has an even number of sides, then this distance is the dimension between two diametrically opposed corners.

Constructions

To construct a regular hexagon given the length of the sides (Fig. 2.27).

1. Draw a circle, radius equal to the length of the side.
2. From any point on the circumference, step the radius around the circle six times. If your construction is accurate, you will finish at exactly the same place that you started.
3. Connect the six points to form a regular hexagon.

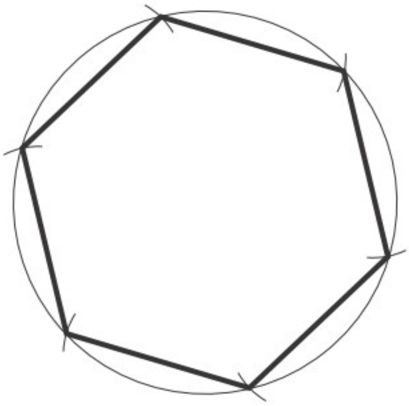

Figure 2.27

To construct a regular hexagon given the diameter (Fig. 2.28).

This construction, using compasses and straight edge only, is quite feasible but is relatively unimportant. What is important is to recognise that a hexagon can be constructed, given the diameter or across-flats dimension, by drawing tangents to the circle with a 60° set square. This is very important when drawing hexagonal-headed nuts and bolts.

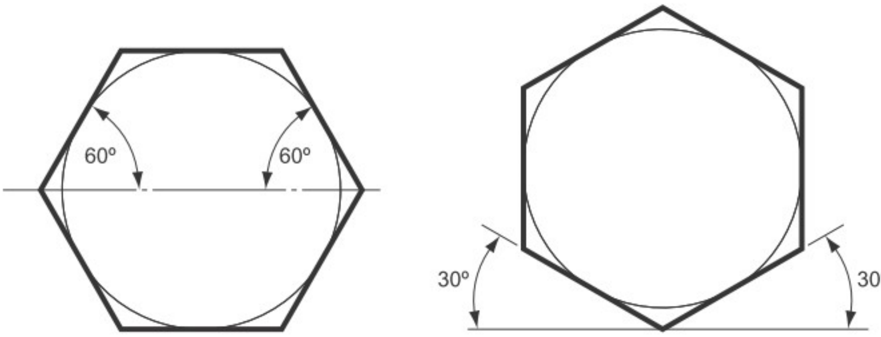

Figure 2.28

To construct a regular octagon given the diagonal, i.e. within a given circle (Fig. 2.29).

1. Draw the circle and insert a diameter AE.
2. Construct another diagonal CG, perpendicular to the first diagonal.
3. Bisect the four quadrants thus produced to cut the circle in B, D, F and H.

ABCDEFGH is the required octagon.

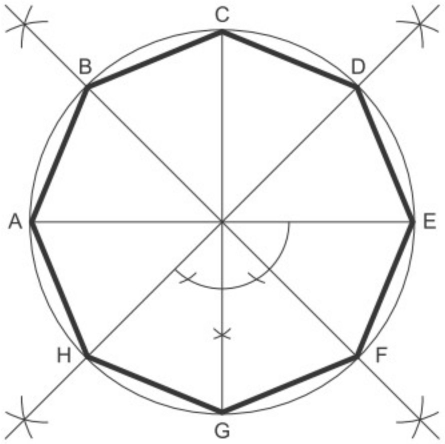

Figure 2.29

To construct a regular octagon given the diameter, i.e. within a given square (Fig. 2.30).

1. Construct a square PQRS, length of side equal to the diameter.
2. Draw the diagonals SQ and PR to intersect in T.
3. With centres P, Q, R and S draw four arcs, radius PT (= QT = RT = ST) to cut the square in A, B, C, D, E, F, G and H.

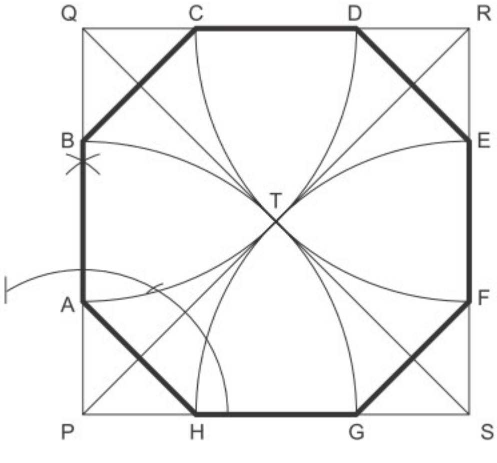

Figure 2.30

ABCDEFGH is the required octagon.

To construct any given polygon, given the length of a side.

There are three fairly simple ways of constructing a regular polygon. Two methods require a simple calculation and the third requires very careful construction if it is to be exact. All three methods are shown. The construction work for any polygon, and a heptagon (seven sides), has been chosen to illustrate them.

Method 1 (Fig. 2.31).

1. Draw a line AB equal in length to one of the sides and produce AB to P.
2. Calculate the exterior angle of the polygon by dividing 360° by the number of sides. In this case the exterior angle is 360°/7 = 51 3°/7.
3. Draw the exterior angle PBC so that BC = AB.
4. Bisect AB and BC to intersect in O.
5. Draw a circle, centre O and radius OA (= OB = OC).
6. Step off the sides of the figure from C to D, D to E, etc.

ABCDEFG is the required heptagon.

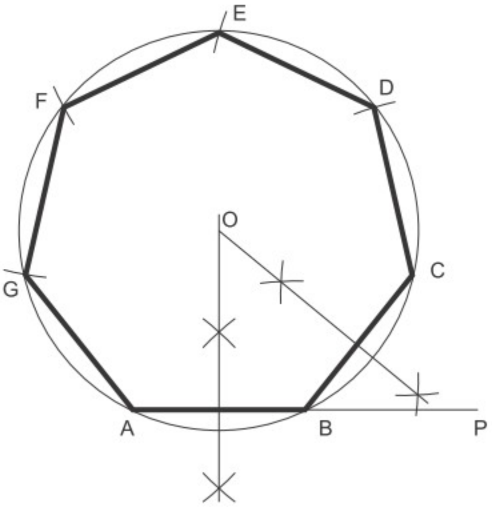

Figure 2.31

Method 2 (Fig. 2.32).

1. Draw a line AB equal in length to one of the sides.
2. From A erect a semi-circle, radius AB to meet BA produced in P.
3. Divide the semi-circle into the same number of equal parts as the proposed polygon has sides. This may be done by trial and error or by calculation (180°/7 = 25 5°/7 for each arc).
4. Draw a line from A to point 2 (for ALL polygons). This forms a second side to the polygon.
5. Bisect AB and A_2 to intersect in O.
6. With centre O draw a circle, radius OB (= OA = O_2).
7. Step off the sides of the figure from B to C, C to D, etc.

ABCDEFG is the required septagon.

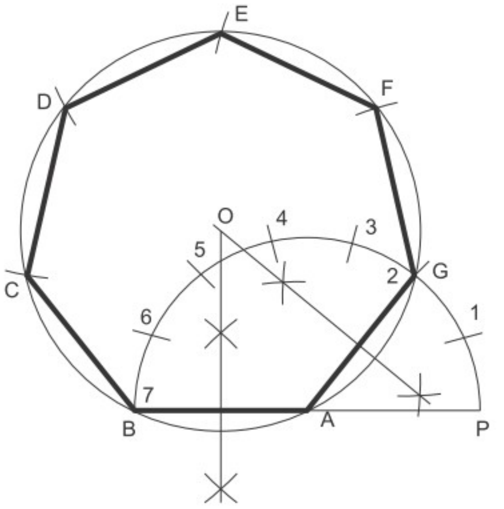

Figure 2.32

Method 3 (Fig. 2.33).

1. Draw a line GA equal in length to one of the sides.
2. Bisect GA.
3. From A construct an angle of 45° to intersect the bisector at point 4.
4. From G construct an angle of 60° to intersect the bisector at point 6.
5. Bisect between points 4 and 6 to give point 5.
   Point 4 is the centre of a circle containing a square. Point 5 is the centre of a circle containing a pentagon. Point 6 is the centre of a circle containing a hexagon. By marking off points at similar distances the centres of circles containing any regular polygon can be obtained.

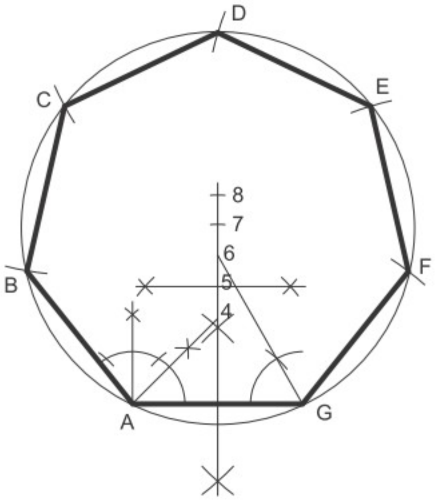

Figure 2.33

6. Mark off point 7 so that 6 to 7 = 5 to 6 (= 4 to 5).
7. With centre at point 7 draw a circle, radius 7 to A (= 7 to G).
8. Step off the sides of the figure from A to B, B to C, etc.

ABCDEFG is the required heptagon.

To construct a regular polygon given a diagonal, i.e. within a given circle (Fig. 2.34).

1. Draw the given circle and insert a diameter AM.
2. Divide the diameter into the same number of divisions as the polygon has sides.
3. With centre M draw an arc, radius MA. With centre A draw another arc of the same radius to intersect the first arc in N.
4. Draw N_2 and produce to intersect the circle in B (for any polygon).
5. AB is the first side of the polygon. Step out the other sides BC, CD, etc.

ABCDE is the required polygon.

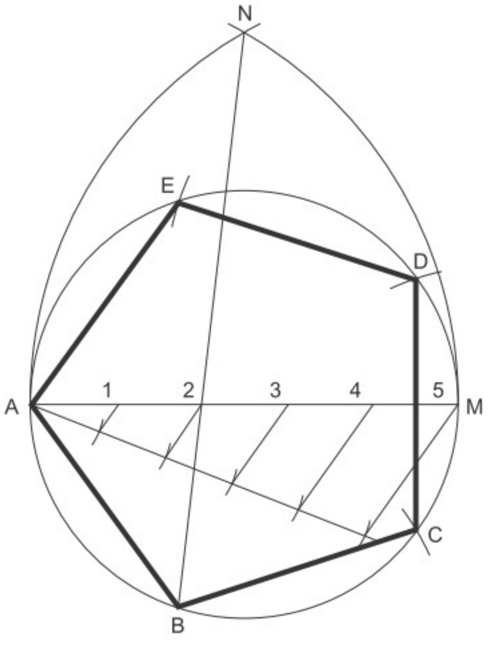

Figure 2.34

To construct a regular polygon given a diameter (Fig. 2.35).

1. Draw a line MN.
2. From some point A on the line draw a semi-circle of any convenient radius.
3. Divide the semi-circle into the same number of equal sectors as the polygon has sides (in this case nine, i.e. 20° intervals).
4. From A draw radial lines through points 1 to 8.

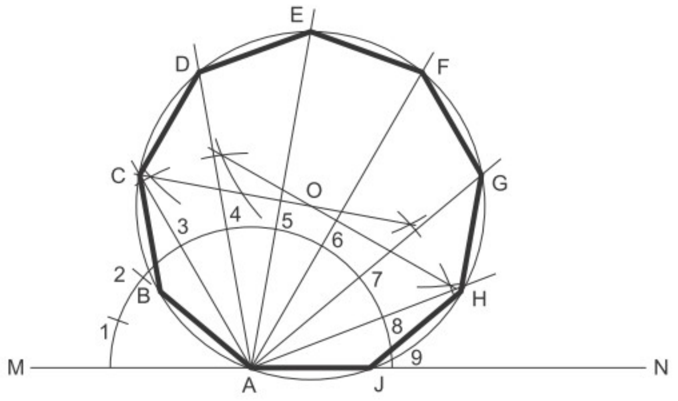

Figure 2.35

5. If the polygon has an even number of sides, there is only one diameter passing through A. In this case, bisect the known diameter to give centre O. If, as in this case, there are two diameters passing through A (there can never be more than two), then bisect both diameters to intersect in O.
6. With centre O and radius OA, draw a circle to intersect the radial lines in C, D, E, F, G and H.
7. From A mark off AB and AJ equal to CD, DE, etc.

ABCDEFGHJ is the required polygon.

The constructions shown above are by no means all the constructions that you may be required to do, but they are representative of the type that you may meet.

If your geometry needs a little extra practice, it is well worthwhile proving these constructions by Euclidean proofs. A knowledge of some geometric theorems is needed when answering many of the questions shown below, and proving the above constructions will make sure that you are familiar with them.

Exercise 2

1. Construct an equilateral triangle with sides 60 mm long.
2. Construct an isosceles triangle that has a perimeter of 135 mm and an altitude of 55 mm.
3. Construct a triangle with base angles 60° and 45° and an altitude of 76 mm.
4. Construct a triangle with a base of 55 mm, an altitude of 62 mm and a vertical angle of $37\frac{1}{2}^\circ$.
5. Construct a triangle with a perimeter measuring 160 mm and sides in the ratio 3:5:6.
6. Construct a triangle with a perimeter of 170 mm and sides in the ratio 7:3:5.
7. Construct a triangle given that the perimeter is 115 mm, the altitude is 40 mm and the vertical angle is 45°.
8. Construct a triangle with a base measuring 62 mm, an altitude of 50 mm and a vertical angle of 60°. Now draw a similar triangle with a perimeter of 250 mm.
9. Construct a triangle with a perimeter of 125 mm, whose sides are in the ratio 2:4:5. Now draw a similar triangle whose perimeter is 170 mm.

10. Construct a square of side 50 mm. Find the mid-point of each side by construction and join up the points with straight lines to produce a second square.

11. Construct a square whose diagonal is 68 mm.

12. Construct a square whose diagonal is 85 mm.

13. Construct a parallelogram given two sides 42 mm and 90 mm long, and the angle between them 67°.

14. Construct a rectangle that has a diagonal 55 mm long and one side 35 mm long.

15. Construct a rhombus if the diagonal is 75 mm long and one side is 44 mm long.

16. Construct a trapezium given that the parallel sides are 50 mm and 80 mm long and are 45 mm apart.

17. Construct a regular hexagon, 45 mm side.

18. Construct a regular hexagon if the diameter is 75 mm.

19. Construct a regular hexagon within an 80 mm diameter circle. The corners of the hexagon must all lie on the circumference of the circle.

20. Construct a square, side 100 mm. Within the square, construct a regular octagon. Four alternate sides of the octagon must lie on the sides of the square.

21. Construct the following regular polygons:
a pentagon, side 65 mm;
a heptagon, side 55 mm;
a nonagon, side 45 mm;
a decagon, side 35 mm.

22. Construct a regular pentagon, diameter 82 mm.

23. Construct a regular heptagon within a circle, radius 60 mm. The corners of the heptagon must lie on the circumference of the circle.

3 Isometric Projection

Engineering drawings are always drawn in orthographic projection. For the presentation of detailed drawings, this system has been found to be far superior to all others. The system has, however, the disadvantage of being very difficult to understand by people not trained in its usage. It is always essential that an engineer be able to communicate his ideas to anybody, particularly people who are not engineers, and it is therefore an advantage to be able to draw using a system of projection that is more easily understood. There are many systems of projection and this book deals with three: isometric, oblique and orthographic projections. Isometric and oblique projections present the more pictorial view of an object.

True isometric projection is an application of orthographic projection and is dealt with in greater detail later in this chapter. The most common form of isometric projection is called ‘conventional isometric’.

Conventional Isometric Projection (Isometric Drawing)

If you were to make a freehand drawing of a row of houses, the house furthest away from you would be the smallest house on your drawing. This is called the ‘perspective’ of the drawing and, in a perspective drawing, none of the lines are parallel. Isometric drawing ignores perspective altogether. Lines are drawn parallel to each other and drawings can be made using a T-square and a set square. This is much simpler than perspective drawing.

Figure 3.1 shows a shaped block drawn in conventional isometric projection.

You will note that there are three isometric axes. These are inclined at 120° to each other. One axis is vertical and the other two axes are therefore at 30° to the horizontal. Dimensions measured along these axes, or parallel to them, are true lengths.

The faces of the shaped block shown in Fig. 3.1 are all at 90° to each other. The result of this is that all of the lines in the isometric drawing are parallel to the isometric axes. If the lines are not parallel to any of the isometric axes, they are no longer true lengths. An example of this is shown in Fig. 3.2 which shows an isometric drawing of a regular hexagonal prism. The hexagon is first drawn as a plane figure and a simple shape, in this case a rectangle, is drawn around the hexagon. The rectangle is easily drawn in isometric and the positions of the corners of the hexagon can be transferred from the plane figure to the isometric drawing with a pair of dividers.

Figure 3.1 Shaped block drawn in conventional isometric projection.

The dimensions of the hexagon should all be 25 mm and you can see from Fig. 3.2 that lines not parallel to the isometric axes do not have true lengths.

Figure 3.3 shows another hexagonal prism. This prism has been cut at an incline and this means that two extra views must be drawn so that sufficient information to draw the prism in isometric can be transferred from the plane views to the isometric drawing.

This figure shows that, when making an isometric drawing, all dimensions must be measured parallel to one of the isometric axes.

Circles and Curves Drawn in Isometric Projection

All of the faces of a cube are square. If a cube is drawn in isometric projection, each square side becomes a rhombus. If a circle is drawn on the face of a cube, the circle will change shape when the cube is drawn in isometric projection. Figure 3.4 shows how to plot the new shape of the circle.

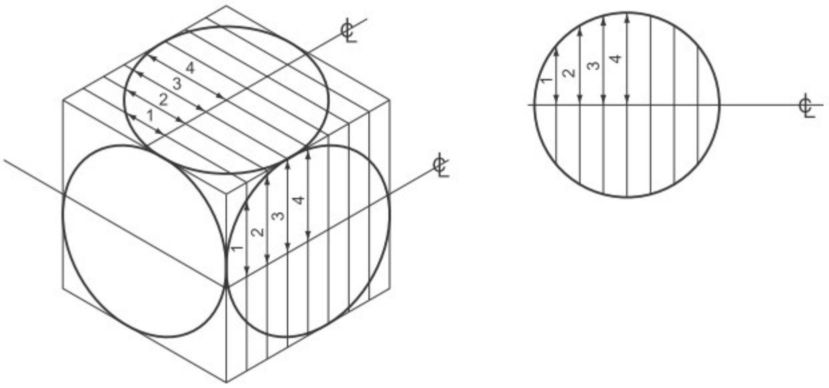

Figure 3.4

The circle is first drawn as a plane figure, and is then divided into an even number of equal strips. The face of the cube is then divided into the same number of equal strips. Centre lines are added and the measurement from the centre line of the circle to the point where strip 1 crosses the circle is transferred from the plane drawing to the isometric drawing with a pair of dividers. This measurement is applied above and below the centre line. This process is repeated for strips 2, 3, etc.

The points that have been plotted should then be carefully joined together with a neat freehand curve.

Figure 3.5 illustrates how this system is used in practice.

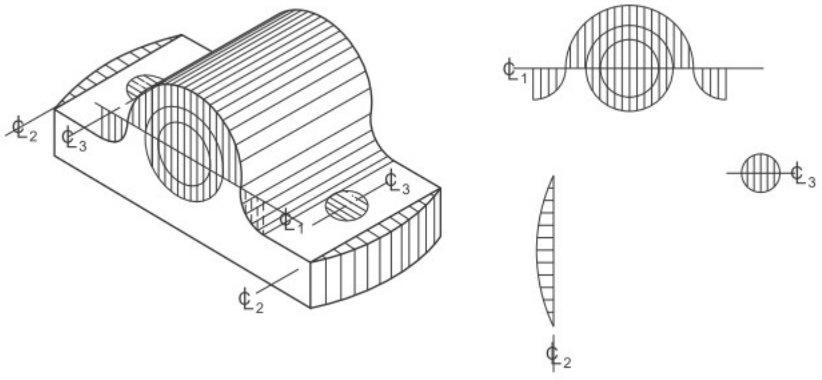

Figure 3.5 How circles and part circles can be drawn isometrically.

Since a circle can be divided into four symmetrical quadrants, it is really necessary to draw only a quarter of a circle instead of a whole plane circle.

The dimensions which are transferred from the plane circle to the isometric view are called 'ordinates' and the system of transferring ordinates from plane figures to isometric views is not confined to circles. It may be used for any regular or irregular shape. Figure 3.6 shows a shaped plate.

There are several points worth noting from Fig. 3.6.

- **(a)** Since the plate is symmetrical about its centre line, only half has been divided into strips on the plane figure.
- **(b)** In proportion to the plate, the holes are small. They have, therefore, ordinates much closer together so that they can be drawn accurately.
- **(c)** The point where the vee cut-out meets the elliptical outline has its own ordinate so that this point can be transferred exactly to the isometric view.
- **(d)** Since the plate has a constant thickness, the top and bottom profiles are the same. A quick way of plotting the bottom profile is to draw several vertical lines down from the top profile and, with dividers set at the required thickness of the plate, follow the top curve with the dividers, marking the thickness of the plate on each vertical line.

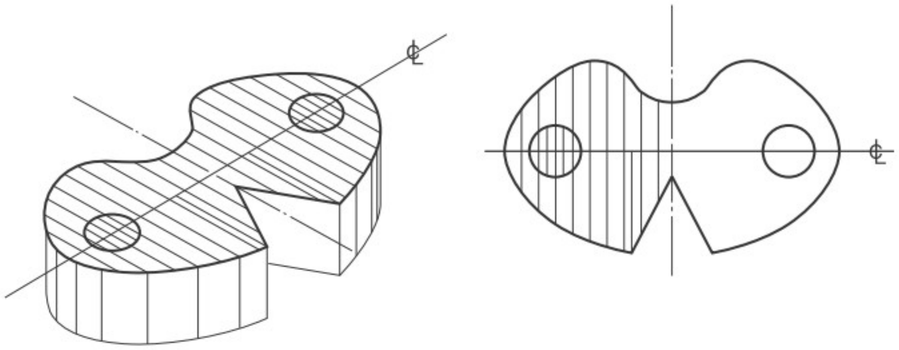

Figure 3.6 A shaped plate drawn in isometric projection.

It is sometimes necessary to draw circles or curves on faces that are not parallel to any of the three isometric axes. Figure 3.7 shows a cylinder cut at 45°. Two views of the cylinder have to be drawn: a plan view and an elevation. The plan view is divided into strips and the positions of these strips are projected onto the elevation.

The base of the cylinder is drawn in isometric projection in the usual way. Points 1 to 20, where the strips cross the circle, are projected vertically upwards and the height of the cylinder, measured from the base with dividers, is transferred for each point in turn from the elevation to the isometric view. These points are then carefully joined together with a neat freehand curve.

True Isometric Projection

Isometric projection is a method of drawing with instruments which gives a pictorial view of an object. It is not often used in industry and, when it is, the vast majority of

drawings are made using conventional isometric projection. Conventional isometric projection is a distorted and simplified form of true isometric. True isometric is found by taking a particular view from an orthographic projection of an object. Figure 3.8 shows a cube, about 25 mm side, drawn in orthographic projection with the cube so positioned that the front elevation is a true isometric projection of the cube. The three isometric axes are still at 120° to each other. In conventional isometric, distances measured parallel to these axes are true lengths. In true isometric projection they are no longer true lengths although they are proportional to their true lengths. However, the horizontal distances on a true isometric projection *are* true lengths. The reduction of lengths measured parallel to the isometric axes makes the overall size of the true isometric drawing appear to look more natural, particularly when directly compared with an orthographic or plane view of the same object (compare the relative sizes of the prism in Fig. 3.2).

If the horizontal length and the length parallel to the isometric axes were both to be true lengths, the isometric axes would have to be at 45° (Fig. 3.9). Since the isometric axes are at 30°, the 45° lengths must be reduced.

Figure 3.10

The ratio between the true length and the isometric length is isometric length = true length × 0.8165.

This ratio is constant for all lines measured parallel to any of the isometric axes. If you are asked to draw an object using an isometric scale, your scale may be constructed as in Fig. 3.10 or you may construct a conventional plain scale as shown in Fig. 3.11. The initial length of this scale is 100 × 0.8165 = 81.65 mm. The scale is then completed as shown in Chapter 1.

4 The Construction of Circles to Satisfy Given Conditions

The Greatest Invention of All Time

About 6000 years ago, an unknown Mesopotamian made one of the greatest inventions of all time: the wheel. This was the most important practical application ever made of a shape that fascinated early mathematicians. The shape is, of course, the circle. After the wheel had been invented, the Mesopotamians found many more applications for the circle than just for transport. The potter's wheel was developed and vessels were made much more accurately and quickly. Pulleys were invented and engineers and builders were able to raise heavy weights. Since that time, the circle has been the most important geometric shape in the development of all forms of engineering.

Apart from its practical applications, the circle has an aesthetic value which makes it unique among plane figures. The ancients called it 'the perfect curve' and its symmetry and simplicity has led artists and craftsmen to use the circle as a basis for design for many thousands of years.

Definitions

A circle is the locus of a point which moves so that it is always a fixed distance from another stationary point.

Concentric circles are circles that have the same centre.
Eccentric circles are circles that are not concentric.

Figure 4.1 shows some of the parts of the circle.

Constructions

The length of the circumference of a circle is πD or $2\pi R$, where D is the diameter and R the radius of the circle, π is the ratio of the diameter to the circumference and may be taken as 22/7 or, more accurately, as 3.142.

If you need to draw the circumference of a circle (this is required quite often in subsequent chapters), you should either calculate it, or use the construction shown in Fig. 4.2. This construction is not exact but is accurate enough for most needs. For the

sake of thoroughness, the corresponding construction, that of finding the diameter from the circumference, is shown in Fig. 4.3.

To construct the circumference of a circle, given the diameter (Fig. 4.2).

1. Draw a semi-circle of the given diameter AB, centre O.
2. From B mark off three times the diameter, BC.
3. From O draw a line at 30° to OA to meet the semi-circle in D.
4. From D draw a line perpendicular to OA to meet OA in E.
5. Join EC.

EC is the required circumference.

Figure 4.2

.6 ' /

To construct the diameter of a circle, given the circumference (Fig. 4.3).

1. Draw the given circumference AB.
2. Bisect AB in C.
3. With centre C, and radius CA, draw a semi-circle.
4. With centre B, and radius BC, draw an arc to cut the semi-circle in D.
5. From D draw a perpendicular to AB, to cut AB in E.
6. With centre E and radius ED, draw an arc to cut AB in F.

AF is the required diameter.

The rest of this chapter shows some of the constructions for finding circles drawn to satisfy certain given conditions.

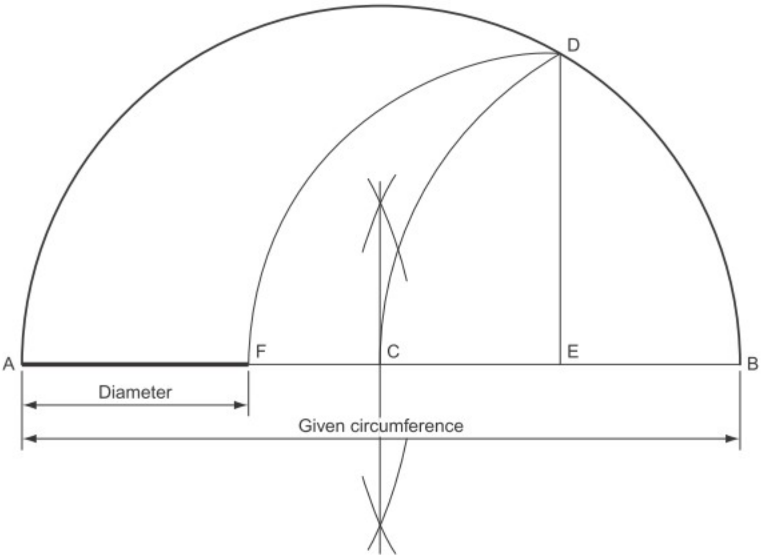

Figure 4.3

To find the centre of any circle (Fig. 4.4).

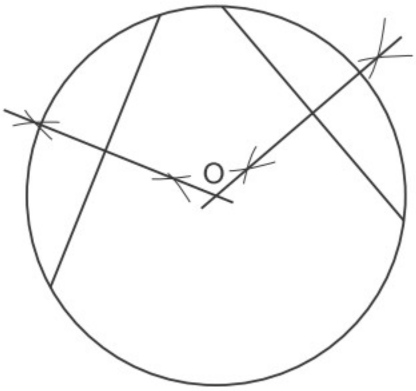

Figure 4.4

1. Draw any two chords.
2. Construct perpendicular bisectors to these chords to intersect in O.

O is the centre of the circle.

To construct a circle to pass through three given points (Fig. 4.5).

1. Draw straight lines connecting the points as shown. These lines are, in fact, chords of the circle.
2. Draw perpendicular bisectors through these lines to intersect in O.

O is the centre of a circle that passes through all three points.

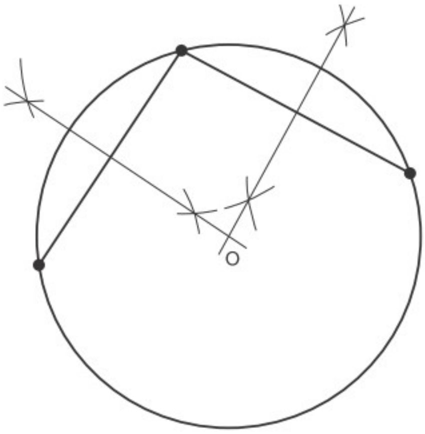

Figure 4.5

To construct the inscribed circle of any regular polygon (in this case, a triangle) (Fig. 4.6).

1. Bisect any two of the interior angles to intersect in O. (If the third angle is bisected it should also pass through O.)

O is the centre of the inscribed circle. This centre is called the 'incentre'.

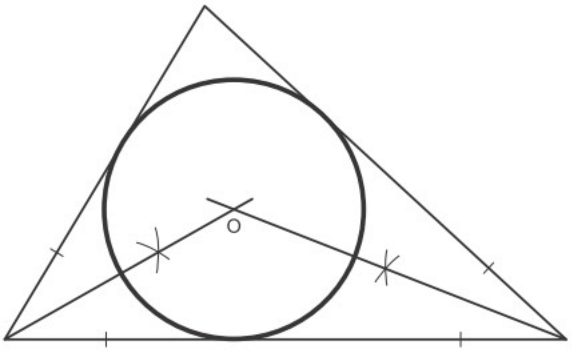

Figure 4.6

To construct the circumscribed circle of any regular polygon (in this case a triangle) (Fig. 4.7).

1. Perpendicularly bisect any two sides to intersect in O. (If the third side is bisected it should also pass through O.)
   O is the centre of the circumscribed circle. This centre is called the 'circumcentre'.

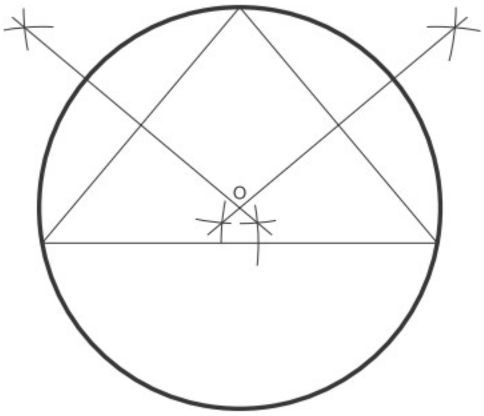

Figure 4.7

To construct the escribed circle to any regular polygon (in this case a triangle) (Fig. 4.8).

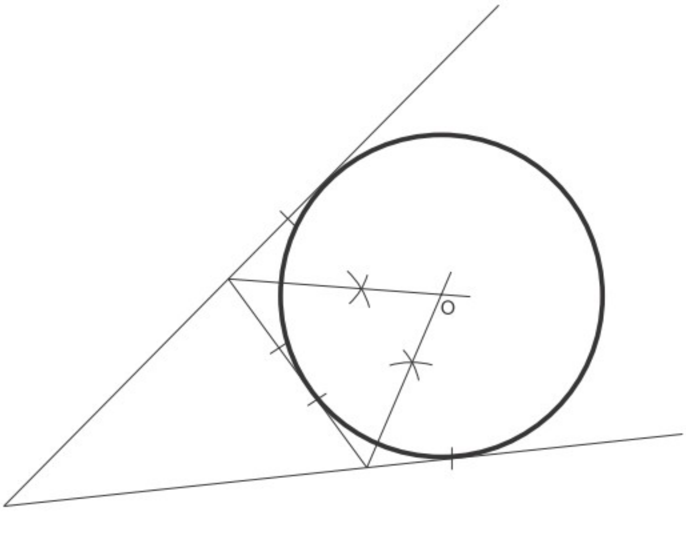

Figure 4.8

1. An escribed circle is a circle that touches a side and the two adjacent sides produced. Thus, the first step is to produce the adjacent sides.
2. Bisect the exterior angles thus formed to intersect in O.

O is the centre of the escribed circle.

To construct a circle that passes through a fixed point A and touches a line at a given point B (Fig. 4.9).

1. Join AB.
2. From B erect a perpendicular BC.
3. From A construct angle $B\hat{A}O$ similar to angle $C\hat{B}A$ to intersect the perpendicular in O.

O is the centre of the required circle.

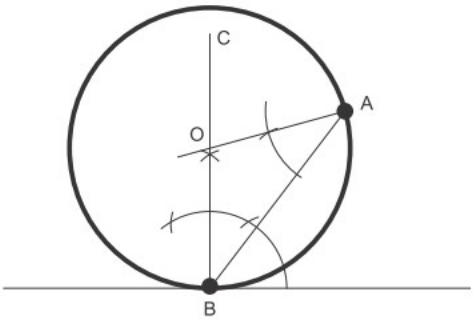

Figure 4.9

To construct a circle that passes through two given points, A and B, and touches a given line (Fig. 4.10).

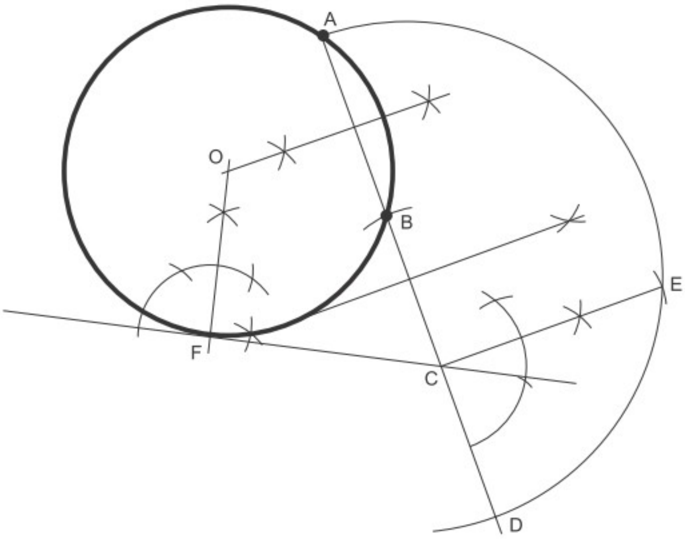

Figure 4.10

1. Join AB and produce this line to D (cutting the given line in C) so that BC = CD.
2. Construct a semi-circle on AD.
3. Erect a perpendicular from C to cut the semi-circle in E.
4. Make CF = CE.
5. From F erect a perpendicular.
6. Perpendicularly bisect AB to meet the perpendicular from F in O.

O is the centre of the required circle.

To construct a circle that touches two given lines and passes through a given point P. There are two circles which satisfy these conditions (Fig. 4.11).

1. If the two lines do not meet, produce them to intersect in A.
2. Bisect the angle thus formed.
3. From any point on the bisector draw a circle, centre B, to touch the two given lines.
4. Join PA to cut the circle in C and D.
5. Draw PO, parallel to CB and PO, parallel to DB.

O_1 and O_2 are the centres of the required circles.

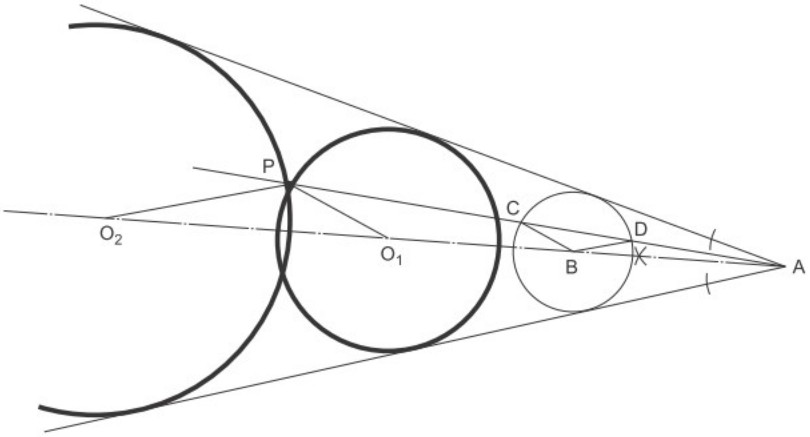

Figure 4.11

To construct a circle, radius *R*, to touch another given circle radius *r*, and a given line (Fig. 4.12).

1. Draw a line parallel to the given line, the distance between the lines equal to R.
2. With compass point at the centre of the given circle and radius set at $R + r$, draw an arc to cut the parallel line in O.

O is the centre of the required circle.

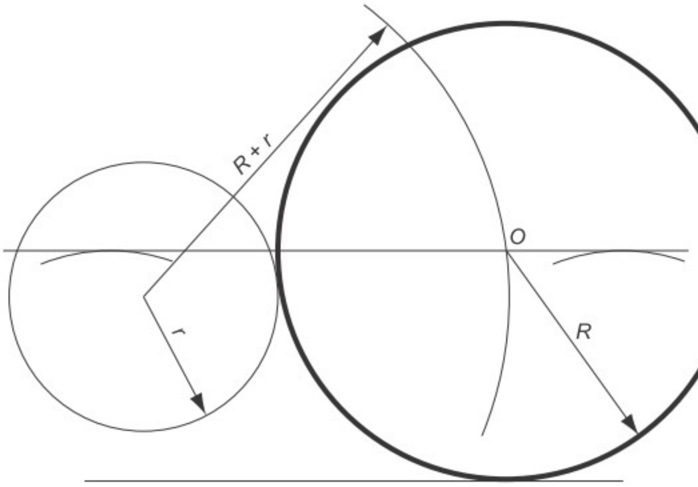

Figure 4.12

To construct a circle that touches another circle and two tangents of that circle (Fig. 4.13).

1. If the tangents do not intersect, produce them to intersect in A.
2. Bisect the angle formed by the tangents.
3. From B, the point of contact of the circle and one of its tangents, construct a perpendicular to cut the bisector in O_1. This is the centre of the given circle.
4. Join BD.
5. Draw EF parallel to DB and FO_2 parallel to BO_1.

O_2 is the centre of the required circle.

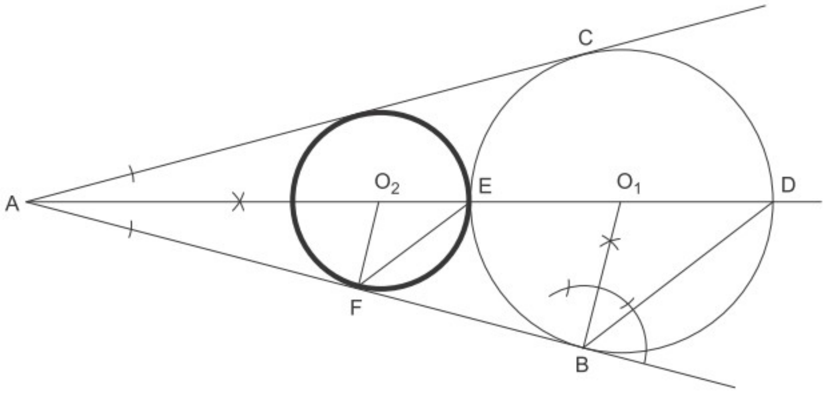

Figure 4.13

To construct a circle that touches another circle and two lines (Fig. 4.14).

1. Draw intersecting lines parallel to the given lines. These lines, AB and AC, must be distance *r*, the radius of the given circle, from the given lines.
2. Repeat construction of Fig. 4.11 and construct a circle that passes through O_1, the centre of the given circle, and touches the two parallel lines.
3. The centre of this circle, O_2, is also the centre of the required circle.

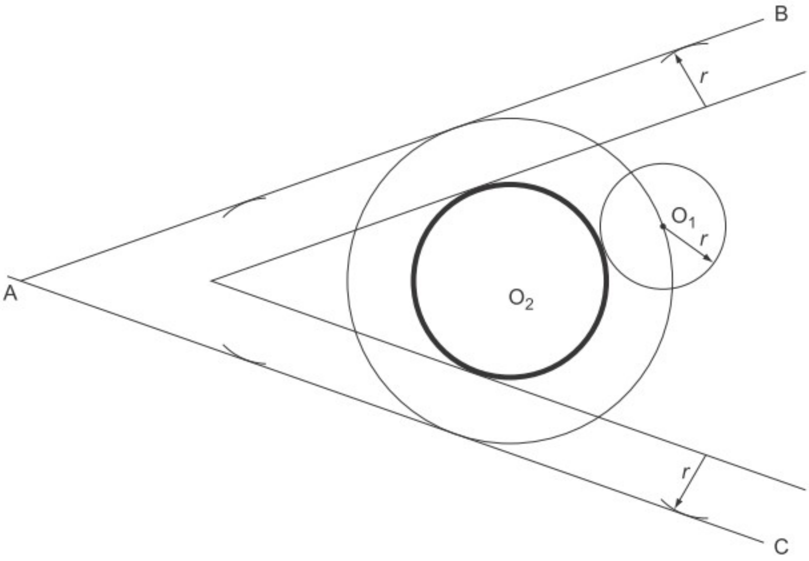

Figure 4.14

To construct a circle that passes through two given points, P and Q, and touches a given circle, centre D (Fig. 4.15).

All of the above constructions are for finding single circles which satisfy given conditions. The rest of the constructions in this chapter are concerned with more than one circle at a time.

1. Join PQ and produce this line.
2. Perpendicularly bisect PQ and, with centre somewhere on this bisector, draw a circle to pass through points P and Q and cut the given circle in A and B.
3. Join AB and produce to cut PQ produced in C.
4. Construct the tangent from C to the given circle. (Join CD, bisect CD in E, compass point at E draw a radius ED to cut the circle in F.)
5. From F erect a perpendicular to cut the bisector of PQ in O.

O is the centre of the required circle.

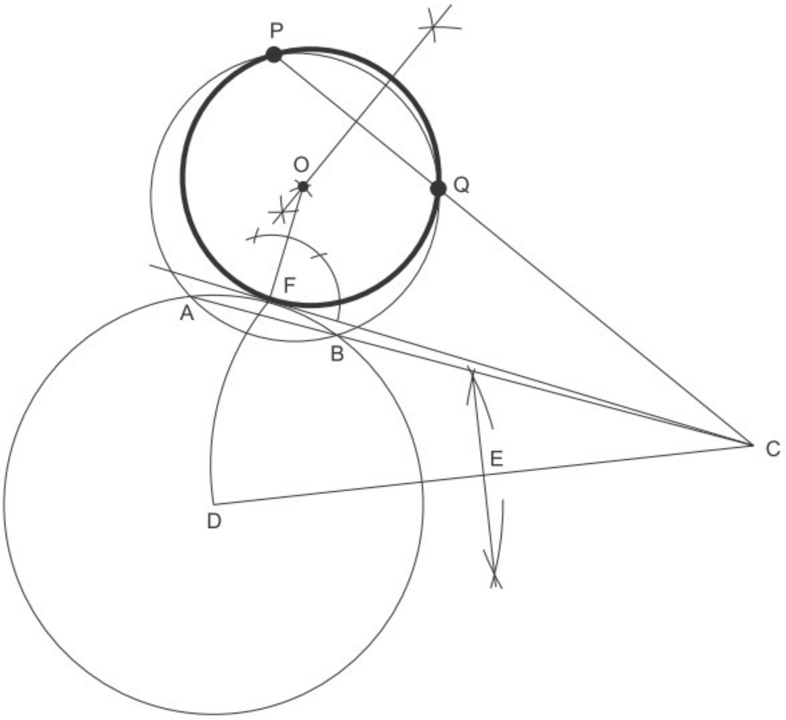

Figure 4.15

To draw three circles which touch each other, given the position of their centres $\mathbf{O_1}$, $\mathbf{O_2}$ and $\mathbf{O_3}$ (Fig. 4.16).

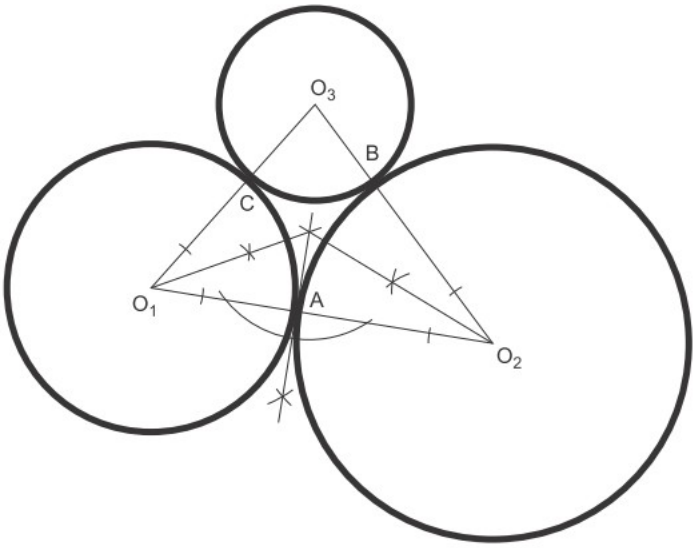

Figure 4.16

1. Draw straight lines connecting the centres.
2. Find the centre of the triangle thus formed by bisecting two of the interior angles.
3. From this centre, drop a perpendicular to cut O_1O_2 in A.
4. With centre O_1 and radius O_1A, draw the first circle.
5. With centre O_2 and radius O_2A, draw the second circle.
6. With centre O_3 and radius O_3C (= O_3B), draw the third circle.

To draw two circles, given both their radii, within a third circle, all three circles to touch each other (Fig. 4.17).

1. Mark off the diameter AB of the largest circle.
2. Mark off AO_1 equal to the radius of one of the other circles and draw this circle, centre O_1, to cut the diameter in C.
3. From C mark off CD equal to the radius of the third circle.
4. Mark off BE equal to the radius of the third circle.
5. With centre O_1 and radius O_1D, draw an arc.
6. With centre O and radius OE, draw an arc to cut the first arc in O_2.

O_2 is the centre of the third circle.

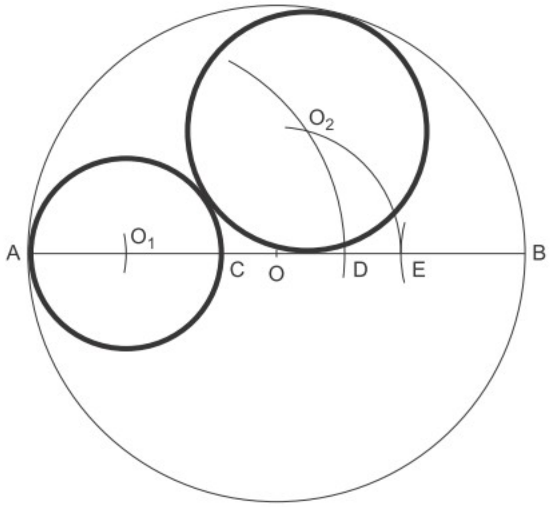

Figure 4.17

To draw any number of equal circles within another circle, the circles all to be in contact (in this case 5) (Fig. 4.18).

1. Divide the circle into the same number of sectors as there are proposed circles.
2. Bisect all the sectors and produce one of the bisectors to cut the circle in D.
3. From D erect a perpendicular to meet OB produced in E.
4. Bisect $D\hat{E}O$ to meet OD in F.
5. F is the centre of the first circle. The other circles have the same radius and have centres on the intersections of the sector bisectors and a circle, centre O and radius OF.

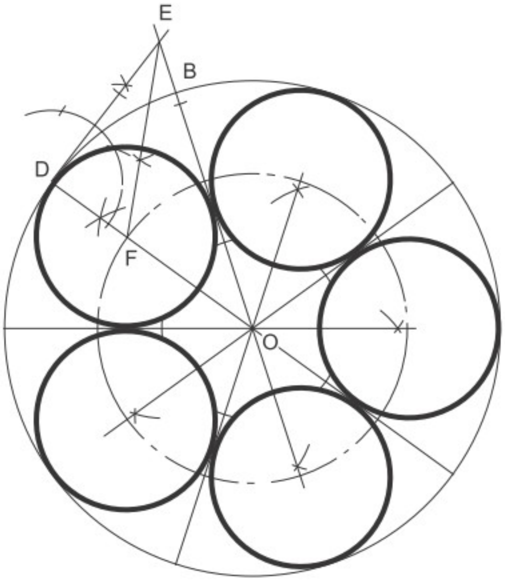

Figure 4.18

To draw several equal circles within a regular polygon to touch each other and one side of the polygon (in this case, a septagon) (Fig. 4.19).

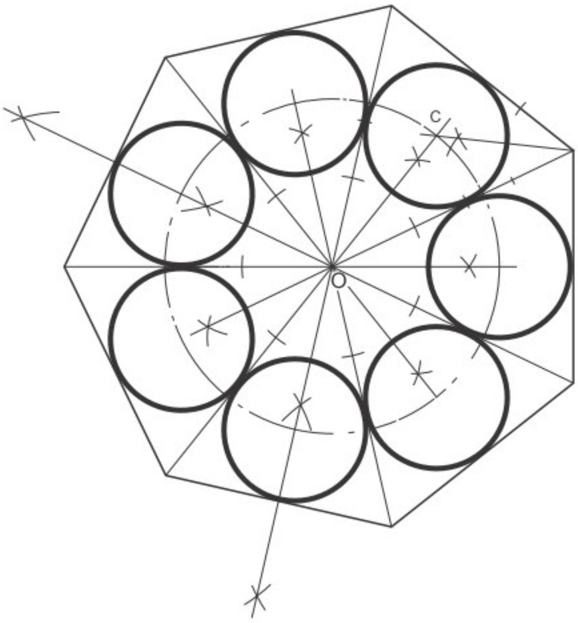

Figure 4.19

1. Find the centre of the polygon by bisecting two of the sides.
2. From this centre, draw lines to all of the corners.
3. This produces several congruent triangles. All we now need to do is to draw the inscribed circle in each of these triangles. This is done by bisecting any two of the interior angles to give the centre C.
4. The circles have equal radii and their centres lie on the intersection of a circle, radius OC and the bisectors of the seven equal angles formed by step 2.

To draw equal circles around a regular polygon to touch each other and one side of the polygon (in this case, a septagon) (Fig. 4.20).

1. Find the centre of the polygon by bisecting two of the sides.
2. From the centre O draw lines through all of the corners and produce them.
3. Bisect angles $C\hat{A}B$ and $D\hat{B}A$ to intersect in E.
4. E is the centre of the first circle. The rest can be obtained by drawing a circle, radius OE, and bisecting the seven angles formed by step 2. The intersections of this circle and these lines give the centres of the other six circles.

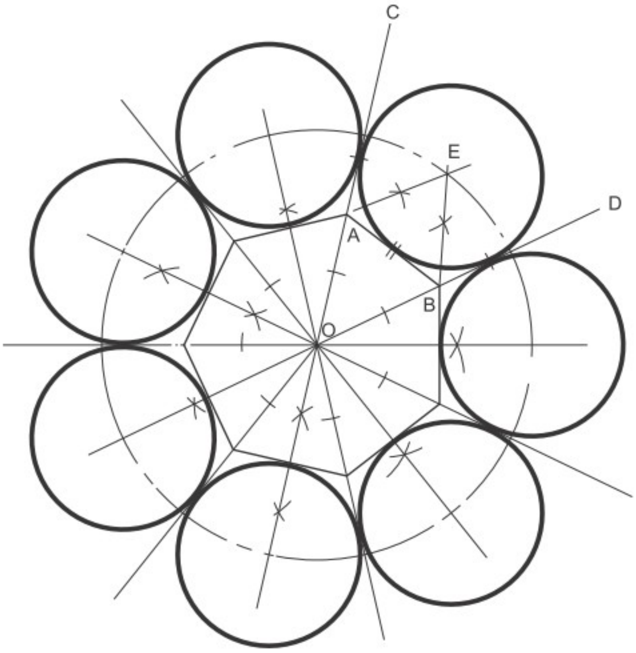

Figure 4.20

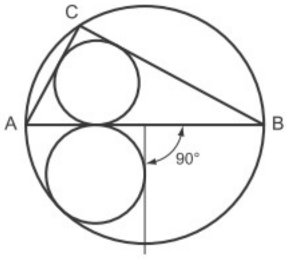
Exercise 4

(All questions originally set in imperial units.)

1. Construct a regular octagon on a base line 25 mm long and draw the inscribed circle. Measure and state the diameter of this circle in mm.

North Western Secondary School Examinations Board (see Chapter 2 for information not in Chapter 4).

2. Describe *three* circles, each one touching the other two externally, their radii being 12, 18 and 24 mm, respectively.
   North Western Secondary School Examinations Board
3. No construction has been shown in Fig. 1. You are required to draw the figure full size showing all construction lines necessary to ensure the circles are tangential to their adjacent lines.
   Southern Regional Examinations Board



AB = ϕ144 mm
AC = 68 mm

Figure 1

4. Construct the triangle ABC in which the base BC = 108 mm, the vertical angle Â = 70° and the altitude is 65 mm.
   D is a point on AB 34 mm from A. Describe a circle to pass through the points A and D and touch (tangential to) the line BC.
   Southern Universities' Joint Board (see Chapter 2 for information not in Chapter 4).
5. Figure 2 shows two touching circles placed in the corner made by two lines which are perpendicular to one another. Draw the view shown and state the diameter of the smaller circle. Your construction must show clearly the method of obtaining the centre of the smaller circle.
   University of London School Examinations

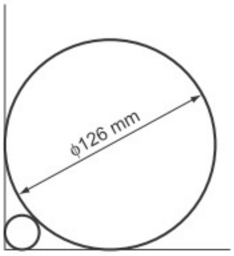


Figure 2

6. Figure 3 shows two intersecting lines AB and BC and the position of a point P. Draw the given figure and find the centre of a circle that will pass through P and touch the lines AB and BC. Draw the circle and state its radius as accurately as possible.
   University of London School Examinations

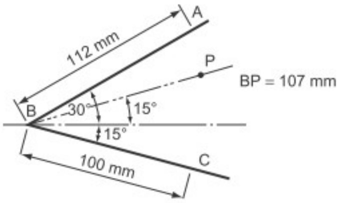

Figure 3

7. A triangle has sides 100, 106 and 60 mm long. Draw the triangle and construct the following: (a) the inscribed circle, (b) the circumscribed circle, (c) the smallest escribed circle.
   University of London School Examinations (see Chapter 2 for information not in Chapter 4).
8. Construct an isosceles triangle ABC where the included angle $A = 67\frac{1}{2}°$, and AB = AC = 104 mm. Draw circles of 43, 37 and 32 mm radius using as centres A, B and C, respectively.
   Construct the smallest circle that touches all three circles.
   Measure and state the diameter of the constructed circle.
   Associated Examining Board (see Chapter 2 for information not in Chapter 4).
9. AB and AC are two straight lines which intersect at an angle of 30°. D is a point between the two lines at perpendicular distances of 37 and 62 mm, respectively from AB and AC. Describe the circle that touches the two converging lines and passes through point D; the centre of this circle is to lie between the points A and D. Now draw two other circles each touching the constructed circle externally and also the converging lines. Measure and state the diameters of the constructed circles.
   Oxford Local Examinations
10. OA and OB are two straight lines meeting at an angle of 30°. Construct a circle of diameter 76 mm to touch these two lines and a smaller circle that will touch the two converging lines and the first circle.
    Also construct a third circle of diameter 64 mm which touches each of the other two circles.
    Oxford Local Examinations
11. Construct a regular octagon of side 75 mm and within this octagon describe eight equal circles each touching one side of the octagon and two adjacent circles. Now draw the smallest circle that will touch all eight circles. Measure and state the diameter of this circle.
    Oxford Local Examinations (see Chapter 2 for information not in Chapter 4).

CHAPTER I.

FORMULATIONS OF THE AXIOMS.

1. THE general considerations which must govern a mathematical investigation on the foundations of Geometry have been explained in Chapter I of the previous tract of this series, on the Axioms of Projective Geometry*. It is explained there that 'Descriptive Geometry' is here used as a generic term for any Geometry in which two straight lines in a plane do not necessarily intersect. Also it is pointed out that the purely classificatory portions of a Descriptive Geometry are clumsy and uninteresting, and that accordingly the idea of order is introduced from the very beginning.

There are three main ways by which this introduction of order can be conveniently managed. In one way, which is represented by Peano's axioms given below (§§ 3—6), the *class* of points which lie *between* any two points is taken as a fundamental idea. It is then easy to define the class of points collinear with the two points and lying *beyond* one of them. Thus these three classes of points, namely the two classes lying beyond the two points respectively and the class lying between the two points, together with the two points themselves form the straight line defined by the two points. Then a set of axioms of the straight line are required, concerned with the idea of 'between,' and also axioms are required respecting coplanar lines.

Another way, which was pointed out by Vailati† and Russell‡, is to conceive a straight line as essentially a serial relation involving two terms. The whole field of such a relation, namely the terms which are thus ranged in order by it, forms the class of points on the straight line. Thus the Geometry starts with the fundamental conception of a class of *relations*. The axioms of the straight line are the axioms which secure that each of these relations is a serial relation. The points are the entities occurring in the fields of any of these relations. The axioms of the plane are the same as in the previous mode of development.

---

* In the sequel this tract will be referred to as 'Proj. Geom.'

† Cf. *Rivista di Matematica*, vol. IV.

‡ Cf. *Principles of Mathematics*, § 376.

The third way, recently developed by Prof. O. Veblen*, is to consider the science of Descriptive Geometry as the study of the properties of one single three-termed relation of order. The entities forming the field of this relation are the points. When this relation holds between three points A, B, and C, it is said that 'the points A, B, and C, are in the linear order ABC.' This method of conceiving the subject results in a notable simplification, and combines advantages from the two previous methods. Veblen's axioms will be stated in full (cf. § 8).

2. The enunciation of the axioms of Descriptive Geometry, which is given in the sections (§§ 3—6) immediately following, is that due to Peano†. His formulation is based upon that of Pasch‡, to whom is due the first satisfactory systematic exposition of the subject. The undefined fundamental ideas are two in number, namely that of a class of entities called 'points,' and that of the 'class of points lying between any two given points.' It has already been explained§ that this undetermined class of points is in fact any class of entities with interrelations, such that the axioms are satisfied when considered as referring to them.

The symbol AB will represent the class of points lying between the points A and B. This class will be called the segment AB.

The first group of axioms, eleven in number, secure the ordinary properties of a straight line with respect to the order of points on it, and also with respect to the division of a line‖ into three parts by any two points on it, and into two parts by any single point on it. The Dedekind property* is not secured by them, but, compactness† is secured by axiom IV.

---

* Cf. *A System of Axioms for Geometry*, Trans. of the Amer. Math. Soc., vol. v., 1904.

† Cf. *I principii di Geometria*, Turin, 1889. These axioms are repeated by him in an article, *Sui fondamenti della Geometria*, Rivista di Matematica, vol. IV. 1894. In this latter article the minute mathematical deductions are omitted, and their place is taken by valuable observations on the main points to be considered. Also a treatment of congruence is given which does not appear in the earlier tract. This article should be studied carefully by every student of the subject.

‡ Cf. *Vorlesungen über neuere Geometrie*, Leipzig, 1882. This treatise is the classic work on the subject.

§ Cf. Proj. Geom. § 2.

‖ Note that 'line' will be habitually used for 'straight line.'

3. Peano's axioms of the straight line are as follows:

I. There is at least one point.

II. If A is any point, there is a point distinct from A.

III. If A is a point, there is no point lying between A and A.

It follows that the class AA possesses no members.

IV. If A and B are distinct points, there is at least one point lying between A and B.

Thus the class AB is not the null class.

V. If the point C lies between A and B, it also lies between B and A.

It easily follows that the classes AB and BA are identical.

VI. The point A does not lie between the points A and B.

Thus the class, or segment, AB does not include its end-points A and B.

Definition. If A and B are points, the symbol $A'B$ represents the class of points, such as C, with the property that B lies between A and C. Thus $A'B$ is the prolongation of the line beyond B, and $B'A$ is its prolongation beyond A.

VII. If A and B are distinct points, there exists at least one member of $A'B$.

VIII. If A and D are distinct points, and C is a member of AD, and B of AC, then B is a member of AD.

IX. If A and D are distinct points, and B and C are members of AD, then either B is a member of AC, or B is identical with C, or B is a member of CD.

X. If A and B are distinct points, and C and D are members of $A'B$, then either C is identical with D, or C is a member of BD, or D is a member of BC.

XI. If A, B, C, D are points, and B is a member of AC, and C of BD, then C is a member of AD.

Definition. The straight line possessing A and B, symbolized by str (A, B), is composed of the three classes $A'B$, AB, $B'A$, together with the points A and B themselves.

Then by the aid of the previous axioms the usual theorems, excluding the Dedekind property, respecting the order of points on a line can be proved. Also any two points are both contained by one and only one line.

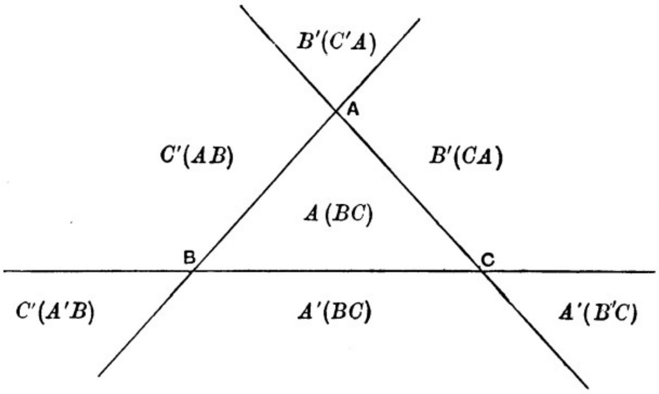
---

* Cf. Proj. Geom. § 19, and § 9 of the present tract.

† Cf. Proj. Geom. § 16.

4. Peano uses the following useful notation which is an extension of his notation for segments and prolongations. If A is a point and u is a class of points, then Au is the class of points lying on the segments between A and points of u, and $A'u$ is the class of points on the prolongations of these segments beyond the points of u.

Then in conformity with this notation the seven regions into which a plane is divided by three lines are as in the figure.



The plane determined by the three non-collinear points A, B, C—written ple (A, B, C)—is defined to be the class of points consisting of the points on the three lines str (BC), str (CA), and str (AB), and of the points in the seven regions $A\,(BC)$, $A'\,(BC)$, $B'\,(CA)$, $C'\,(AB)$, $A'\,(B'C)$, $B'\,(C'A)$, $C'\,(A'B)$.

5. Three axioms are required to establish the Geometry of a plane.

XII. If r is a straight line, there exists a point which does not lie on r.

Note that it would be sufficient to enunciate this axiom for one straight line.

XIII. If A, B, C are three non-collinear points, and D lies on the segment BC, and E on the segment AD, there exists a point F on both the segment AC and the prolongation $B'E$ (cf. fig. i, p. 5).

XIV. If A, B, C are three non-collinear points, and D lies on the segment BC, and F on the segment AC, there exists a point E lying on both the segments AD and BF (cf. fig. ii).

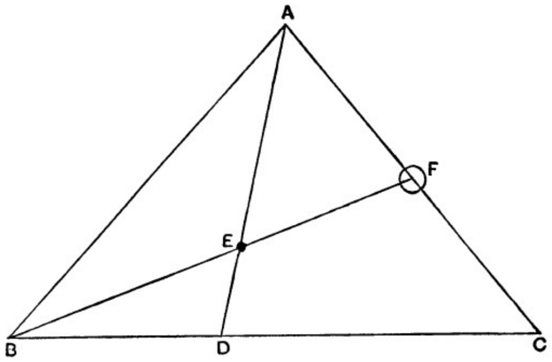


Fig. i.

With these axioms all the usual properties of the division of a plane by a line, and of the inside and outside of a plane closed figure,

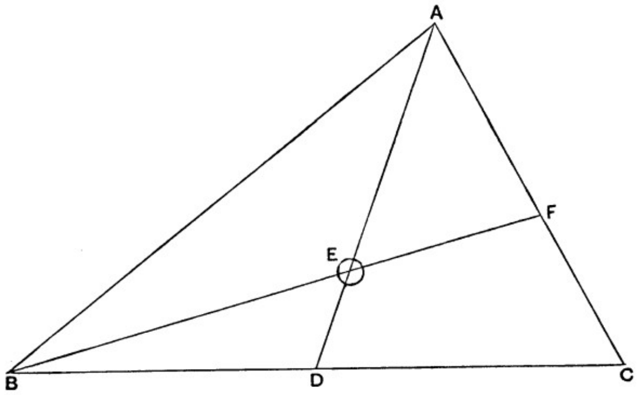

Fig. ii.

can be proved. Thus if ABC form a triangle and a coplanar line intersect the segment BC, it must intersect one and only one of the segments CA and AB.

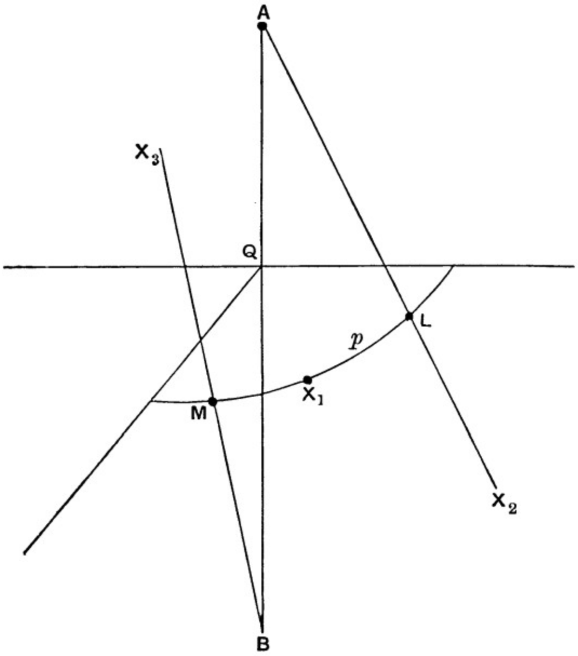
Also any three non-collinear points lie in one and only one plane; and the line determined by any two points lying in a plane lies entirely in that plane. But, as the case of Euclidean Geometry shews, we cannot prove from these axioms that any two lines in a plane intersect.

6. For three-dimensional Geometry two other axioms are required.

XV. A point can be found external to any plane. The enunciation of this axiom can be restricted to a particular plane.

XVI. Given any plane p, and any point A outside it, and any point Q on it, and any point B on the prolongation $A'Q$, then, if X is any other point, either X lies on the plane p, or AX intersects the plane p, or BX intersects the plane p.

The annexed figure illustrates the axiom, the points X_1, X_2, X_3 being positions of X which illustrate the three alternatives contemplated in the axiom. Thus X_1 lies on the plane p; X_2 lies on the same side of p as B, so that AX_2 must cut p in some point L; X_3 lies on the same side of p as A, so that BX_3 must cut p in some point M.



Axiom XVI secures the limitation to three dimensions, and the division of space by a plane. It can also be proved from the axioms that, if two planes intersect in at least one point, they intersect in a straight line.

7. A point will be said to divide a line into two half-rays which emanate from it.

A line will be said to divide a plane into two half-planes which are bounded by it.

A plane will be said to divide space into two half-spaces which are bounded by it.

A sheaf of lines is a complete set of coplanar lines concurrent at one point (the vertex). A sheaf of half-rays is a complete set of coplanar half-rays emanating from one point (the vertex).

A bundle of lines is a complete set of lines concurrent at one point (the vertex). A bundle of half-rays is a complete set of half-rays emanating from one point (the vertex).

If p, q, r are three half-rays belonging to a sheaf of half-rays, then r is said to 'lie between' p and q, if points A and B can be found on p and q respectively, such that the segment AB intersects r.

It can be proved that if r lies between p and q, then p does not lie between r and q.

The complete set of planes through a given line (the axis) is called a sheaf of planes. The axis divides each plane into two half-planes. These half-planes form a sheaf of half-planes.

If p, q, r are three half-planes belonging to a sheaf of half-planes, then r is said to 'lie between' p and q, if points A and B can be found on p and q respectively, such that the segment AB intersects r.

It can be proved that if r lies between p and q, then p does not lie between r and q.

The theorems indicated in this and in the preceding sections, and allied theorems, are not always very easy to prove. But their proofs depend so largely upon the particular mode of formulation of the axioms, that it would be outside the scope of this tract to enter into a consideration of them. In the sequel we shall assume that the whole class of theorems of the types, which have been thus generally indicated, can be proved from the axioms stated.

8. Formulations of the axioms of Descriptive Geometry have also been given by Hilbert*, and by E. H. Moore†, and by B. Russell‡, and by O. Veblen§. Veblen's memoir represents the final outcome of these successive labours, and his formulation will be given now. The axioms are stated in terms of 'points' and of a relation among three points called 'order.' Points and order are not defined.

I. There exist at least two distinct points.

§ *A System of Axioms for Geometry*, Trans. of the Amer. Math. Soc., vol. V., 1904.

II. If the points A, B, C are in the order ABC, they are in the order CBA.

III. If the points A, B, C are in the order ABC, they are not in the order BCA.

IV. If the points A, B, C are in the order ABC, then A is distinct from C.

V. If A and B are any two distinct points, there exists a point C such that A, B, C are in the order ABC.

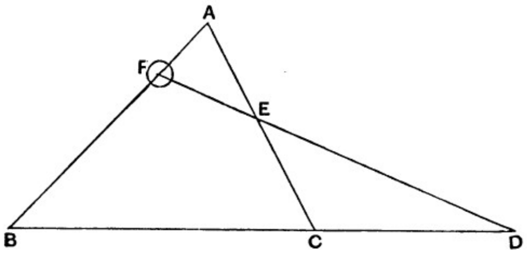
Definition 1. The line AB $(A \neq B)$ consists of A and B, and of all points X in one of the possible orders ABX, AXB, XAB. The points X in the order AXB constitute the 'segment' AB. A and B are the 'end-points' of the segment, but are not included in it.

VI. If points C and D $(C \neq D)$ lie on the line AB, then A lies on the line CD.

VII. If there exist three distinct points, there exist three points A, B, C not in any of the orders ABC, BCA, or CAB.

Definition 2. Three distinct points not lying on the same line are the 'vertices' of a 'triangle' ABC, whose sides are the segments AB, BC, CA, and whose 'boundary' consists of its vertices and the points of its sides.

VIII. If three distinct points A, B, C do not lie on the same line, and D and E are two points in the orders BCD and CEA, then a point F exists in the order AFB and such that D, E, F lie on the same line.



Definition 5. A point O is 'in the interior of' a triangle, if it lies on a segment, the end-points of which are points of different sides of a triangle. The set of such points O is 'the interior' of the triangle.

Definition 6. If A, B, C form a triangle, the 'plane' ABC consists of all points collinear with any two points of the sides of the triangle.

IX. If there exist three points not lying in the same line, there exists a plane *ABC* such that there is a point *D* not lying in the plane *ABC*.

Definition 7. If *A*, *B*, *C*, and *D* are four points not lying in the same plane, they form a 'tetrahedron' *ABCD*, whose 'faces' are the interiors of the triangles *ABC*, *BCD*, *CDA*, *DAB*, whose 'vertices' are the four points *A*, *B*, *C*, and *D*, and whose 'edges' are the segments *AB*, *BC*, *CD*, *DA*, *AC*, *BD*. The points of faces, edges, and vertices constitute the 'surface' of the tetrahedron.

Definition 8. If *A*, *B*, *C*, *D* are the vertices of a tetrahedron, the space *ABCD* consists of all points collinear with any two points of the faces of the tetrahedron.

X. If there exist four points, neither lying in the same line, nor lying in the same plane, there exists a space *ABCD*, such that there is no point *E* not collinear with two points of the space *ABCD*.

The above axioms of Veblen are equivalent to the axioms of Peano which have been previously given. Both Peano and Veblen give an axiom securing the Dedekind property (cf. § 9). Also Veblen gives an axiom securing the 'Euclidean' property (cf. § 10).

9. Dedekind's original formulation* of his famous property applies directly to the case of a descriptive line and is as follows:

"If all points of the straight line fall into two classes such that every point of the first class lies to the left of every point of the second class, then there exists one and only one point which produces this division of all points into two classes, this severing of the straight line into two portions."

It is of course to be understood that the dividing point itself belongs to one of the two classes.

It follows immediately that the boundary of a triangle consists of points in a compact closed order possessing the Dedekind property as already formulated for closed series†.

This definition may be repeated here to exhibit its essential independence of the special definition of projective segments upon which the previous formulation rests.

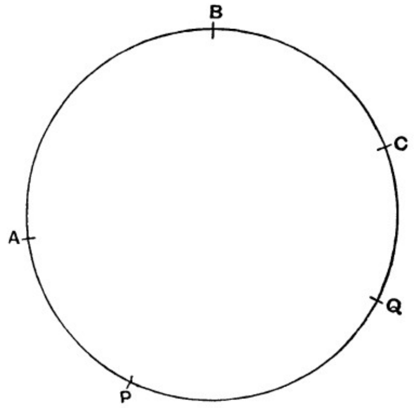
Let *A*, *B*, *C* be any three points of a closed series. Then by

---

* Cf. his *Continuity and Irrational Numbers*, ch. III.; the quotation here is from Beman's translation, Chicago, 1901.

† Cf. Proj. Geom. § 19 (*a*).

hypothesis the series is such that there are two ways round from A to C, namely, one through B and one not through B. Let segm (ABC) denote the points, excluding A and C, which are traversed from A to C through B, and let segm $(A\hat{B}C)$ denote the remaining points of the series. Again let a class u of the points of the series be called a segment of the series, when (1) there is a point B of the series which does not belong to u, and (2) if P and Q be any two points of u then segm $(P\hat{B}Q)$ belongs entirely to u.

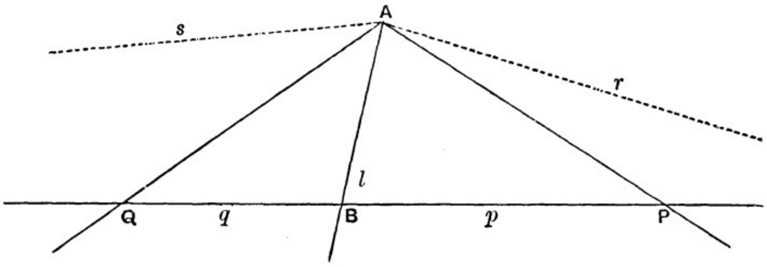


Then the series possesses the Dedekind property if any segment such as u (which excludes more than one point of the series) must possess two boundary points, that is to say, if there must exist points A and C such that segm $(A\hat{B}C)$, with the possible exception of either or both of A and C, is identical with u. Here—as above—B is a point which does not belong to u.

Hence a sheaf of half-rays can also be considered as a closed compact series with the Dedekind property. This is made immediately evident by surrounding the vertex by a triangle in the plane of the sheaf. Then each half-ray of the sheaf intersects the boundary of the triangle in one and only one point. Also the order of the points on the boundary is the order of the corresponding half-rays of the sheaf. But the boundary of the triangle is a closed series with the Dedekind property.

10. By the aid of the Dedekind axiom and of the preceding axioms, it can now be proved that, if l be any line and A be any point, not incident in l, then in the plane Al at least one line can be drawn through A, which does not intersect l.

For take any point B on l, and let p and q be the two supplementary half-rays of l which emanate from B. Consider the sheaf of half-rays, vertex A, in the plane Al. Some of these half-rays intersect p and some intersect q, and these classes are mutually exclusive.



Also, from the Dedekind property, there exist two semi-rays which are limits of the semi-rays intersecting p. AB is one of the semi-rays, let r be the other. Now the semi-ray p has no end-point. Hence r is not among the semi-rays intersecting p. Again by similar reasoning there is a semi-ray s which is the limit of the semi-rays intersecting q, and s does not intersect q.

Now first let r and s be not collinear, and let r' and s' be the half-rays supplementary to r and s respectively. Consider the set (α, say) of lines through A with one set of their half-rays between r and s', and therefore with their supplementary half-rays between r' and s. There are an infinite number of such lines. Now all half-rays emanating from A and lying between the half-ray AB and r intersect p, and no other half-rays from A intersect p. Similarly for the half-rays AB and s and q. Also if s' lie between the half-ray AB and r, then r' lies between the half-ray AB and s; and in this case every line of the set α intersects the line l twice, namely once for each of its pair of supplementary half-rays emanating from A. But this is impossible. Hence neither the supplement of r nor that of s can intersect l. Secondly if r and s are collinear, then the complete line formed by r and s cannot intersect l. For neither r nor s intersects l.

Thus taking any point A and any line l, the sheaf of lines, vertex A and in the plane Al, falls into two parts, namely the lines which intersect l, called the lines 'secant' to l, and the lines which do not intersect l, called the lines 'non-secant' to l. The non-secant lines of the sheaf may reduce to one line. The supposition that this is the case is the 'Euclidean Axiom.'

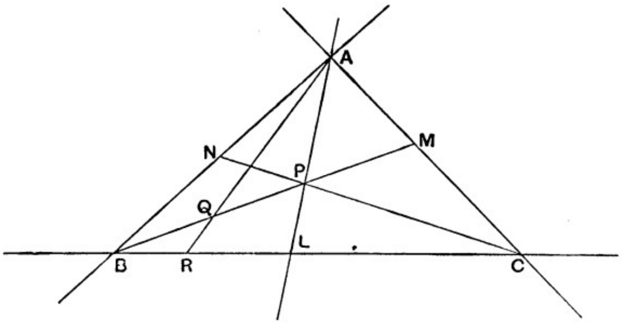
CHAPTER II.

THE ASSOCIATED PROJECTIVE SPACE.

11. We have now to establish the relation of Descriptive Geometry to an associated Projective Geometry. In a Projective Space let a 'convex region' be defined to be a region which (1) does not include the whole of any line, and (2) includes the whole of one of the two segments between any two points within it. It is easy to prove that such regions exist. For remembering* that we can employ the ordinary theory of homogeneous coordinates, the surface

$$x^2 + y^2 + z^2 - u^2 = 0$$

is well known to enclose such a region. Let a quadric enclosing a convex region be called a 'convex quadric.' Again in two dimensions let A, B, C be any three non-collinear points, and let P be any point not collinear with any two of them. Let AP meet the line BC in L, BP meet CA in M, CP meet AB in N.



Define the triangular region (ABC/P) to be the set of points formed by the collection of segments such as segm (AQR)†, where Q is any point on segm (BPM), and R is the point where the line

---

* Cf. Proj. Geom. §§ 37 and 42.

† Cf. Proj. Geom. § 13.

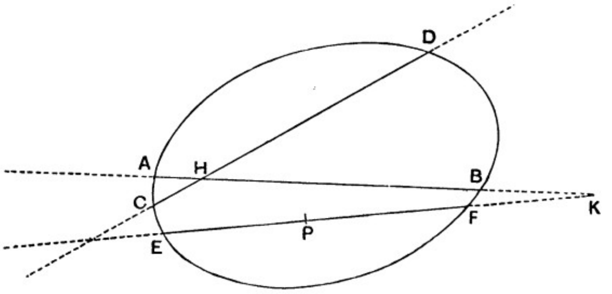
AQ intersects BC. The points A, B, C can be interchanged in this definition without altering the region obtained.

Similarly in three dimensions, if A, B, C, D are the vertices of a non-degenerate tetrahedron, and P be any point not on any of the planes, ABC, BCD, etc., the 'tetrahedral region' $(ABCD/P)$ can be similarly defined. From the ordinary theory of homogeneous coordinates, it is well known that a triangular region in two dimensions, and a tetrahedral region in three dimensions, are both convex regions.

Again the triangular region (ABC/P) considered above has as its 'boundary' the segments (BLC), (CMA), (ANB), together with the points A, B, C. Also considering the tetrahedral region $(ABCD/P)$, let AP intersect BCD in L, BP intersect CDA in M, CP intersect DAB in N, DP intersect ABC in O. Then the 'boundary' of the tetrahedral region $(ABCD/P)$ consists of the triangular regions (BCD/L), (CDA/M), (DAB/N), (ABC/O), together with the boundaries of these triangular regions.

It is now a well-known result from the use of coordinates that in two dimensions any line through a point in a triangular region cuts the boundary in two points only; and that in three dimensions any line through a point in a tetrahedral region cuts the boundary in two points only.

12. Now consider a convex region, let it be either the region within a convex quadric, or a tetrahedral region. Call the points within it 'Descriptive points'; and call the portions of lines within it 'Descriptive lines.' The projective order of points on a line becomes an open order for Descriptive points on Descriptive lines. Then by the use of coordinate Geometry it is easy to prove that all the Descriptive axioms of the present tract, either in Peano's form or in



Veblen's form, are satisfied, including the Dedekind axiom, but excluding the Euclidean axiom. Thus in the figure the lines AB and CD

intersect at a point H in Descriptive Space; but the lines AB and EF do not intersect in Descriptive Space, since K lies outside it. Also it is evident that through any point P an infinite number of lines can be drawn, coplanar with AB, and not intersecting it in Descriptive Space.

13. The previous article (§ 12) proves* the existence theorem for Descriptive Space with the negation of the Euclidean axiom; in other words, it proves the independence of the Euclidean axiom.

The existence theorem for Descriptive Space with the Euclidean axiom is immediately proved by considering the region of Projective Space found by excluding all the points on one projective plane. The region is convex according to the above definition; also all the Descriptive axioms, together with the Dedekind axiom and the Euclidean axiom, hold for it†.

14. The independence of the Dedekind axiom of the other axioms, combined with the negation of the Euclidean axiom, is proved by considering, as in § 12, Descriptive Space to be a tetrahedral region in Projective Space, but confining ourselves to the points whose coordinates are algebraic numbers‡, as in the corresponding proof for Projective Geometry.

The independence of the Dedekind axiom of the other axioms, combined with the Euclidean axiom, is similarly proved by considering Descriptive Space to be the region in Projective Space found by excluding a particular plane; and further, as before, we confine our consideration to the points whose coordinates are algebraic numbers.

---

* Cf. Proj. Geom. § 43.

† In the later Greek period, and during the seventeenth and eighteenth centuries, the discussion of the foundations of Geometry was almost entirely confined to attempts to prove the Euclidean axiom. The explicit recognitions of its independence by Lobatschefskij (1828), and by J. Bolyai (1832) laid the foundation of the existing theories of non-Euclidean Geometry. For the literature of the whole question cf. Stäckel and Engel, *Die Theorie der Parallellinien von Euklid bis auf Gauss*, Leipzig, 1895, and also their *Urkunden zur Geschichte der Nichteuklidischen Geometrie, I. Lobatschefskij*, Leipzig, 1898.

‡ Cf. Proj. Geom. § 43 (α). An oversight in this proof may be here corrected. The proof, as printed, proceeds by considering only points with rational coordinates. But then a difficulty arises as to the theory of segments given in Chapter IV. of Proj. Geom. For it is necessary that the real double points of a hyperbolic involution should belong to the points considered. But these double points are given by a quadratic equation. Thus algebraic numbers (*i.e.* numbers which can occur as the roots of equations with integral coefficients) should be substituted for rational numbers. The proof proceeds without other alteration. I am indebted to Mr G. G. Berry of the Bodleian Library for this correction.

15. It has been proved in §§ 12 and 13 that a convex region of a Projective Space is a Descriptive Space. The converse problem has now to be considered in this and in the next chapter; namely, given a Descriptive Space, to construct a Projective Space of which the Descriptive Space is part. This effects a very considerable simplification in the investigation of the properties of Descriptive Space owing to the superior generality of the analogous properties of Projective Space. Thus a Projective Space affords a complete interpretation of all the entities indicated in coordinate geometry. It is in order to gain this simplification that the 'plane at infinity' is introduced into ordinary Euclidean Geometry. We have in effect to seek the logical justification for this procedure by indicating the exact nature of the entities which are vaguely defined as the 'points at infinity'; and the procedure is extended by shewing that it is not necessarily connected with the assumption of the Euclidean axiom. This investigation is the Theory of Ideal Points*, or of the generation of 'Proper and Improper Projective Points' in Descriptive Geometry. The Euclidean axiom will not be assumed except when it is explicitly introduced. The remainder of this chapter will be occupied with the general theorems which are required for the investigation.

16. If A be any point and l be any line not containing A, then the plane Al divides the bundle of half-rays emanating from A into three sets, (1) the half-rays in the plane Al, (2) the half-rays on one side of the plane, (3) the half-rays on the other side of the plane. The sets (2) and (3) are formed of half-rays supplementary one to the other.

Lemma. With the above notation, it is possible to find a plane through the line l and intersecting any finite number of the half-rays either of set (2) or of set (3).

For let $a_1, \dots a_n$ be n half-rays of one of the two sets. Let B_1 be any point on a_1, and B_2 be any point on a_2. Then either the plane

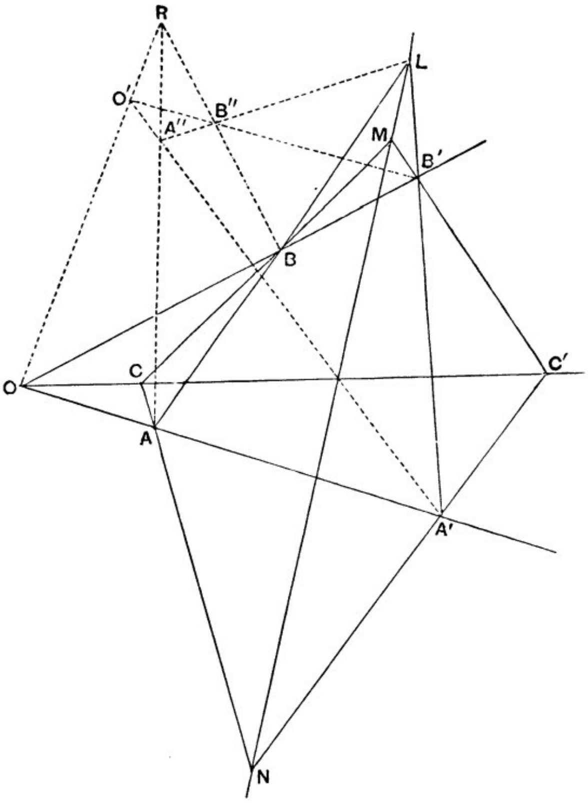
---

* Originally suggested by Klein (extending an earlier suggestion of von Staudt), *Math. Annal.* vols. IV. and VI., 1871 and 1872; first worked out in detail by Pasch, *loc. cit.*, §§ 6—9. In the text I have followed very closely a simplification of the argument given by R. Bonola, *Sulla Introduzione degli Enti Improprii in Geometria Projectiva*, Giornale di Matematiche, vol. XXXVIII., 1900.

B_1l lies between the planes B_2l and Al, or the plane B_2l lies between the planes B_1l and Al, or the planes B_1l and B_2l are identical. But in either of the first two cases the intermediate plane intersects both semi-rays a_1 and a_2. Hence a plane is found through l, intersecting both a_1 and a_2. Call it the plane $B_2'l$. Again take any point B_3 on a_3; and the same argument shews that at least one of $B_2'l$ and B_3l intersects a_1, a_2, and a_3. Proceeding in this way, a plane is finally found which intersects each of the n semi-rays.

17. Desargues' Perspective theorems* can be enunciated in the following modified forms:

(1) If two coplanar triangles ABC and $A'B'C'$ are such that the lines AA', BB', CC' are concurrent in a point O, then the three intersections of BC and $B'C'$, CA and $C'A'$, AB and $A'B'$, if they exist, are collinear.



---

* Cf. Proj. Geom. § 7.

(2) If the pairs of homologous sides of the two coplanar triangles ABC and $A'B'C'$, namely, BC and $B'C'$, CA and $C'A'$, AB and $A'B'$, intersect in three collinear points, then the lines AA', BB', CC', if any two intersect, are concurrent in the same point.

Considering the first proposition let AB and $A'B'$ intersect in L, BC and $B'C'$ in M, CA and $C'A'$ in N. Now it is not possible both for A' to lie on the segment OA, and for A to lie on the segment OA'. Assume that A' does not lie on the segment OA. Let R be any point external to the given plane (α, say). Now by the lemma of § 16, it is possible to find a plane through LM, lying between the planes LMR and LMA (*i.e.* the plane α), and intersecting the three lines RA, RB, RC, say, in the points A'', B'', C'' (in the figure C'' is not shewn). Then evidently A'' must lie in the segment RA. Hence $A'A''$, since A' does not lie in the segment OA, must intersect OR in the segment OR. Thus the intersection of the lines $A'A''$ and OR is secured. Let it be the point O'. Again the lines $O'A'$ and $O'B'$ are the projections from R on the plane $A'O'B'$ of the lines OA' and OB'. Now $A''B''$ passes through L. Hence B'' lies on the plane $A'A''B'$, *i.e.* on the plane $OA'B'$. Hence B'' is on the projection of the line OB' on the plane $O'A'B'$, *i.e.* B'' lies on $O'B'$. Thus $B'B''$ passes through O'.

Reasoning in exactly the same way for BC and $B'C'$, it follows that $C'C''$ passes through O'. The same figure has now been constructed as in the proof of the corresponding theorem for Projective Geometry*. Accordingly the theorem follows by the same reasoning.

In order to demonstrate the converse theorem, we proceed exactly as above, except that, L, M, N are now assumed to be collinear, O is the point of intersection of AA' and BB'. Then the same construction is made as before, and it is successively proved by similar reasoning that every pair of the lines $A'A''$, $B'B''$, $C'C''$ intersect. But the lines are not coplanar. Hence they intersect in the same point O'. But O' must lie on RO. Thus CC' passes through O.

Corollary. The enunciation of the first theorem can be modified by removing the assumption that AC and $A'C'$ intersect, but by adding the assumption that AC intersects LM.

18. A trihedron is the figure formed by three lines concurrent in the same point, and not all coplanar. The three lines form the edges of the trihedron; the three planes containing the lines, two by two, form the faces of the trihedron; the point of concurrence of the three edges is the vertex of the trihedron.

---

* Cf. Proj. Geom. § 7.

It follows (cf. § 6) that, if two trihedrons have the same vertex, any two faces, one from each trihedron, must intersect in a line through the vertex; also that any two planes each containing two edges, one edge from each trihedron, must intersect in a line through the vertex.

Desargues' theorems can be applied to two trihedrons with the same vertex; only in this case, as in Projective Geometry, there are no exceptional cases depending on non-intersection.

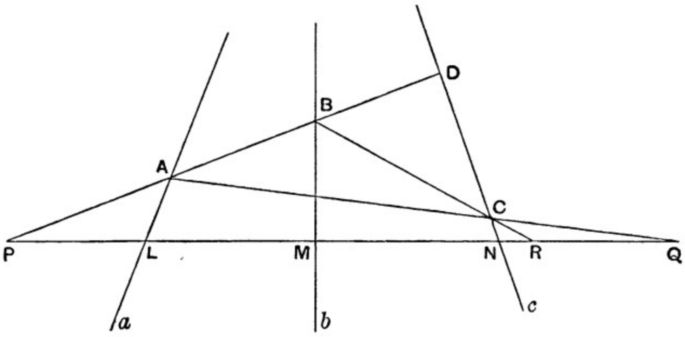
The enunciations are as follows:

(1) If a, b, c and a', b', c' are the edges of two trihedrons with the same vertex, such that the planes containing a and a', b and b', c and c', are concurrent in a line s (*i.e.* belong to the same sheaf), then the three intersections of the planes bc and $b'c'$, ca and $c'a'$, ab and $a'b'$ are coplanar.

(2) If a, b, c and a', b', c' are the edges of two trihedrons with the same vertex, such that the three intersections of the planes bc and $b'c'$, ca and $c'a'$, ab and $a'b'$, are coplanar, then the three planes containing a and a', b and b', c and c' belong to the same sheaf.

These propositions immediately follow from the case of triangles by noticing that, by the lemma of § 16, the six edges of the trihedrons can be cut by a plane, not through the vertex. Hence by the previous remarks on trihedrons, Desarguesian triangles are obtained without the exceptions due to non-intersection.

19. The two theorems of the present and next articles are the central theorems of the whole theory of Ideal Points.



If the lines a, b, c are the intersections of three planes α, β, γ of a sheaf with a plane π, not belonging to the sheaf, and if O be any point not incident in π, then the three planes Oa, Ob, Oc belong to one sheaf.

If the axis (r) of the sheaf intersect the plane π in a point S, then the three lines a, b, c pass through S, and the line OS is evidently contained in Oa, Ob, Oc, and thus forms the axis of the new sheaf.

Consider now the case when the axis (r) of the sheaf does not intersect π. Then a, b, c are not concurrent, and no two of them intersect. Hence one of the three (b, say) must lie between [*i.e.* any segment, joining a point on a and a point on c, intersects b] the other two. Take any two points L and N on a and c respectively, then the segment LN intersects b in a point M. Take two other points P and Q on LN so that we have the order P, L, M, N, Q. Take any point D on c; then the segment PD must intersect a and b in two points A and B respectively; and the segment AQ must intersect the segment DN in a point C. Then the line BC must intersect the segment NQ in a point R. Thus a triangle ABC has been formed, whose vertices lie on a, b, c, and whose sides AB, AC, BC pass through P, Q, R respectively.

By taking another point D' on c, another triangle $A'B'C'$ can be similarly formed, whose vertices lie on a, b, c, and whose sides $A'B'$ and $A'C'$ pass through P and Q respectively.

We have first to shew that $B'C'$ passes through R. For taking any point T on the axis (r) of the sheaf, the lines TA, TB, TC form the edges of one trihedron, and the lines TA', TB', TC' form the edges of another trihedron with the same vertex.

Also the planes TAA', TBB', TCC' belong to the same sheaf. Hence the three intersections of the pairs of planes TAB and $TA'B'$, TAC and $TA'C'$, TBC and $TB'C'$ are coplanar; hence they lie in the plane TPQ. Hence $B'C'$ passes through R.

Now considering the two trihedrons with edges OA, OB, OC, and OA', OB', OC', the intersections of the pairs of faces OAB and $OA'B'$, OAC and $OA'C'$, OBC and $OB'C'$, are respectively OP, OQ, OR; and these are coplanar. Hence by the converse part of Desargues' theorem for trihedrons, the planes OAA', OBB', OCC' belong to the same sheaf. Hence Oa, Ob, Oc belong to the same sheaf (*i.e.* have a common line of intersection).

20. If any two of the lines a, b, c are coplanar, but the three lines are not coplanar, and similarly for the lines a, b, d, then c and d are coplanar.

If a and b intersect, the theorem is evident; for a, b, c are concurrent, and a, b, d are concurrent. Hence c and d are concurrent.

Assume that a and b do not intersect. Then it is easy to prove that no two of the lines intersect. It follows that no one of the lines c, b, d can intersect any of the planes ab, ac, ad in which it does not lie.

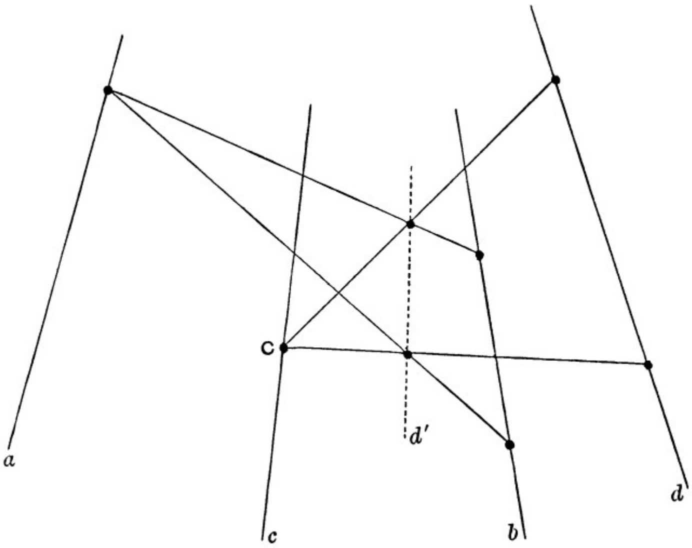


Fig. 1.

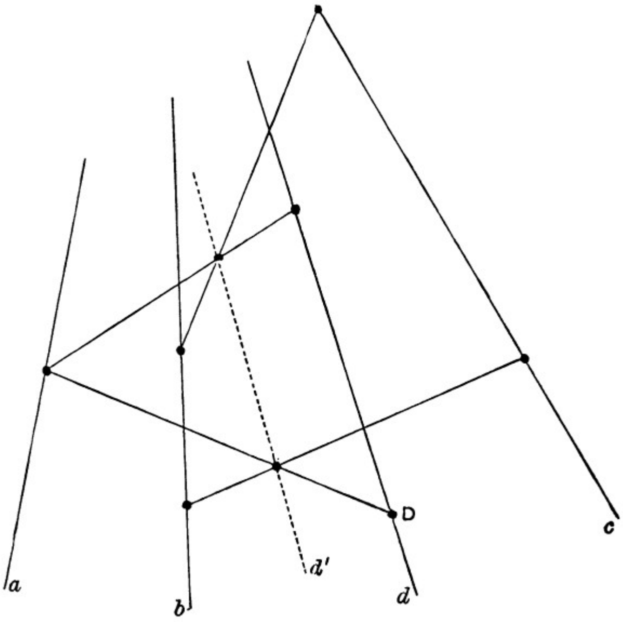

Fig. 2.

Hence it follows that either *c* and *d* lie on opposite sides of the plane *ab*, or *d* and *b* on opposite sides of the plane *ac*, or *b* and *c* on opposite sides of the plane *ad*.

First, let *c* and *d* lie on opposite sides of the plane *ab* (cf. fig. 1). Take any point *C* on *c*. Then the plane *Cd* must intersect the plane *ab* in a line, *d'*, say. Then the lines *a*, *b*, *d'* are the intersections of the three planes *da*, *db*, *dC* with the plane *ab*; and these three planes belong to the same sheaf. Hence (cf. § 19) the three planes through the lines *a*, *b*, *d'* respectively and through any point not on *ab* belong to the same sheaf. But *C* is such a point. Hence the planes *Ca*, *Cb*, *Cd'* belong to the same sheaf. But *c* is the common line of *Ca* and *Cb*. Hence *Cd'* contains the line *c*. Hence *c* and *d* are coplanar.

Secondly, let the plane *ad* lie between *b* and *c*. Then the plane *bc* must intersect the plane *ad* in some line, *d'* say. Thus the three lines *b*, *d'*, *c* are the intersections of the three planes *ab*, *ad*, *ac* with the plane *bc*. These three planes belong to the same sheaf. Hence (cf. § 19), if *D* is any point on *d*, not on *bc*, the planes *Db*, *Dc*, *Dd'* belong to the same sheaf. But *Db* and *Dd'* intersect in the line *d*; hence *Dc* passes through the line *d*. Thus *c* and *d* are coplanar.

Thirdly, let the plane *ac* lie between *b* and *d*. Then the proof is as in the second case, interchanging *c* and *d*.

Growth of semiconductor crystals

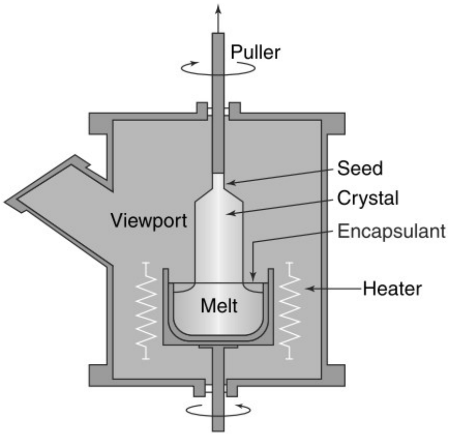

Figure 4-6 Experimental setup of Czochralski growth of semiconductor crystals

The fabrication of semiconductor devices requires highly pure and mono-crystalline semiconductors. The Czochralski method, invented by the Polish scientist Jan Czochralski in 1916, is the preferred method for high-volume production of high quality Si single crystals. The silicon is pulled from a bath of molten silicon to form mono-crystalline silicon using a small seed crystal, as shown in Fig. 4-6. The semiconductor crystals can be obtained by cooling the molten semiconductor material. Incidentally, this procedure yields poly-crystalline material since crystals start growing in different locations with a different orientation. Single-crystal silicon can be grown by dipping one end of a seed crystal in the melt and by controlling the temperature difference between the seed crystal and the molten silicon. The output is large single-crystal silicon, cylindrical in shape. The diameter of the silicon will depend on the rotation of the seed crystal during the stages of its growth and partly on the cylindrical shape of the crucible containing the melt.

The cylindrical silicon is then cut into smaller wafers with a diamond saw and again polished to yield the substrate material for the silicon device fabrication.

4-2-2 Mechanical Properties

In the presence of stress, the tensorial nature of Hooke's law becomes prominent. Only the second- and third-order elastic constants are being affected in the presence of stress. In the *n*-type germanium, the shear elastic constant is being reduced by 8 per cent. In view of large changes of the elastic constants with the carrier density, the experiments on the velocity of sound involving shear mode as a function of carrier concentration exhibit the contribution of the electrons to the mechanical properties.

4-2-3 Energy Band Theory

In the energy band theory, we are only concerned with the conduction band and the valance band separated by a band gap. By using this theory, we can differentiate among insulators, metals and semiconductors. Another attribute of this theory is the formulation of the carrier energy spectrum, which in turn controls all the physical properties of semiconductors and semi metals in general.

Energy levels in atoms

The sum of the kinetic and potential energies of an electron orbiting a nucleus can only assume a set of discrete values; those for the simplest atom (hydrogen) are shown in Fig. 4-7. This happens because the electrons exhibit wave-like properties.

To be stable, the electron wave must repeat itself exactly at the same time when it is on a circular path around the nucleus. This is illustrated schematically in Fig. 4-8. It leads to the conclusion that in such a state an integral number of wavelengths must fit into its path. This state is termed *quantization condition*.

The electron's wavelength (λ) is inversely proportional to its momentum (p) as defined by de Broglie's relation of the wave-particle duality:

$$\lambda = \frac{h}{p} \tag{4-1}$$

The constant h is called Planck constant, and has the value 6.6×10^{-34} Js. The graph of Eq. (4-1) is rectangular hyperbolic in $p - \lambda$ plane. The quantization condition, thus, fixes the electron momentum to one of a set of discrete values, depending on the number of wavelengths fitting the circular path. The number, known as a *quantum number*, determines which set of discrete energies the electron has, since the energy is directly related to the electron's momentum. Four quantum numbers are needed to describe the electron in the hydrogen atom.

It should be noted that an electron freed from its parent nucleus can have any wavelength, and hence any kinetic energy. This explains the continuum of energy levels above the zero of energy, given in Fig. 4-7. When an atom contains many electrons, no more than two are found to exist simultaneously in the same state of nature. One of these electrons spins clockwise, the other anticlockwise. So the above rule can be expressed by stating, "In a closed system, no two electrons can occupy the same state." This is known as the Pauli exclusion principle.

In the simplest cases, when each state has a different energy we find electrons filling energy levels from the lowest up, one to each state. In the more general cases, it is possible for two or more orbits, or states, to have the same energy. Thus, a limited number of electrons are in the highest filled atomic energy levels, and these are the valence electrons, which take part in bonding an atom within a molecule or solid.

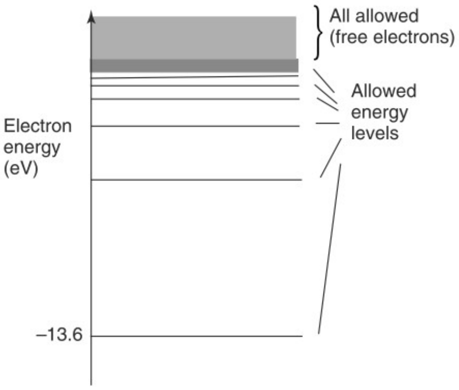

Figure 4-7 Energy level diagram for a hydrogen atom

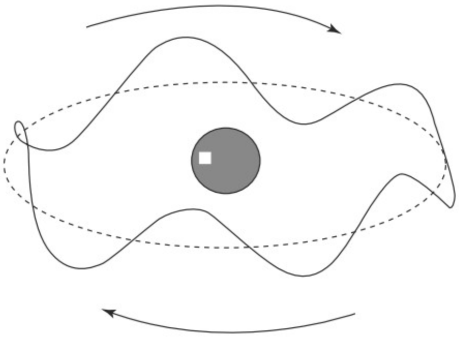

Figure 4-8 Continuity of the electron wave around the nucleus resulting in an integral number of wavelengths fitting into any circular path

Solved Examples

Example 4-1 When a photon impinges upon a semiconductor it can take an electron from the valence band to the conduction band. The momentum is conserved in such transitions. Calculate the value of the wave vector that a 2.0 eV photon carries. The electron in the valence band can go into the conduction band with the momentum change of the photon.

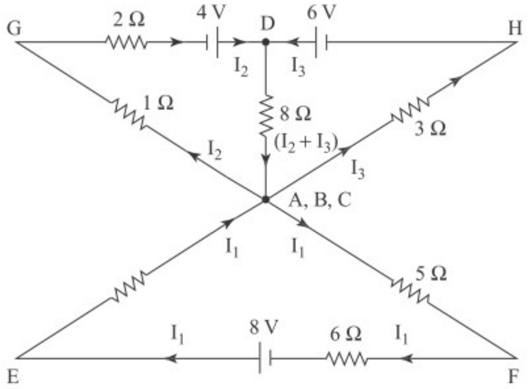

Figure 2.25

In the loop EA FE, current I_1 will flow. No current from this loop will flow to the other two loops. Current flowing from E to A is to be the same as the current flowing from A to F.

The distribution of currents in loop GDAG and HDAH have been shown. By applying KVL in these loops we write:

for loop GDAG

$$-2\,I_2 + 4 - 8(I_2 + I_3) - I_2 = 0$$

or, $$11\,I_2 + 8\,I_3 = 4 \qquad \text{(i)}$$

for loop HDAH

$$6 - 8\,(I_2 + I_3) - 3\,I_3 = 0 \qquad \text{(ii)}$$

or, $$8I_2 + 11\,I_3 = 6$$

Solving eqs. (i) and (ii)

$$I_3 = 0.6 \text{ A and } I_2 = -0.07 \text{ A}$$

Current through the 8 Ω resistor $= I_2 + I_3$

$$= -0.07 + 0.6$$
$$= 0.53 \text{ A}$$

So far, we have assumed branch currents in a network and applying KVL written the voltage equations. From the loop equations, we have calculated the branch currents. Two other methods, namely Maxwell's mesh current method and Node voltage method, are described in the following sections.

2.6 MAXWELL'S MESH CURRENT METHOD

A mesh is a smallest loop in a network. KVL is applied to each mesh in terms of mesh currents instead of branch currents. As a convention, mesh currents are assumed to be flowing in the clockwise direction without branching out at the junctions. Applying KVL, the voltage equations are framed. By knowing the mesh currents, the branch currents can be determined. The procedure followed is explained through an example. Let us calculate the current flowing through the branches in the circuit given in Fig. 2.26.

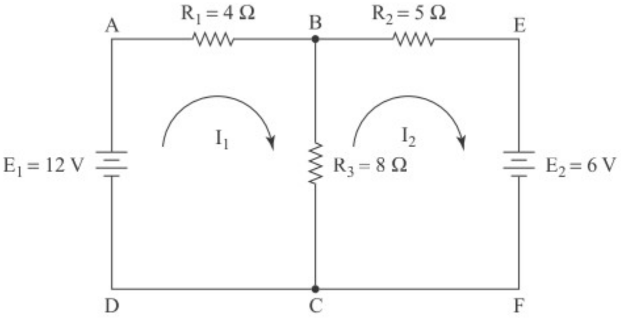

Figure 2.26

We have assumed loop currents I_1 and I_2 flowing in the clockwise direction as shown.

It may be noted that current flowing through the resistor R_3 is the algebraic sum of the two currents I_1 and I_2. Here I_1 is flowing in the downward direction while I_2 is flowing in the upward direction.

We will now write the voltage equations for the two loops applying KVL and then solve the equations. If the value of any mesh currents is calculated as negative, we will take the direction of that mesh current opposite to the assumed clockwise direction.

For loop DABCD, the voltage equation is

$$12 - 4\,I_1 - 8(I_1 - I_2) = 0$$

or,
$$3\,I_1 - 2I_2 = 3 \tag{i}$$

For loop BEFCB, the voltage equation is

$$-5\,I_2 - 6 - (I_2 - I_1)\,8 = 0$$

or,
$$8\,I_1 - 13\,I_2 = 6 \tag{ii}$$

solving eqs. (i) and (ii), we get

$$I_1 = 1.17\text{ A},\ I_2 = 0.26\text{ A}$$

and current flowing through R_3 is $(I_1 - I_2) = 0.91$ A

I_1 is flowing through R_1, I_2 is flowing through R_2 and $(I_1 - I_2)$ is flowing through R_3.

Example 2.8 Using the mesh current method calculate the current flowing through the resistors in the circuit shown in Fig. 2.27.

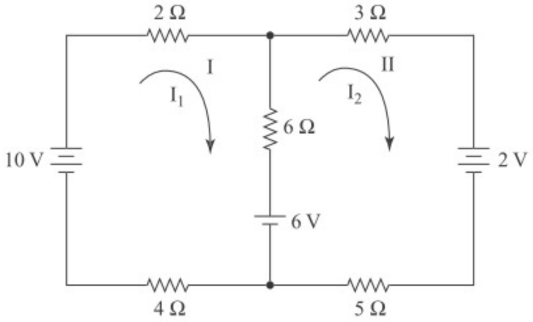

Figure 2.27

Solution:

Applying KVL in mesh I,

$$10 - 2\,I_1 - 6\,(I_1 - I_2) - 6 - 4\,I_1 = 0$$

or,
$$6\,I_1 + 3\,I_2 = 2 \qquad \text{(i)}$$

Applying KVL in mesh II,

$$-3I_2 - 2 - 5I_2 + 6 + 6\,(I_1 - I_2) = 0$$

or,
$$-6I_1 + 14\,I_2 = 4 \qquad \text{(ii)}$$

Adding eqs. (i) and (ii)

$$11\,I_2 = 6$$

or,
$$I_2 = \frac{6}{11}\,\text{A}$$

and
$$I_1 = \frac{2+3I_2}{6} = \frac{2+3\times 6/11}{6} = \frac{20}{33}\,\text{A}$$

Current through the 6 Ω resistor is $(I_1 - I_2)$ which is equal to $\frac{2}{33}$ A.

Example 2.9 A network with three meshes has been shown in Fig. 2.28. Applying Maxwell's mesh current method determine the value of the unknown voltage, V for which the mesh current, I_1 will be zero.

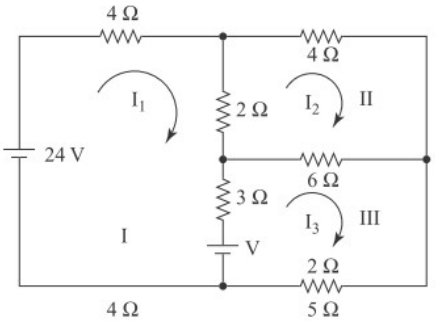

Figure 2.28

Solution:

Applying KVL in mesh I, II, and III respectively, we get

$$-4\,I_1 - 2\left(I_1 - I_2\right) - 3\left(I_1 - I_3\right) - V + 24 = 0$$

or,
$$9\,I_1 - 2\,I_2 - 3\,I_3 = 24 - V \qquad \text{(i)}$$

$$-4\,I_2 - 6\left(I_2 - I_3\right) - 2\left(I_2 - I_1\right) = 0$$

or,
$$I_1 - 6\,I_2 + 3\,I_3 = 0 \qquad \text{(ii)}$$

$$-6\left(I_3 - I_2\right) - 2\,I_3 + V - 3\left(I_3 - I_1\right) = 0$$

or,
$$3I_1 + 6\,I_2 - 11\,I_3 = -V \qquad \text{(iii)}$$

From (i), (ii), and (iii) the determinants Δ and Δ_a or Δ_1 are

$$\Delta = \begin{vmatrix} 9 & -2 & -3 \\ 1 & -6 & 3 \\ 3 & 6 & -11 \end{vmatrix}$$

$$\Delta_1 = \begin{vmatrix} 24-v & -2 & -3 \\ 0 & -6 & 3 \\ -v & 6 & -11 \end{vmatrix}$$

According to Cramer's rule,

$$I_1 = \frac{\Delta_1}{\Delta}, \quad I_2 = \frac{\Delta_2}{\Delta} \quad I_3 = \frac{\Delta_3}{\Delta}$$

Here condition is that I_1 must be zero.

$$I_1 = \frac{\Delta_1}{\Delta} = 0. \text{ So, } \Delta_1 \text{ must be zero}$$

Thus, we equate Δ_1 to zero.

$$\begin{vmatrix} 24-v & -2 & -3 \\ 0 & -6 & 3 \\ -v & 6 & -11 \end{vmatrix} = 0$$

or, $$(24-v)\begin{vmatrix} -6 & 3 \\ 6 & -11 \end{vmatrix} - (-2)\begin{vmatrix} 0 & 3 \\ -v & -11 \end{vmatrix} - 3\begin{vmatrix} 0 & -6 \\ -v & 6 \end{vmatrix} = 0$$

$$(24 - V)\,[66 - 18] + 2\,[0 - (-3V)] - 3[0 - 6V] = 0$$

or, $$(24 - V)\,48 + 6V + 18V = 0$$

or, $$24 \times 48 - 48V + 24V = 0$$

or, $$24V = 24 \times 48$$

or, $$V = 48 \text{ Volts}$$

2.7 NODAL VOLTAGE METHOD (NODAL ANALYSIS)

In the nodal analysis method a reference node in the network is chosen. Then the unknown voltages at the other nodes are determined with respect to the reference node. After determining the node voltages, currents in all branches can be calculated. This method of circuit analysis is suitable where a network has a number of loops, and hence a large number of simultaneous equations are to be solved. The procedure for the node voltage method is explained through an example.

Example 2.10 For the circuit shown in Fig. 2.29 determine the voltages at nodes B and C and calculate the current through the 8 Ω resistor.

Chapter 9

The Sphere

In a sequel to *Flatland*, an octagon by the name of Mr. Puncto surveys some rather large triangles and finds that each has angles that add up to slightly more than 180°! This discovery excites Mr. Puncto, and, after double checking his data, he makes the discovery public. Unfortunately neither the civil authorities nor the scientific establishment shares his excitement. They suspect he is merely inventing excuses to explain some errors in his measurements, and they dismiss him from his job. The true explanation is that the Flatlanders are living not in a plane but on a sphere, and on a sphere the angles of a triangle really do add up to more than 180°, as we shall soon see. This incident and much more is described in the book *Sphereland* by Dionys Burger. I heartily recommend *Sphereland* to all readers of the present book (just don't be put off by the rather dull summary of *Flatland* at the beginning).

A triangle drawn on a sphere is called a *spherical triangle* (Figure 9.1). Each side of a spherical triangle is required to be a geodesic; that is, it is required to be intrinsically straight in the sense that a Flatlander on the sphere would perceive it as bending neither to the left nor to the

07:40:41.

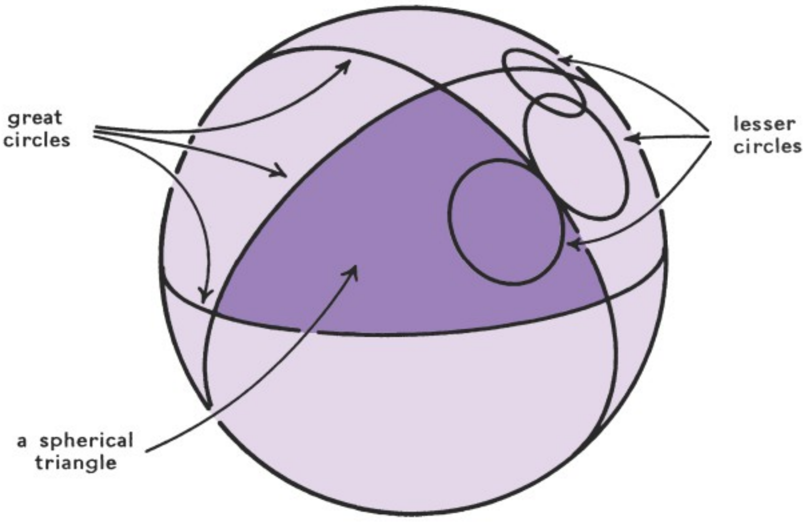

Figure 9.1: On any sphere, the great circles are those circles that are as big as possible. A great circle appears straight to a Flatlander on the sphere. By contrast, any lesser circle appears to bend to one side or the other.

right. A side of a spherical triangle is thus an arc of a so-called *great circle* (see Figure 9.1).

From now on we will *measure all angles in radians*, to facilitate easier comparison of angles and areas (in a minute you'll see how and why we want to do this). Recall that π radians = 180°, $\pi/2$ radians = 90°, etc. Except when specified otherwise, we will henceforth assume that all spheres are unit spheres, i.e. they all have radius one.

Exercise 9.1 For each spherical triangle in Figure 9.2 compute (1) the sum of its angles in radians, and (2) its area. To compute the areas, use the fact that the unit sphere has area 4π. For example, the first triangle shown occupies $1/8$ of the sphere, so its area is $(4\pi)/8 = \pi/2$.

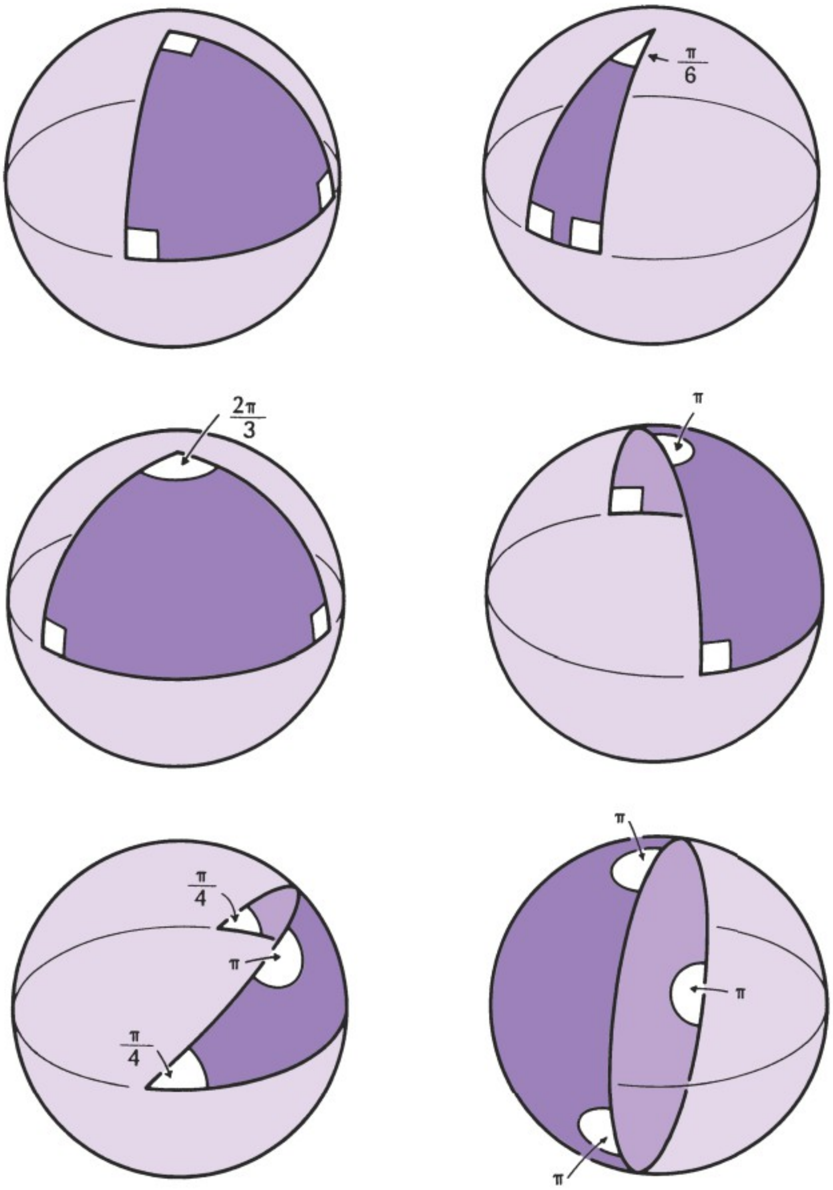

Figure 9.2: Some assorted spherical triangles. Three of the triangles are "degenerate" in the sense that each has one or more angles equal to π*. The last triangle occupies an entire hemisphere, and its three sides all lie on the same great circle.*

Exercise 9.2 Using your answers to Exercise 9.1, find a formula relating a spherical triangle's angle-sum to its area. This formula appeared in 1629 in the section "De la mesure de la superfice des triangles et polygones sphéricques, nouvellement inventée" of the book *Invention nouvelle en l'algebre* by Albert Girard. You should try to find the formula before reading on, because the following paragraphs give it away.

Exercise 9.3 What is the area of a spherical triangle whose angles in radians are $\pi/2$, $\pi/3$, and $\pi/4$? What is the area of a spherical triangle with angles of 61°, 62°, and 63°?

The proof of the formula you just discovered is simple and elegant. (It is not, however, the sort of thing you're likely to stumble onto on your own. I struggled for hours without being able to prove the formula at all.) The easiest proof uses "lunes".

A *lune* is a region on a sphere bounded by two great semi-circles, as shown in Figure 9.3. As you increase a lune's angle θ from 0 to 2π, the area A that it encloses increases proportionally from 0 to the whole area of the sphere, which is 4π. In symbols, $A = 2\theta$.

Now we'll find the formula for the area of a spherical triangle with angles α, β, and γ. First extend the sides of the triangle all the way around the sphere to form three great circles, as shown in Figure 9.4. An "antipodal triangle", identical to the original, is formed on the back side of the sphere. Figure 9.5*(a)* shows three colored lunes. These lunes have respective angles $\pi - \alpha$, $\pi - \beta$, and $\pi - \gamma$, and therefore have areas $2(\pi \quad \alpha)$, $2(\pi - \beta)$, and $2(\pi - \gamma)$.

07:40:41.

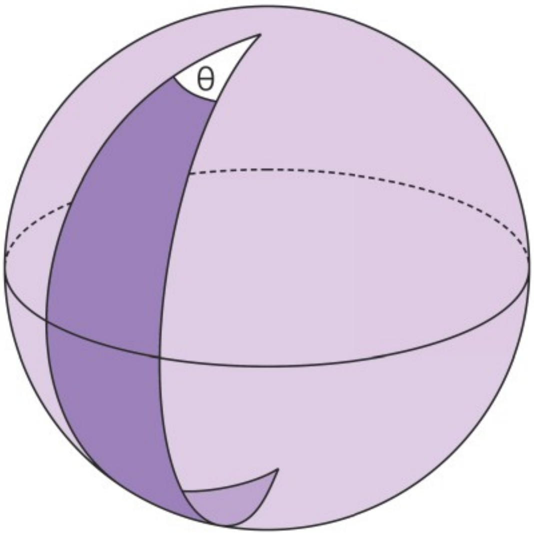

Figure 9.3: A lune with angle θ

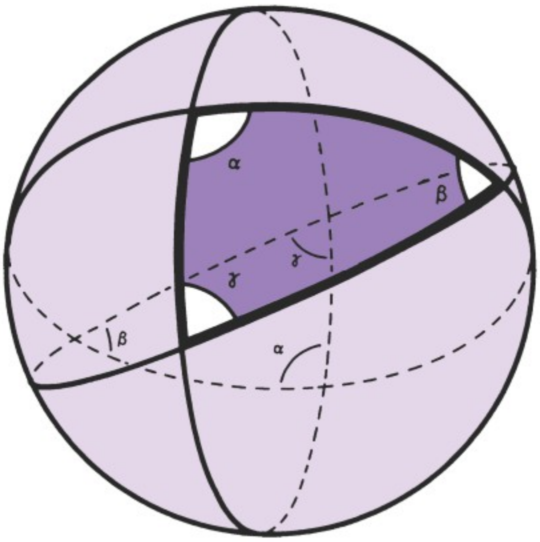

Figure 9.4: Extend the edges of the spherical triangle, and the resulting great circles will form an "antipodal triangle" on the back side of the sphere.

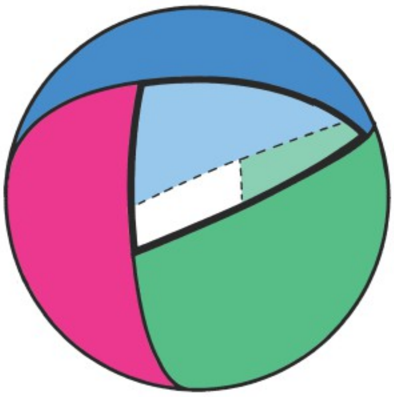
(a) Three colored lunes



(b) The three colored lunes fill the whole sphere except for the original and antipodal triangles.

Figure 9.5

07:40:41.

Taken together (Figure 9.5*(b)*), the three colored lunes fill almost the whole sphere, except for the original and antipodal triangles. So . . .

$$\begin{array}{ccccccccccc} \begin{pmatrix}\text{area}\\ \text{of red}\\ \text{lune}\end{pmatrix} & + & \begin{pmatrix}\text{area}\\ \text{of blue}\\ \text{lune}\end{pmatrix} & + & \begin{pmatrix}\text{area}\\ \text{of green}\\ \text{lune}\end{pmatrix} & + & \begin{pmatrix}\text{area of}\\ \text{original}\\ \text{triangle}\end{pmatrix} & + & \begin{pmatrix}\text{area of}\\ \text{antipodal}\\ \text{triangle}\end{pmatrix} & = & \begin{pmatrix}\text{area}\\ \text{of entire}\\ \text{sphere}\end{pmatrix} \\ 2(\pi-\alpha) & + & 2(\pi-\beta) & + & 2(\pi-\gamma) & + & A & + & A & = & 4\pi \end{array}$$

$$6\pi - 2(\alpha+\beta+\gamma) + 2A = 4\pi$$

$$A = (\alpha+\beta+\gamma) - \pi$$

which is just what we wanted to prove! In words, this formula says that the sum of the angles of a spherical triangle exceeds π by an amount equal to the triangle's area.

Exercise 9.4 The formula $A = (\alpha+\beta+\gamma) - \pi$ applies only to triangles on a sphere of radius one. How must you modify the formula to apply to triangles on a sphere of radius two? What about radius three? Write down a general formula for triangles on a sphere of radius r.

Exercise 9.5 A society of Flatlanders lives on a sphere whose radius is exactly 1000 meters. A farmer has a triangular field with perfectly straight (i.e. geodesic) sides and angles, which have been carefully measured as 43.624°, 85.123°, and 51.270°. What is the area of the field? Don't forget to convert the angles to radians. (Bonus Question: How accurately do you know the field's area? That is, by plus or minus what percent?)

07:40:41.

Exercise 9.6 A society of Flatlanders lives on a sphere. They carefully survey a triangle and find its angles to be 60.0013°, 60.0007°, and 60.0011°, while its area is 5410.52 m^2. What is the area of the entire sphere?

Exercise 9.7 Estimate the angle-sum of each of the following spherical triangles. *Hint:* First make a rough estimate of the area enclosed by each triangle, and then apply the formula from Exercise 9.4. Because you have to guess the areas of the triangles, you'll get only approximate, not exact, answers. The radius of the Earth is roughly 6400 km.

1. The triangle formed by Providence, Newport, and Westerly, Rhode Island. These cities are roughly 50 km apart.
2. The triangle formed by Houston, El Paso, and Amarillo, Texas. These cities are roughly 1000 km apart.
3. The triangle formed by Madras, India; Tokyo, Japan; and St. Petersburg, Russia. These cities are roughly 7000 km apart.

We've now seen the first major way in which the geometry of a sphere differs from the geometry of a plane. Namely, the sum of the angles of a spherical triangle exceeds π by an amount proportional to the triangle's area, whereas the sum of the angles of a Euclidean (= flat) triangle equals π exactly (study Figure 9.6 for a proof of this last fact).

07:40:41.

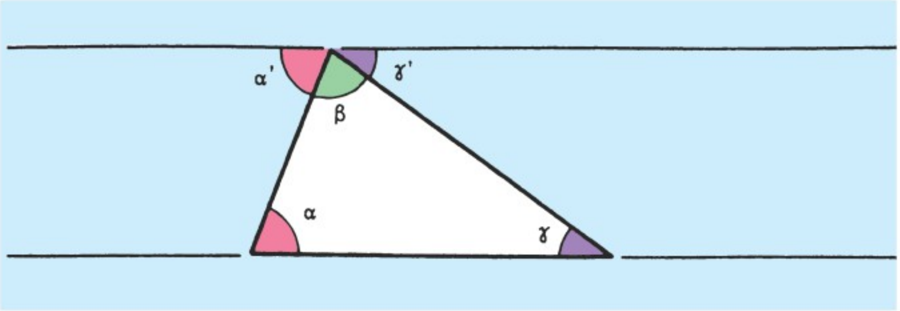


Figure 9.6: A quick proof that the sum of the angles in a Euclidean triangle is π*:*

$$\alpha' + \beta + \gamma' = \pi,$$

$$\alpha = \alpha' \text{ and } \gamma = \gamma',$$

$$\text{therefore } \alpha + \beta + \gamma = \pi.$$

A piece of a sphere rips open when flattened onto a plane (Figure 9.7). This shows that a circle on a sphere has a smaller circumference and encloses less area than a circle of the same radius in a plane. I should stress that the

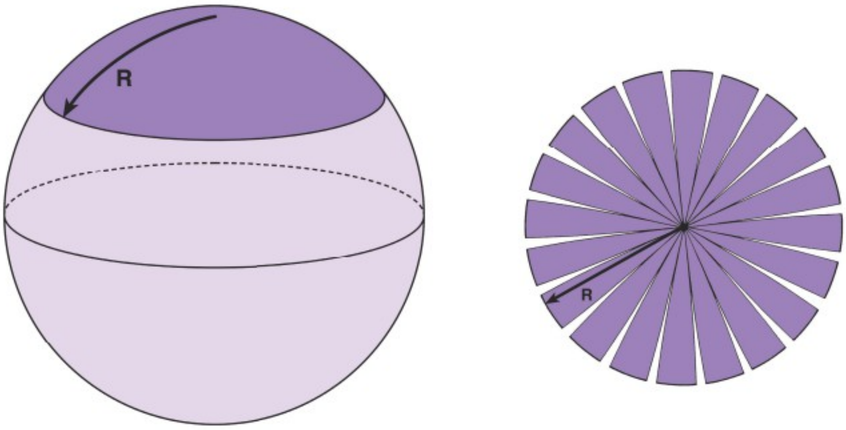

Figure 9.7: A piece of a sphere splits open when flattened.

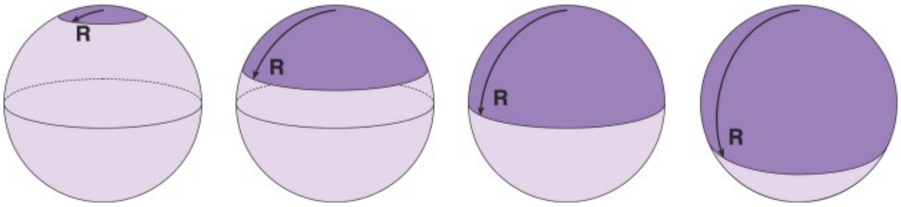

Figure 9.8: The circle's circumference first increases, but then decreases once the circle is past the equator.

radius of a circle on a sphere is measured along the sphere itself—the way a Flatlander would measure it. Figure 9.8 shows that on a sphere a circle's circumference can actually shrink, even though the circle's (intrinsically measured) radius is still increasing.

Exercise 9.8 *(Review exercise)* What other surface has the local geometry of a sphere? Could Flatlanders living on this other surface tell that they weren't on a sphere?

1. The Basics

◆ 1.1. MEASUREMENT

SUPPLIES

tape measure
ruler

These first two sections are intended to remind you of some basic tools and formulae which will be used throughout the text. The word geometry comes from the Greek words for earth and measurement. The first known application of geometry was surveying, most especially in Egypt where annual floods both enriched the soil and eradicated the demarcations between fields. Geometry provided the theoretical tools needed to accurately and efficiently divide up the land into individual holdings. Thus, we begin this book with some quick and easy exercises in measurement.

While the Egyptians developed a great deal of practical geometry, the Greeks developed its theoretical underpinnings, culminating in Euclid's *The Elements*, circa 300 B.C. Euclid's text contains most of the developments in mathematics known at the time, all contained in a superlatively clear and logical structure, wherein each result leads naturally to the next. *The Elements* is one of the most influential texts in the history of western civilization, perhaps only surpassed by the Bible. However, our purpose is not to recapitulate the standard results of Euclidean geometry. We are going to assume that you have already studied these, though we will provide significant prompting at times. We will make note of some of the particular results when we need to use them, such as the properties of isosceles triangles and the various ways of showing congruence.

It is often useful to be able to get a rough idea how big something is, even if you don't happen to have a ruler handy. The exercises that follow are intended to lead you to find readily portable substitutes for a ruler or yardstick.

▷ **Exercise 1.** Find a part of yourself an inch long. I use the first joint on the middle finger of my left hand which happens to be almost exactly one inch long. For some reason the corresponding joint on my right hand is a little longer.

▷ **Exercise 2.** Find a part of yourself a foot long. Use this and your "inch" measure of Exercise 1 to measure the length and width of your desk. Compare this with the actual length and width you find using your ruler. If you are too far off (more than 10%), explain why.

▷ **Exercise 3.** Find a part of yourself a yard long. Use this to measure the length and width of the blackboard. Compare this with the actual dimensions. If you are too far off (more than 10%), explain why.

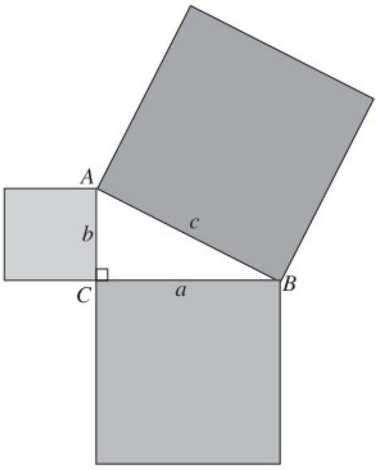
▷ **Exercise 4.** Measure the length of your stride. Use this to measure the dimensions of your classroom. Compare this with the actual dimensions. If you are too far off (more than 10%), explain why.

The Pythagorean Theorem

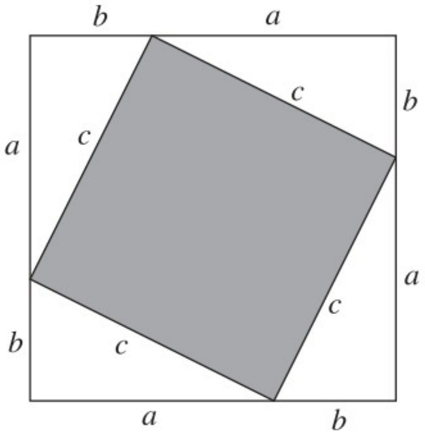
One of the most useful tools in geometry is the Pythagorean theorem:

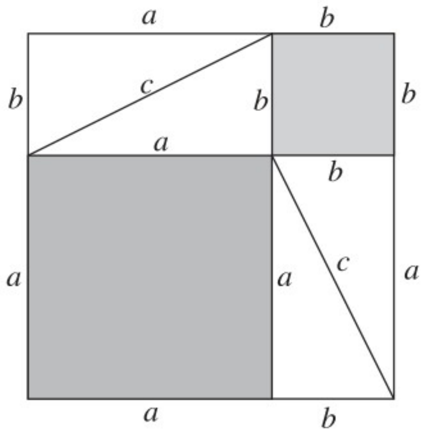
Pythagorean Theorem: If *ABC* is a right triangle with the right angle at vertex *C*, then the side *AB* opposite vertex *C* is called the hypotenuse and its length squared is the sum of the squares of the other two sides, *BC* and *AC*. I.e., $(AB)^2 = (BC)^2 + (AC)^2$, or if we label the sides *a*, *b*, and *c* as in the picture, then $c^2 = a^2 + b^2$.

Another way of stating the Pythagorean theorem in purely geometric terms is that the area of the square built with side *c* is equal to the combined areas of the squares built with sides *a* and *b*.

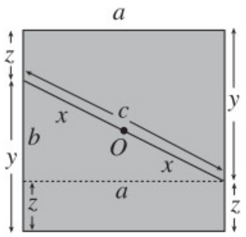


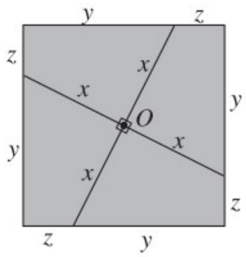
There are many different proofs of this theorem. Elisha Loomis has collected 367 of these in his book *The Pythagorean Proposition*, including one by President Garfield. My favorite of these is the following: Four copies of triangle ΔABC can be arranged as in the picture below on the left to form part of a square with side $(a + b)$. Thus the big square has area equal to the areas of four triangles plus the area of a $c \times c$ square. But the same four triangles can be rearranged inside the same big square as on the right, so that the area of the big square with side $(a + b)$ is also equal to the areas of the four triangles plus the areas of an $a \times a$ square and a $b \times b$ square. Thus, $c^2 = a^2 + b^2$:

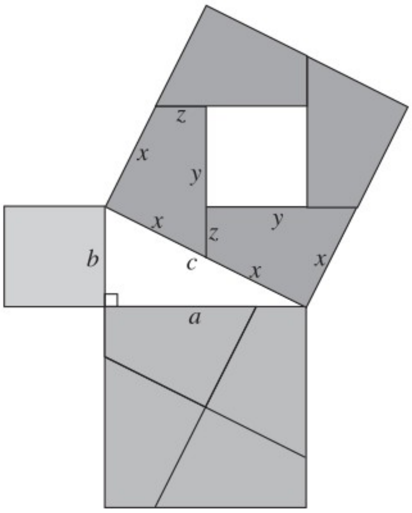




Another proof of the Pythagorean theorem involves cutting up the middle-sized square, which has side a. A copy of the triangle ΔABC can be positioned inside the $a \times a$ square so the edge c goes through the point O at the center of the square as in the figure on the next page. The point O divides length c into two equal pieces, labelled x in the diagram, so that $c = 2x$. The side of the square is also divided into two pieces: a longer one marked y and a shorter one marked z. The diagram makes it clear that $y - z = b$, where b is the shortest side of the triangle. Draw another line perpendicular to the edge c as shown at the bottom left. These two lines divide the $a \times a$ square up into four identical pieces. These four pieces can be rearranged in the larger $c \times c$ square to leave a small square at the center. We must show that this small square is $b \times b$. From the lengths of the sides indicated, the small square has side equal to $y - z$, which we already know is equal to b. Thus the hole is a $b \times b$ square and so the largest $c \times c$ square has area equal to the sum of the areas of the middle-sized $a \times a$ square plus the $b \times b$ square. Therefore $c^2 = a^2 + b^2$:







▷ **Exercise 5.** Redraw the figures for the proof above for the case in which *a* and *b* are the same length.

The converse of the Pythagorean theorem is also true:

Theorem: If a triangle has sides *a*, *b*, and *c*, and $c^2 = a^2 + b^2$, then the triangle is a right triangle with the right angle opposite the side *c*.

▷ **Exercise 6.** If a triangle has sides of lengths 3, 4, and 5, is it a right triangle, and, if so, where is the right angle?

► **Exercise 7.** If a right triangle has shorter sides of lengths 5 and 12, how long is the hypotenuse?

▷ **Exercise 8.** Triples of integers, such as those occurring in Exercise 6: 3-4-5 and Exercise 7: 5-12-?, are called Pythagorean triples, since they occur as the side lengths in right triangles and thus satisfy the Pythagorean theorem. Give one more example of an **integer** Pythagorean triple.

Since 1993 there has been a lot of publicity about Fermat's Last Theorem. This all started in 1637 when Pierre de Fermat, a French lawyer and very good amateur mathematician, was reading a book in which there was a proof that there are infinitely many Pythagorean triples. He scribbled in the book that he had a wonderful proof that this statement was false for higher powers, but there was not enough space in the margin for him to write it down. In other words, he was claiming that there are never integers *a*, *b*, and *c* satisfying the equation $a^n + b^n = c^n$ for any integer $n \geq 3$. For example, we showed above that a $c \times c$ square can be made out of an $a \times a$ square and a $b \times b$ square. Fermat's Last

Theorem says, for example, that a $c \times c \times c$ cube cannot be made from the pieces of a $a \times a \times a$ cube and $b \times b \times b$ cube for any integers a, b, and c. For many years, mathematicians tried to prove this theorem. It was finally proven in 1994 by Andrew Wiles. Wiles used extremely sophisticated techniques, so it is unlikely that Fermat's idea for a proof, whatever it was, was correct.

Perimeter

The *perimeter*, or *circumference*, of a geometric figure is the sum of the lengths of all of the sides, or the distance to walk all the way around the figure. For circles, one can use the formula

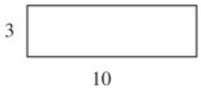
$$P = 2\pi r$$

to figure out the perimeter, or distance around the circle, where r is the radius of the circle (the distance from the center to the outside). This formula can be used to find the perimeter if you know the radius, or to find the radius if you know the perimeter.

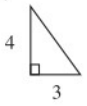
▷ **Exercise 9.** (a) If a half-circle has radius 3, what is its perimeter? (Measure only the curved part of the semicircle.)
(b) If the perimeter of a circle is 8π, what is its radius?

► **Exercise 10.** Find the perimeter of each of these regions. Some of the figures in this exercise are composites of rectangles and portions of circles.

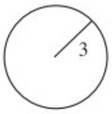
(a)



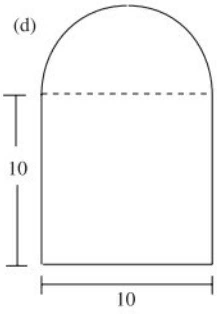
(b)



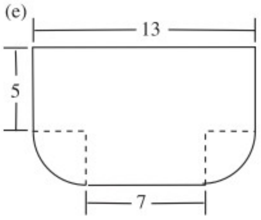
(c)



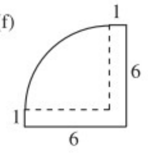
(d)



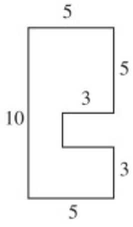
(e)



(f)

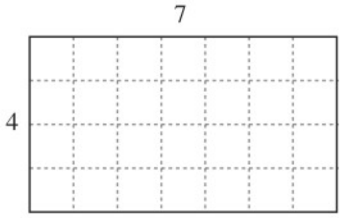


(g)



Area

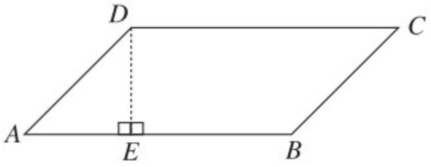
The figure whose area is easiest to measure is the rectangle. For example, below is a 7 by 4 rectangle, which is 7 units wide and 4 units tall, and thus has area 7 times 4, or 28, square units. You can see in the picture that the rectangle contains 28 small squares.



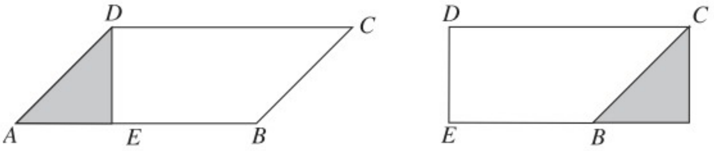
Thus the area of a rectangle is always the width times the height:

$$A(\text{rectangle}) = w \cdot h.$$

Next, we can figure out the area of a parallelogram labeled *ABCD* by dropping a perpendicular line from *D* to the point *E* on line *AB*.



Notice that if the triangle *AED* is cut off and then glued back so that *AD* is glued to *BC*, a rectangle is formed that has the same area as the original parallelogram:

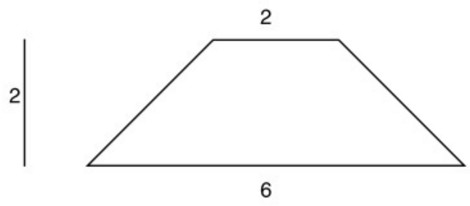


Thus, the area of a parallelogram is also width times height, but the height must be measured by dropping a perpendicular to the side that represents the width.

$$A(\text{parallelogram}) = w \cdot h.$$

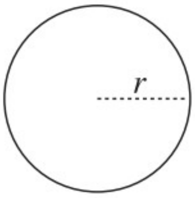
▷ **Exercise 11.** You probably remember the formula for the area of a triangle from high school. State the formula and give an explanation of why this is the correct rule. You should model your explanation on the one above for the area of the parallelogram.

▷ **Exercise 12.** Figure out the area of the isosceles trapezoid shown below:



▷ **Exercise 13.** Figure out and state clearly a rule for the area of any trapezoid. Give an explanation of why your formula is correct. Be careful not to assume all trapezoids are as symmetrical as the one in Exercise 12.

The area formulae for other polygons are deduced from the ones above. The exception is the area of a circle.



The radius r is measured from the center of the circle to the rim. The area is given by

$$A(\text{circle}) = \pi \cdot r^2.$$

Most other curved shapes require calculus in order to find their areas.

Now use these formulae to figure out the areas of the following figures. Some of the figures in Exercise 14 are composites of rectangles and portions of circles.

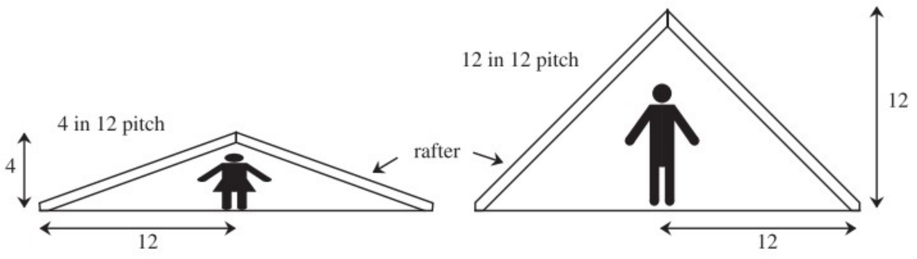
Angles

Angles are used to measure steepness or inclination. A 0° angle is considered horizontal, while a 90°, or right angle, is perpendicular to the horizontal. To draw a right angle, an architect or builder uses ruler and compass, or, either a T-square (a sort of T-shaped ruler that has a precut right angle) or a triangle template. We shall assume that you had plenty of practice with angle measure in previous courses.

Some professions use other ways to describe angles or steepness. Builders talk of the pitch of a roof and will describe it, say, as a 4 in 12 pitch, meaning that for every 12 feet of horizontal distance, the roof goes up 4 feet.

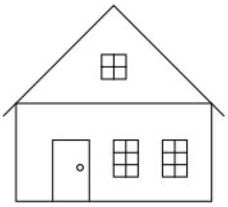


4 in 12 pitch
4
12
rafter
12 in 12 pitch
12
12

Different roof pitches have different advantages and disadvantages. A flat roof or a roof with low pitch (generally, a pitch less than 4 in 12 is considered low) minimizes the area of the roof, requiring less material for construction, but building codes require that leak-prone continuous membrane roofing be used on flat roofs and on roofs with pitch less than 3 in 12. Higher pitch roofs provide better runoff for rain and snow but require more building materials and form awkward interior spaces. Pitches greater than 12 in 12 are very rarely used.

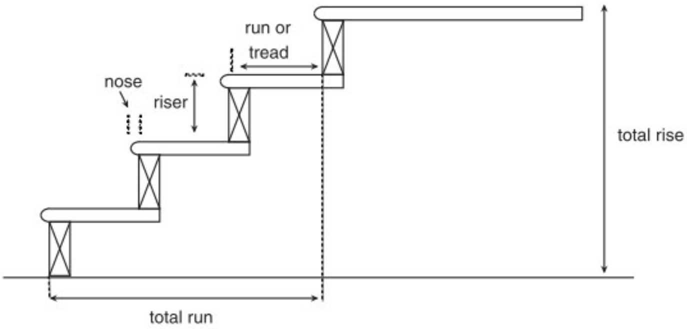
▷ **Exercise 15.** What angle does a 12 in 12 pitch roof make with the horizontal?

► **Exercise 16.** If the building below has a roof with a 12 in 12 pitch and the building is 50 feet wide, how high is the peak of the roof from the attic floor? If the overhang is 1 foot, how long must the rafters be? What is the total area of the roof surface if the building is 75 feet long?



▷ **Exercise 17.** If a building has a roof with a 4 in 12 pitch and the building is 50 feet wide, how high is the peak of the roof from the attic floor? If the overhang is 1 foot, how long must the rafters be? What is the total area of the roof surface if the building is 75 feet long?

Stairs in buildings are commonly specified by riser and tread: the riser is the vertical height of the step, and the tread is the depth of the horizontal part of the step. Thus, an architect may specify a stair with a 7.5 inch riser and an 11 inch tread with a 1 inch nose, as pictured below:

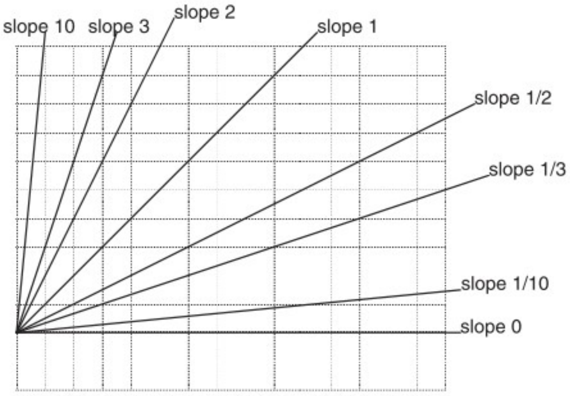


▷ **Exercise 18.** Design two different stairs from the first to the second story of a house if the distance from the floor to the ceiling is 7 feet and the interstitial space (the space between the ceiling and the floor of the story above) is 6 inches. Your stairs must satisfy the National Fire Codes for public buildings, which specify a maximum riser height of 7 inches and a minimum tread depth of 11 inches, and that treads must have uniform depth and risers uniform height. Use different risers and treads for each of your stairs.

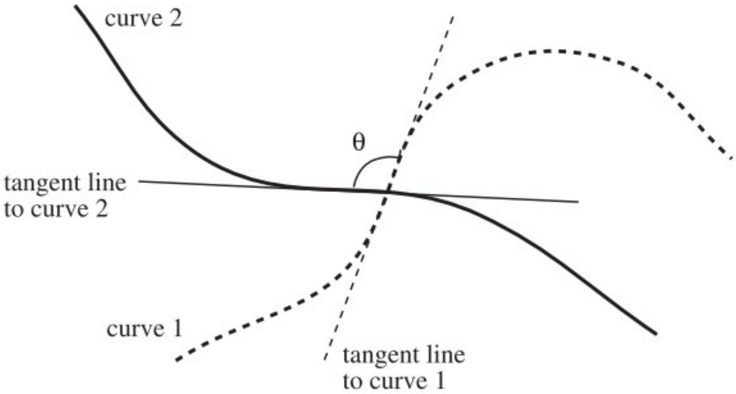
Ramps are also specified by rise and run. The maximum steepness allowed for handicapped accessibility is a 1:12 slope, i.e., a handicapped ramp can go up at most 1 foot for every 12 feet of horizontal distance.

▷ **Exercise 19.** Check one handicapped ramp for compliance with the building codes.

In mathematics, slope is also described as the relation between rise and run, but is usually written as a fraction $\frac{rise}{run}$, so that instead of 1 in 12 or 1:12, a mathematician would describe the ramp as having slope $\frac{1}{12}$. A line 45° from the horizontal will have slope 1. Slopes more than 1 give steeper lines, while slopes less than 1 are more shallow.

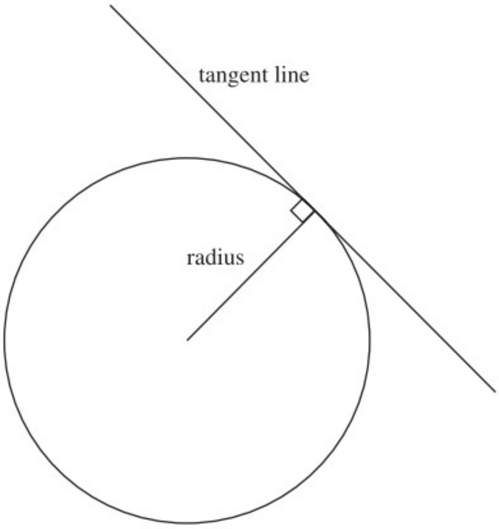


While finding the angle between two lines is a familiar task, sometimes one needs to find the angle between two curves. The angle between two curves is defined to be the angle between their *tangent lines* at the point where they intersect. The tangent line is the line that best approximates the curve at that point. The angle θ is formed between the curves shown:



curve 2
θ
tangent line
to curve 2
curve 1
tangent line
to curve 1

In general, one needs calculus in order to find a tangent line. The one easy case is a circle: it happens that the tangent line to a circle at a point is perpendicular to the radial line from the center to that point.



tangent line
radius

When one talks about the angle formed between a line and a circle, one refers to the angle θ formed by the line and this tangent line:

Solution. We have

$$\frac{e^z}{z^3} = \frac{1}{z^3}\left(1+z+\frac{z^2}{2!}+\frac{z^3}{3!}+\dots\right)$$

$$= \frac{1}{z^3}+\frac{1}{z^2}+\frac{1}{2!z}+\frac{1}{3!}+\frac{1}{4!}z+\dots$$

Thus, the principal part of the Laurent expansion consists of three terms and so $\frac{e^z}{z^3}$ has a pole of order 3 at $z = 0$.

EXAMPLE 1.76

Show that $z \sin \frac{1}{z}$ has essential singularity at $z = 0$.

Solution. We have

$$z\sin\frac{1}{z} = z\left\{\frac{1}{z}-\frac{1}{3!z^3}+\frac{1}{5!z^5}-\dots\right\}$$

$$= 1-\frac{1}{3!z^2}+\frac{1}{5!z^4}+\dots$$

Since the series *does not terminate*, $z = 0$ is an *essential singularity*.

Definition 1.31. A function $f(z)$ is said to be *meromorphic* if it is analytic in the finite part of the plane except at a finite number of poles.

1.6 RESIDUES AND CAUCHY'S RESIDUE THEOREM

Definition 1.32. Let the Laurent series expansion of a function $f(z)$ at isolated singularity z_0 be

$$f(z) = \sum_{n=1}^{\infty}\frac{b_n}{(z-z_0)^n}+\sum_{n=0}^{\infty}a_n(z-z_0)^n \quad (1.40)$$

The coefficient b_1, in the principal part of the expansion, given by

$$b_1 = \frac{1}{2\pi i}\int_C f(\xi)\,d\xi \quad (1.41)$$

for the contour C: $|z - z_0| = r < R$ is called *residue* of $f(z)$ at z_0 and is denoted by Res(z_0).

The residue of $f(z)$ at $z = \infty$ is defined by

$$-b_1 = \frac{-1}{2\pi i}\int_C f(\xi)\,d\xi.$$

It is the coefficient of $\frac{1}{z}$ with its sign changed in the expansion of $f(z)$ in the neighbourhood of $z = \infty$.

If $f(z)$ has a pole of order m at z_0, then the Laurent expansion of $f(z)$ is

$$f(z) = \frac{b_m}{(z-z_0)^m}+\frac{b_{m-1}}{(z-z_0)^{m-1}}+\dots+\frac{b_1}{(z-z_0)}$$
$$+a_0+a_1(z-z_0)+a_2(z-z_0^2)+\dots$$

Multiplying both sides by $(z - z_0)^m$, we have

$$(z-z_0)^m f(z) = b_m + b_{m-1}(z-z_0)$$
$$+\dots+b_1(z-z_0)^{m-1}$$
$$+a_0(z-z_0)^m$$
$$+a_1(z-z_0)^{m+1}+\dots,$$

which is Taylor's series of the analytic function $(z - z_0)^m f(z)$. Differentiating both sides $m - 1$ times with respect to z, we have

$$\frac{d^{m-1}}{dz^{m-1}}[(z-z_0)^m f(z)] = b_1(m-1)!$$
$$+m(m-1)\dots 2a_0(z-z_0)+\dots$$

Letting $z \to z_0$, we get

$$\lim_{z\to z_0}\frac{d^{m-1}}{dz^{m-1}}[(z-z_0)^m f(z)] = b_1(m-1)!$$

and so

$$b_1 = \text{Res}(z_0)$$
$$= \frac{1}{(m-1)!}\lim_{z\to z_0}\frac{d^{m-1}}{dz^{m-1}}[(z-z_0)^m f(z)]. \quad (1.42)$$

If z_0 is a simple pole, that is, $m = 1$, then

$$\text{Res}(z_0) = b_1 = \lim_{z\to z_0}(z-z_0)f(z). \quad (1.43)$$

If

$$f(z) = \frac{p(z)}{q(z)},$$

where $p(z)$ and $q(z)$ are analytic at $z = z_0$, $p(z_0) \neq 0$ and $q(z)$ has a simple zero at z_0, that is, $f(z)$ has

Solution. We have

$$\frac{e^z}{z^3} = \frac{1}{z^3}\left(1 + z + \frac{z^2}{2!} + \frac{z^3}{3!} + \ldots\right)$$

$$= \frac{1}{z^3} + \frac{1}{z^2} + \frac{1}{2!\,z} + \frac{1}{3!} + \frac{1}{4!}z + \ldots$$

Thus, the principal part of the Laurent expansion consists of three terms and so $\frac{e^z}{z^3}$ has a pole of order 3 at $z = 0$.

EXAMPLE 1.76

Show that $z \sin \frac{1}{z}$ has essential singularity at $z = 0$.

Solution. We have

$$z \sin\frac{1}{z} = z\left\{\frac{1}{z} - \frac{1}{3!\,z^3} + \frac{1}{5!\,z^5} - \ldots\right\}$$

$$= 1 - \frac{1}{3!\,z^2} + \frac{1}{5!\,z^4} + \ldots$$

Since the series *does not terminate*, $z = 0$ is an *essential singularity*.

Definition 1.31. A function $f(z)$ is said to be *meromorphic* if it is analytic in the finite part of the plane except at a finite number of poles.

1.6 RESIDUES AND CAUCHY'S RESIDUE THEOREM

Definition 1.32. Let the Laurent series expansion of a function $f(z)$ at isolated singularity z_0 be

$$f(z) = \sum_{n=1}^{\infty} \frac{b_n}{(z - z_0)^n} + \sum_{n=0}^{\infty} a_n (z - z_0)^n \quad (1.40)$$

The coefficient b_1, in the principal part of the expansion, given by

$$b_1 = \frac{1}{2\pi i}\int_C f(\xi)\, d\xi \quad (1.41)$$

for the contour C: $|z - z_0| = r < R$ is called *residue* of $f(z)$ at z_0 and is denoted by Res(z_0).

The residue of $f(z)$ at $z = \infty$ is defined by

$$-b_1 = \frac{-1}{2\pi i}\int_C f(\xi)\, d\xi.$$

It is the coefficient of $\frac{1}{z}$ with its sign changed in the expansion of $f(z)$ in the neighbourhood of $z = \infty$.

If $f(z)$ has a pole of order m at z_0, then the Laurent expansion of $f(z)$ is

$$f(z) = \frac{b_m}{(z - z_0)^m} + \frac{b_{m-1}}{(z - z_0)^{m-1}} + \ldots + \frac{b_1}{(z - z_0)}$$
$$+ a_0 + a_1(z - z_0) + a_2(z - z_0^2) + \ldots$$

Multiplying both sides by $(z - z_0)^m$, we have

$$\begin{aligned}(z - z_0)^m f(z) = b_m &+ b_{m-1}(z - z_0) \\ &+ \ldots + b_1(z - z_0)^{m-1} \\ &+ a_0(z - z_0)^m \\ &+ a_1(z - z_0)^{m+1} + \ldots,\end{aligned}$$

which is Taylor's series of the analytic function $(z - z_0)^m f(z)$. Differentiating both sides $m - 1$ times with respect to z, we have

$$\frac{d^{m-1}}{dz^{m-1}}[(z - z_0)^m f(z)] = b_1(m-1)!$$
$$+ m(m-1)\ldots 2a_0(z - z_0) + \ldots$$

Letting $z \to z_0$, we get

$$\lim_{z \to z_0} \frac{d^{m-1}}{dz^{m-1}}[(z - z_0)^m f(z)] = b_1(m-1)!$$

and so

$$\begin{aligned} b_1 &= \text{Res}(z_0) \\ &= \frac{1}{(m-1)!}\lim_{z \to z_0} \frac{d^{m-1}}{dz^{m-1}}[(z - z_0)^m f(z)]. \quad (1.42)\end{aligned}$$

If z_0 is a simple pole, that is, $m = 1$, then

$$\text{Res}(z_0) = b_1 = \lim_{z \to z_0}(z - z_0) f(z). \quad (1.43)$$

If

$$f(z) = \frac{p(z)}{q(z)},$$

where $p(z)$ and $q(z)$ are analytic at $z = z_0$, $p(z_0) \neq 0$ and $q(z)$ has a simple zero at z_0, that is, $f(z)$ has a simple pole at z_0. Then $q(z) = (z - z_0)\, g(z)$, $g(z_0) \neq 0$ and $q(z_0) = 0$. Hence (1.43) reduces to

$$\operatorname{Res}(z_0) = \lim_{z\to z_0} (z - z_0)\, f(z) = \lim_{z\to z_0} (z - z_0)\, \frac{p(z)}{q(z)}$$

$$= \lim_{z\to z_0} \frac{p(z)}{\dfrac{q(z) - q(z_0)}{z - z_0}} = \frac{p(z_0)}{q'(z_0)} \qquad (1.44)$$

Thus, the residues at poles can be calculated using the formulas (1.42), (1.43), and (1.44).

EXAMPLE 1.77

Find residues of

(i) $f(z) = \dfrac{z^2 - 2z}{(z+1)^2\,(z^2+4)}$

(ii) $f(z) = \dfrac{e^{z^2}}{(z-i)^3}$

at all its poles.

Solution. (i) The function $f(z)$ has a pole of order 2 at $z = -1$ and simple poles at $z = \pm 2i$. Therefore,

$$\operatorname{Res}(-1) = \lim_{z\to -1} \frac{d}{dz}\left[(z+1)^2\, \frac{z^2 - 2z}{(z+1)^2 (z^2+4)}\right]$$

$$= \lim_{z\to -1} \frac{(z^2+4)\,(2z-2) - (z^2 - 2z)(2z)}{(z^2+4)^2}$$

$$= -\frac{14}{25}$$

$$\operatorname{Res}(2i) = \lim_{z\to 2i} (z - 2i)\frac{z^2 - 2z}{(z+1)^2\,(z^2+4)}$$

$$= \lim_{z\to 2i} \frac{z^2 - 2z}{(z+1)^2 (z+2i)} = \frac{7+i}{25}$$

$$\operatorname{Res}(-2i) = \lim_{z\to -2i} (z+2i)\frac{z^2 - 2z}{(z+1)^2\,(z-2i)\,(z+2i)}$$

$$= \frac{7-i}{25}$$

(ii) $f(z)$ has a pole of order 3 at $z = i$. Hence

$$\operatorname{Res}(i) = \frac{1}{2!}\lim_{z\to i}\frac{d^2}{dz^2}[(z-i)^3\, f(z)]$$

$$= \frac{1}{2}\lim_{z\to i}\frac{d^2}{dz^2}(e^{z^2})$$

$$= \lim_{z\to i}[2z^2 e^{z^2} + e^{z^2}]$$

$$= -\frac{1}{e}.$$

EXAMPLE 1.78

Find the residue of $f(z) = \cot z$ at its poles.

Solution. We have

$$f(z) = \cot z = \frac{\cos z}{\sin z}.$$

The poles of $f(z)$ are given by $\sin z = 0$. Thus $z = n\pi$, $n = 0, \pm 1, \pm 2, \ldots$ are the simple poles. Using formula (1.44), the residue at $z = n\pi$ is given by

$$\operatorname{Res}(n\pi) = \lim_{z\to n\pi} \frac{\cos z}{\dfrac{d}{dz}(\sin z)} = \lim_{z\to n\pi} \frac{\cos z}{\cos z} = 1.$$

EXAMPLE 1.79

Find the residue at each pole of $f(z) = \dfrac{ze^{iz}}{z^2 + a^2}$.

Solution. We have

$$f(z) = \frac{ze^{iz}}{(z+ai)\,(z-ai)}$$

Therefore, $f(z)$ has simple poles at $z = \pm\, ai$. Now

$$\operatorname{Res}(ai) = \lim_{z\to ai} (z - ai) f(z)$$

$$= \lim_{z\to ai} (z - ai)\frac{ze^{iz}}{(z+ai)\,(z-ai)}$$

$$= \lim_{z\to ai} \frac{ze^{iz}}{z+ai} = \frac{e^{-a}}{2},$$

$$\operatorname{Res}(-ai) = \lim_{z\to -ai} (z+ai)\, f(z)$$

$$= \lim_{z\to -ai} \frac{ze^{iz}}{z - ai} = \frac{e^{a}}{2}.$$

EXAMPLE 1.80

Find the residue of $f(z) = \dfrac{1-e^{2z}}{z^4}$ at its poles.

Solution. The function $f(z)$ has a pole of order 4 at $z = 0$. Therefore,

$$\text{Res}(0) = \frac{1}{3!}\lim_{z\to 0}\frac{d^3}{dz^3}[(z-0)^4\ f(z)]$$

$$= \frac{1}{6}\lim_{z\to 0}\frac{d^3}{dz^3}[1-e^{2z}]$$

$$= \frac{1}{6}\lim_{z\to 0}\frac{d^3}{dz^3}\left[1-\left\{1+2z+4z^2+8z^3+\frac{16z^4}{4!}+\dots\right\}\right]$$

$$= \frac{1}{6}\lim_{z\to 0}\frac{d^3}{dz^3}\left[-2z-2z^2-\frac{8}{6}z^3-\frac{16}{24}z^4-\dots\right]$$

$$= \frac{1}{6}\lim_{z\to 0}\left[-8-\frac{294}{24}z-\dots\right] = -\frac{4}{3}.$$

EXAMPLE 1.81

Find the residues of $f(z) = \dfrac{z^3}{(z-1)(z-2)(z-3)}$. at $z = 1$, 2, and 3 and ∞ and show that their sum is zero.

Solution. The function

$$f(z) = \frac{z^3}{(z-1)(z-2)(z-3)}$$

has simple poles at $z = 1$, 2, and 3. Now

$$\text{Res}(1) = \lim_{z\to 1}(z-1)\ f(z) = \lim_{z\to 1}\frac{z^3}{(z-2)(z-3)} = \frac{1}{2}$$

$$\text{Res}(2) = \lim_{z\to 2}(z-2)\ f(z) = \lim_{z\to 2}\frac{z^3}{(z-1)(z-3)} = -8$$

$$\text{Res}(3) = \lim_{z\to 3}(z-3)\ f(z) = \lim_{z\to 3}\frac{z^3}{(z-1)(z-2)} = \frac{27}{2}.$$

To find residue at ∞, we expand $f(z)$ in the neighbourhood of $z = \infty$ as follows:

$$f(z) = \frac{z^3}{z^3\left(1-\frac{1}{z}\right)\left(1-\frac{2}{z}\right)\left(1-\frac{3}{z}\right)}$$

$$= \left(1-\frac{1}{z}\right)^{-1}\left(1-\frac{2}{z}\right)^{-1}\left(1-\frac{3}{z}\right)^{-1}$$

$$= 1+\frac{6}{z}+ \textit{higher powers} \text{ of } \frac{1}{z}.$$

Now residue at ∞ is coefficient of $\frac{1}{z}$ with sign changed. Thus Res(∞) = –6. Hence, the sum of the residues equals $\frac{1}{2}-8+\frac{27}{2}-6 = 0$.

To compute the values of integrals in our study, we shall require the following theorem.

Theorem 1.21. (Cauchy's Residue Theorem). If $f(z)$ is analytic within and on a closed contour C except at finitely many poles lying in C, then

$$\int_C f(z)\ dz = 2\pi i\ \Sigma\ R,$$

where ΣR denotes the sum of residues of $f(z)$ at the poles within C.

Proof: Let $z_1, z_2, \dots, z_n$ be the n poles lying in C. Let $C_1, C_2, \dots, C_n$ be the circles with centre $z_1, z_2, \dots, z_n$ and radius ρ such that all these circles lie entirely within C and do not overlap (Fig. 1.14)

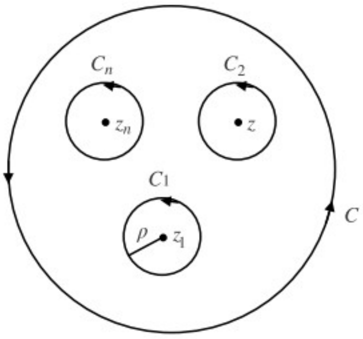

Figure 1.14

Then $f(z)$ is analytic in the region between C and the circles. Hence, by Cauchy-Goursat theorem

$$\int_C f(z)\ dz = \int_{C_1} f(z)\ dz + \int_{C_2} f(z)\ dz + \dots$$
$$+ \int_{C_n} f(z)\ dz. \tag{1.45}$$

If $f(z)$ has a pole of order m_1 at $z = z_1$, then

$$f(z) = \phi_1(z) + \sum_{r=1}^{m_1} \frac{b_r}{(z-z_1)^r},$$

where $\phi_1(z)$ is regular within and on C_1. Therefore,

$$\int_{C_1} f(z)\,dz = \int_{C_1} \phi_1(z)\,dz + \int_{C_1} \frac{b_1}{(z-z_1)}\,dz$$

$$+ \int_{C_1} \frac{b_2}{(z-z_2)^2}\,dz + \ldots + \int_{C_1} \frac{bm_1}{(z-z_1)^r}\,dz. \qquad (1.46)$$

Since $\phi_1(z)$ is analytic within and on C_1, by Cauchy-Goursat theorem

$$\int_{C_1} \phi_1(z)\,dz = 0.$$

Moreover, substituting $z - z_1 = \rho\, e^{i\theta}$, we have

$$\int_{C_1} \frac{bm_1}{(z-z_1)^r}\,dz \;= \int_0^{2\pi} \frac{bm_1 .\rho i e^{i\theta}}{e^{m_1}\; e^{m_1 i\theta}}\,d\theta$$

$$= \frac{ibm_1}{e^{m_1-1}} \int_0^{2\pi} e^{-(m_1-1)i\theta} d\theta = 0$$

for $m_1 \neq 1$

and

$$\int_{C_1} \frac{b_1}{(z-z_1)}\,dz = \int_0^{2\pi} \frac{b_1 \rho i e^{i\theta}\,d\theta}{\rho e^{i\theta}} = 2\pi i\, b_1.$$

Hence (1.46) reduces to

$$\int_{C_1} f(z)\,dz = 2\pi i R_1,$$

where R_1 is the residue of $f(z)$ at $z = z_1$. Similarly,

$$\int_{C_2} f(z)\,dz = 2\pi i\, R_2,$$

....

$$\int_{C_n} f(z)\,dz = 2\pi i\, R_n,$$

where R_i is the residue of $f(z)$ at $z = z_i$. Hence (1.45) becomes

$$\int_C f(z)\,dz = 2\pi i(R_1 + R_2 + \ldots + R_n) = 2\pi i\, \Sigma R,$$

where $\Sigma R = R_1 + R_2 + \ldots + R_n$.

Remark 1.10. In the assumptions of Cauchy's integral formula, $f(z)$ is assumed to be analytic within and on a closed curve. Therefore, $\frac{f(z)}{z-a}$ has a simple pole at $z = a$. Then

$$\text{Res}(a) = \lim_{z\to a} (z-a)\frac{f(z)}{(z-a)} = f(a).$$

Hence, by Cauchy's Residue theorem, we have

$$\int_C \frac{f(z)}{z-a}\,dz = 2\pi i\; f(a),$$

that is,

$$f(a) = \frac{1}{2\pi i}\int_C \frac{f(z)}{z-a}\,dz.$$

It follows, therefore, that Cauchy's integral formula is a particular case of Cauchy's Residue theorem.

EXAMPLE 1.82

Evaluate

$$\int_C \frac{dz}{z^2(z+1)(z-1)}, \quad C: |z| = 3.$$

Solution. The integrand has simple poles at $z = 1$ and $z = -1$ and double poles at $z = 0$ lying in C. Therefore,

$$\text{Res}(1) = \lim_{z\to 1}(z-1) f(z)$$

$$= \lim_{z\to 1} \frac{1}{z^2(z+1)} = \frac{1}{2},$$

$$\text{Res}(-1) = \lim_{z\to -1}(z+1) f(z)$$

$$= \lim_{z\to -1} \frac{1}{z^2(z-1)} = -\frac{1}{2},$$

$$\text{Res}(0) = \lim_{z\to 0} \frac{d}{dz}[(z-0)^2 f(z)]$$

$$= \lim_{z\to 0} \frac{d}{dz}\left[\frac{1}{(z+2)(z-1)}\right]$$

$$= \lim_{z\to 0} \frac{-2z-1}{(z^2+z-2)^2} = \frac{-1}{4}.$$

Hence, by Cauchy-Residue theorem,

$$\int_C \frac{dz}{z^2(z+1)(z-1)} = 2\pi i\left[\frac{1}{2}-\frac{1}{2}-\frac{1}{4}\right] = -\frac{\pi i}{2}.$$

EXAMPLE 1.83

Evaluate the integral

$$\int_{|z|=1} \frac{4z^2-4z+1}{(z-2)(4+z^2)}\,dz.$$

Solution. Let

$$f(z) = \frac{4z^2-4z+1}{(z-2)(4+z^2)}.$$

The poles of $f(z)$ are $z = 2$, $z = \pm 2i$. We note that none of these poles lie in the curve $|z| = 1$. Thus the function is analytic within and on $|z| = 1$. Hence, by Cauchy-Goursat theorem,

$$\int_{|z|=1} \frac{4z^2-4z+1}{(z-2)(4+z^2)}\,dz = 0.$$

EXAMPLE 1.84

Evaluate $\int_C \frac{dz}{(z^2+4)^2}$, where C is the curve $|z-i| = 2$.

Solution. Let

$$f(z) = \frac{1}{(z^2+4)^2} = \frac{1}{(z+2i)^2\,(z-2i)^2}.$$

Thus $f(z)$ has two double poles at $z = 2i$ and $z = -2i$, out of which only $z = 2i$ lies within $|z-i| = 2$. Now

$$\begin{aligned}\text{Res}(2i) &= \lim_{z\to 2i} \frac{d}{dz}[(z-2i)^2.f(z)]\\ &= \lim_{z\to 2i} \frac{d}{dz}\left[\frac{1}{(z+2i)^2}\right]\\ &= \lim_{z\to 2i}\left[\frac{-2z-4i}{(z+2i)^4}\right] = \frac{-i}{32}.\end{aligned}$$

Hence, by Cauchy's Residue theorem, we have

$$\int_C \frac{dz}{(z^2+4)^2} = 2\pi i\left(-\frac{i}{32}\right) = \frac{\pi}{16}.$$

EXAMPLE 1.85

Evaluate

$$\int_C \frac{1-\cos 2(z-3)}{(z-3)^3}\,dz,$$

where C is the curve $|z-3| = 1$.

Solution. Expanding $\cos 2(z-3)$, we have

$$\begin{aligned} f(z) &= \frac{1-\cos 2(z-3)}{(z-3)^3}\\ &= \frac{1}{(z-3)^3}\left[1-1+\frac{4(z-3)^2}{2!}-\frac{16(z-3)^4}{4!}+\ldots\right]\\ &= \frac{2}{z-3}-\frac{16}{4!}(z-3)+\ldots.\end{aligned}$$

Thus $f(z)$ has a simple pole at $z = 3$. The Laurent's series is in the power of $z-3$. The coefficient of $\frac{1}{z-3}$ is 2. Hence, the residue of $f(z)$ at $z = 3$ is 2 and so by Cauchys Residue theorem

$$\int_C f(z)dz = 2\pi i(2) = 4\pi i.$$

EXAMPLE 1.86

Evaluate

$$\int_{|z|=3} \frac{\sin \pi z^2+\cos \pi z^2}{(z-1)^2(z-2)}\,dz.$$

Solution. The integrand has simple pole at $z = 2$ and a pole of order 2 at $z = 1$. But these poles lie within $|z| = 3$. Now

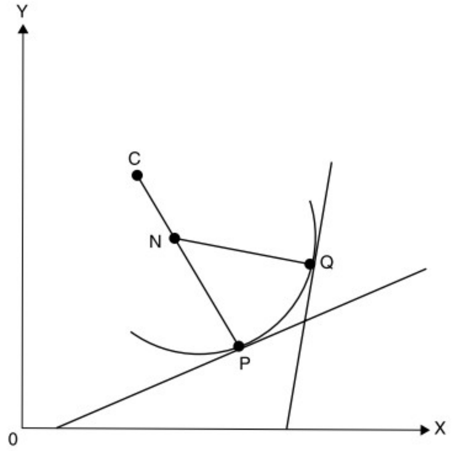
3 Curvature

Let P be any point on a given curve and Q a neighboring point of P such that the arc PQ is concave towards its chord. Let the normals at P and Q intersects at N.

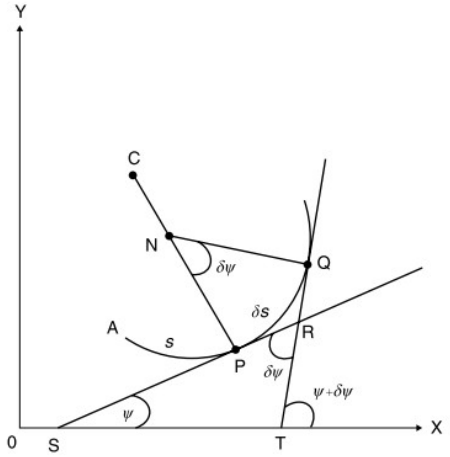


When Q → P, N tends to a definite position C, called the *center of curvature* of the curve at P. The distance CP is called the *radius of curvature* of the curve at the point P and is denoted by ρ. The circle with center at C and the radius ρ, equal to CP, is called the *circle of curvature* of the given curve at the point P. Any chord of the circle of curvature drawn through the point P is called the *chord of curvature*. The reciprocal of the radius of curvature is called the *curvature of the curve* at the point P and is denoted by K.

3.1 RADIUS OF CURVATURE OF INTRINSIC CURVES

Let A be a fixed point on a given curve and P and Q be two neighboring points on the curve. Let arcs AP and PQ be s and δs, respectively. Let the tangents at P and Q make angles ψ and $\psi + \delta\psi$ with the x-axis so that the angle between the tangents at P and Q is $\delta\psi$. Let R be the point of intersection of the tangents at P and Q and let N be the intersection of normals at P and Q. We have

$$\angle PNQ = \angle SRT = \delta\psi.$$



From the triangle PNQ,

$$\frac{PN}{\sin\angle NQP} = \frac{\text{chord } PQ}{\sin\angle PNQ} = \frac{\text{chord } PQ}{\sin\delta\psi}$$

and so,

$$\begin{aligned} PN &= \frac{\text{chord } PQ}{\sin\delta\psi}\cdot\sin\angle NQP \\ &= \frac{\text{chord } PQ}{\delta s}\frac{\delta s}{\delta\psi}\frac{\delta\psi}{\sin\delta\psi}\sin\angle NQP. \end{aligned}$$

If Q→P, $\delta\psi\to 0$, and $\delta s\to 0$, and the chord PQ tends to the tangent at P and QN tends to the normal at P. Consequently, $\angle NQP\to\frac{\pi}{2}$.

Suppose N approaches C as Q approaches P. Then the radius of curvature at P is given by

$$\rho = \lim_{Q\to P} \mathrm{PN}$$

$$= \lim_{Q\to P}\left(\frac{\text{chord PQ}}{\text{arc PQ}}\right)\left(\lim_{\delta\psi\to 0}\frac{\delta s}{\delta\psi}\right).\left(\lim_{\delta\psi\to 0}\frac{\delta\psi}{\sin\delta\psi}\right)$$

$$\times\left(\lim_{Q\to P}\sin\angle \mathrm{NQP}\right)$$

$$= 1.\frac{ds}{d\psi}.1.\sin\frac{\pi}{2} = \frac{ds}{d\psi}.$$

Consequently,

$$\mathrm{K} = \frac{1}{\rho} = \frac{d\psi}{ds}.$$

Since the relation between arc length s and ψ is called the *intrinsic equation of a curve*, the formula $\rho = \frac{ds}{d\psi}$ is known as the *intrinsic formula for the radius of curvature* of the curve. Since the unit of $\delta\psi$ is radian, the unit of curvature is radian per unit length.

3.2 RADIUS OF CURVATURE FOR CARTESIAN CURVES

Let the equation of the curve be $y = f(x)$. Let ψ be the angle which the tangent at any point (x,y) makes with the x-axis. Then

$$\tan\psi = \frac{dy}{dx}.$$

Differentiating with respect to s, we have

$$\sec^2\psi\frac{d\psi}{ds} = \frac{d}{ds}\left(\frac{dy}{dx}\right) = \frac{d}{dx}\left(\frac{dy}{dx}\right).\frac{dx}{ds}$$

or

$$\frac{1}{\rho}\sec^2\psi = \frac{d^2y}{dx^2}.\frac{dx}{ds} = \frac{d^2y}{dx^2}\cos\psi,\ \text{since}\ \frac{dx}{ds} = \cos\psi$$

or

$$\rho = \frac{\sec^3\psi}{\frac{d^2y}{dx^2}} = \frac{(1+\tan^2\psi)^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{\left[1+\left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{(1+y_1^2)^{\frac{3}{2}}}{y_2}.$$

Remark 3.1.

(i) If the tangent at the point is parallel to the y-axis, then $\frac{dy}{dx}$ is infinite and so the above formula for ρ does not hold good in that case.

(ii) The value ρ is positive or negative in accordance with y_2 being positive or negative. However, we will ignore the negative sign as we shall be interested only in finding the length of the radius of curvature.

(iii) The value of ρ depends on the curve and not on the coordinate axes chosen. Therefore, interchanging x and y in the above formula, we get

$$\rho = \frac{\left[1+\left(\frac{dx}{dy}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2x}{dy^2}},$$

the formula which is used when $\frac{dy}{dx}$ is infinite, that is, when the tangent is parallel to the y-axis.

(iv) The point (x, y) on a curve is called a *point of inflexion* if $\frac{d^2y}{dx^2} = 0$ at that point.

(v) If the equation of the curve is given in an implicit form $f(x,y) = 0$, then since $\frac{dy}{dx} = \frac{-f_x}{f_y}$, $f_y \neq 0$, we have

$$\frac{d^2y}{dx^2} = -\frac{f_{xx}(f_y)^2 - 2f_x f_y f_{xy} + f_{yy}\,(f_x)^2}{(f_y)^3}.$$

Hence, the formula for radius of curvature reduces to

$$\rho = \frac{\left[1+\left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{-\left[1+\left(\frac{-f_x}{f_y}\right)^2\right]^{\frac{3}{2}}(f_y)^3}{f_{xx}(f_y)^2 - 2f_xf_yf_{xy} + f_{yy}(f_x)^2}$$

$$= \frac{\left[(f_x)^2+(f_y)^2\right]^{\frac{3}{2}}}{f_{xx}(f_y)^2 - 2f_xf_yf_{xy} + f_{yy}(f_x)^2}\ \text{(in magnitude)}.$$

EXAMPLE 3.1

Find the radius of curvature at the point (s, ψ) on the following curves:

(i) $s = c\log\sec\psi$.

(ii) $s = a\log\tan\left(\frac{\pi}{4}+\frac{\psi}{2}\right)$.

(iii) $s = a\log\cot\left(\frac{\pi}{4}-\frac{\psi}{2}\right) + a\frac{\sin\psi}{\cos^2\psi}$.

(iv) $s^2 = 8ay$.

Solution.

(i) We have $s = c\log\sec\psi$. Therefore,

$$\rho = \frac{ds}{d\psi} = c.\frac{1}{\sec\psi}.\sec\psi\tan\psi = c\tan\psi.$$

(ii) We are given that

$$s = a\log\tan\left(\frac{\pi}{4}+\frac{\psi}{2}\right).$$

Therefore,

$$\begin{aligned}\rho &= \frac{ds}{d\psi}\\ &= a\frac{1}{\tan\left(\frac{\pi}{4}+\frac{\psi}{2}\right)}\cdot \sec^2\left(\frac{\pi}{4}+\frac{\psi}{2}\right)\cdot\frac{1}{2}\\ &= a\frac{\cos\left(\frac{\pi}{4}+\frac{\psi}{2}\right)}{\sin\left(\frac{\pi}{4}+\frac{\psi}{2}\right)}\cdot\frac{1}{\cos^2\left(\frac{\pi}{4}+\frac{\psi}{2}\right)}\cdot\frac{1}{2}\\ &= \frac{a}{2\,\sin\left(\frac{\pi}{4}+\frac{\psi}{2}\right)\cos\left(\frac{\pi}{4}+\frac{\psi}{2}\right)}\\ &= \frac{a}{\sin 2\left(\frac{\pi}{4}+\frac{\psi}{2}\right)}\\ &= \frac{a}{\sin\left(\frac{\pi}{2}+\psi\right)}\\ &= \frac{a}{\cos\psi}\\ &= a\ \sec\psi.\end{aligned}$$

(iii) Since $s = a\ \log\ \cot\left(\frac{\pi}{4}-\frac{\psi}{2}\right) + a\frac{\sin\psi}{\cos^2\psi}$, we have

$$\begin{aligned}\rho=\frac{ds}{d\psi}&=\frac{d}{d\psi}\left[a\log\cot\left(\frac{\pi}{4}-\frac{\psi}{2}\right)+a\sin\psi\sec^2\psi\right]\\ &=a.\frac{1}{\cot\left(\frac{\pi}{4}-\frac{\psi}{2}\right)}\left[-\mathrm{cosec}^2\left(\frac{\pi}{4}-\frac{\psi}{2}\right)\right]\left(-\frac{1}{2}\right)\\ &\quad+a\sin\psi(2\sec\psi\sec\psi\tan\psi)+a\cos\psi\sec^2\psi\\ &=\frac{a}{2\sin\left(\frac{\pi}{4}-\frac{\psi}{2}\right)\cos\left(\frac{\pi}{4}-\frac{\psi}{2}\right)}+\frac{2a\sin^2\psi}{\cos^3\psi}+\frac{a}{\cos\psi}\\ &=\frac{a}{\sin 2\left(\frac{\pi}{4}-\frac{\psi}{2}\right)}+\frac{2a\sin^2\psi}{\cos^3\psi}+\frac{a}{\cos\psi}\\ &=\frac{a}{\sin\left(\frac{\pi}{2}-\psi\right)}+\frac{2a\sin^2\psi}{\cos^3\psi}+\frac{a}{\cos\psi}\\ &=\frac{2a}{\cos\psi}+\frac{2a\sin^2\psi}{\cos^3\psi}\\ &=\frac{2a}{\cos^3\psi}(\cos^2\psi+\sin^2\psi)=2a\sec^3\psi.\end{aligned}$$

(iv) We are given that

$$s^2 = 8\,a\,y.$$

Differentiating with respect to s, we get

$$2s = 8a\frac{dy}{ds} = 8a\ \sin\psi, \text{since}\sin\psi = \frac{dy}{ds}$$

or

$$s = 4a\ \sin\psi.$$

Therefore,

$$\rho = \frac{ds}{d\psi} = 4a\cos\psi = 4a\sqrt{1-\sin^2\psi}$$

$$= 4a\sqrt{1-\frac{s^2}{16a^2}} = 4a\sqrt{1-\frac{8ay}{16a^2}} = 4a\sqrt{1-\frac{y}{2a}}.$$

EXAMPLE 3.2

Show that for any curve the following relation holds:

$$\frac{1}{\rho} = \frac{d}{dx}\left(\frac{dy}{ds}\right).$$

Solution. We know that

$$\frac{dy}{ds} = \sin\psi.$$

Therefore,

$$\begin{aligned}\frac{d}{dx}\left(\frac{dy}{ds}\right) &= \frac{d}{dx}[\sin\psi] = \cos\psi\frac{d\psi}{dx} = \cos\psi\frac{d\psi}{ds}\cdot\frac{ds}{dx}\\ &= \cos\psi.\frac{1}{\rho}.\sec\psi,\ \sec\psi = \frac{ds}{dx}\\ &= \frac{1}{\rho}, \text{which proves the result.}\end{aligned}$$

EXAMPLE 3.3

Find the radius of curvature of the curve, $s = a\ e^{\frac{x}{a}}$.

Solution. The equation of the curve is $s = a\ e^{\frac{x}{a}}$. Differentiating with respect to x, we get

$$\frac{ds}{dx} = a\ e^{\frac{x}{a}}.\frac{1}{a} = e^{\frac{x}{a}} = \frac{s}{a}$$

or

$$s = a\frac{ds}{dx} = a\ \sec\psi,\ \text{since}\ \sec\psi = \frac{ds}{dx}.$$

Therefore,

$$\begin{aligned}\rho &= \frac{ds}{d\psi}\\ &= a\ \sec\psi\tan\psi\\ &= s\tan\psi = s\sqrt{\sec^2\psi - 1}\\ &= s\sqrt{\frac{s^2}{a^2}-1} = \frac{s}{a}\sqrt{s^2-a^2}.\end{aligned}$$

EXAMPLE 3.4

Find the radius of curvature of the following curves:

(i) $x^{\frac{2}{3}} + y^{\frac{2}{3}} = a^{\frac{2}{3}}$ at (x, y).

(ii) $xy = c^2$ at (x, y).

(iii) $y = 4\sin x - \sin 2x$ at $x = \frac{\pi}{2}$.

(iv) $x^3 + y^3 = 3axy$ at the point $\left(\frac{3a}{2}, \frac{3a}{2}\right)$.

Solution.

(i) The equation of the given curve is

$$x^{\frac{2}{3}} + y^{\frac{2}{3}} = a^{\frac{2}{3}}.$$

Any point on this curve may be taken as ($a\cos^3 t$, $a\sin^3 t$) where t is a parameter. Then,

$$\frac{dx}{dt} = -3a\cos^2 t\sin t \text{ and } \frac{dy}{dt} = 3a\sin^2 t\cos t.$$

Therefore,

$$\frac{dy}{dx} = \frac{\frac{dy}{dt}}{\frac{dx}{dt}} = -\frac{3a\sin^2 t\ \cos t}{3a\cos^2 t\ \sin t} = -\tan t$$

and

$$\frac{d^2y}{dx^2} = \frac{d}{dx}(-\tan t) = \frac{d}{dt}(-\tan t)\frac{dt}{dx} = -\sec^2 t.\frac{dt}{dx}$$

$$= -\sec^2 t.\frac{1}{-3a\cos^2 t\ \sin t} = \frac{1}{3a}\sec^4 t\operatorname{cosec} t.$$

Hence ρ at the point ($a\cos^3 t$, $a\sin^3 t$) is given by

$$\rho = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{3a\,(1 + \tan^2 t)^{\frac{3}{2}}}{\sec^4 t\operatorname{cosec} t}$$

$$= \frac{3a\sec^3 t}{\sec^4 t\operatorname{cosec} t} = 3a\sin t\cos t.$$

But $x = a\cos^3 t$ and $y = a\sin^3 t$ imply $\cos t = \left(\frac{x}{a}\right)^{\frac{1}{3}}$ and $\sin t = \left(\frac{y}{a}\right)^{\frac{1}{3}}$. Hence,

$$\rho = 3a\left(\frac{x}{a}\right)^{\frac{1}{3}}\left(\frac{y}{a}\right)^{\frac{1}{3}} = 3a^{\frac{1}{3}}x^{\frac{1}{3}}y^{\frac{1}{3}}.$$

(ii) The given curve is

$$xy = c^2 \quad \text{or} \quad y = \frac{c^2}{x}.$$

Therefore,

$$\frac{dy}{dx} = -\frac{c^2}{x^2} \text{ and } \frac{d^2y}{dx^2} = \frac{2c^2}{x^3}.$$

Hence,

$$\rho = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{\left(1 + \frac{c^4}{x^4}\right)^{\frac{3}{2}}}{\frac{2c^2}{x^3}}$$

$$= \frac{(x^4 + c^4)^{\frac{3}{2}}}{2c^2x^3} = \frac{(x^4 + x^2y^2)^{\frac{3}{2}}}{2c^2x^3}, \text{ since } xy = c^2$$

$$= \frac{(x^2 + y^2)^{\frac{3}{2}}}{2c^2} = \frac{r^3}{2c^2}, \text{where } r^2 = x^2 + y^2.$$

(iii) The equation of the given curve is

$$y = 4\sin x - \sin 2x.$$

Therefore,

$$\frac{dy}{dx} = 4\cos x - 2\cos 2x \text{ and}$$

$$\frac{d^2y}{dx^2} = -4\sin x + 4\sin 2x$$

and so,

$$\left(\frac{dy}{dx}\right)_{x=\frac{\pi}{2}} = 4\cos\frac{\pi}{2} - 2\cos\pi = 2 \text{ and}$$

$$\left(\frac{d^2y}{dx^2}\right)_{x=\frac{\pi}{2}} = -4\sin\frac{\pi}{2} + 4\sin\pi = -4.$$

Hence,

$$\rho = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{(1+4)^{\frac{3}{2}}}{-4}$$

$$= \frac{5\sqrt{5}}{4} \text{ (ignoring sign).}$$

(iv) The given curve is

$$x^3 + y^3 = 3axy.$$

Differentiating both sides with respect to x, we get

$$3x^2 + 3y^2\frac{dy}{dx} = 3a\left(x\frac{dy}{dx} + y\right)$$

or

$$(y^2 - ax)\frac{dy}{dx} = ay - x^2 \tag{1}$$

or

$$\frac{dy}{dx} = \frac{ay - x^2}{y^2 - ax}$$

so that,

$$\left(\frac{dy}{dx}\right)_{\left(\frac{3a}{2},\frac{3a}{2}\right)} = -1. \tag{2}$$

Further, differentiating (1) again, we get

$$(y^2 - ax)\frac{d^2y}{dx^2} + \left(2y\frac{dy}{dx} - a\right)\frac{dy}{dx} = a\frac{dy}{dx} - 2x$$

or

$$(ax - y^2)\frac{d^2y}{dx^2} = 2x + 2y\left(\frac{dy}{dx}\right)^2 - 2a\frac{dy}{dx}.$$

Therefore at the point $\left(\frac{3a}{2}, \frac{3a}{2}\right)$, we have

$$\left(\frac{d^2y}{dx^2}\right)_{\left(\frac{3a}{2},\frac{3a}{2}\right)} = -\frac{32}{3a}, \text{[using(2)]}.$$

Hence, the radius of curvature ρ at $\left(\frac{3a}{2}, \frac{3a}{2}\right)$ is

$$\rho = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{(1+1)^{\frac{3}{2}}}{-\frac{32}{3a}}$$

$$= \frac{3a}{8\sqrt{2}} \text{(in magnitude)}.$$

EXAMPLE 3.5

Find the radius of curvature of the following curves:

(i) $y = c\cosh\left(\frac{x}{c}\right)$ at $(0, c)$.

(ii) $\sqrt{x} + \sqrt{y} = \sqrt{a}$ at (x, y).

Solution.

(i) The equation of the curve is

$$y = c\ \cosh\left(\frac{x}{c}\right).$$

Therefore,

$$\frac{dy}{dx} = c\sinh\left(\frac{x}{c}\right)\frac{1}{c} = \sinh\left(\frac{x}{c}\right)$$

and

$$\frac{d^2y}{dx^2} = \frac{1}{c}\cosh\left(\frac{x}{c}\right).$$

Hence, the radius of curvature is

$$\rho = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{\left[1 + \sinh^2\left(\frac{x}{c}\right)\right]^{\frac{3}{2}}}{\frac{1}{c}\cosh\left(\frac{x}{c}\right)}$$

$$= \frac{c\left[\cosh^2\left(\frac{x}{c}\right)\right]^{\frac{3}{2}}}{\cosh\left(\frac{x}{c}\right)}$$

$$= c\cosh^2\left(\frac{x}{c}\right)$$

$$= c\left(\frac{y}{c}\right)^2 = \frac{y^2}{c}.$$

Thus, ρ at $(0, c)$ is

$$\rho = \frac{c^2}{c} = c.$$

(ii) The equation of the curve is

$$\sqrt{x} + \sqrt{y} = \sqrt{a}.$$

Differentiating with respect to x, we get

$$\frac{1}{2}x^{-\frac{1}{2}} + \frac{1}{2}y^{-\frac{1}{2}}\frac{dy}{dx} = 0,$$

which yields

$$\frac{dy}{dx} = -\frac{x^{-\frac{1}{2}}}{y^{-\frac{1}{2}}} = -y^{\frac{1}{2}}x^{-\frac{1}{2}}.$$

Differentiating again with respect to x, we have

$$\frac{d^2y}{dx^2} = -\left(\frac{1}{2}y^{-\frac{1}{2}}\frac{dy}{dx}\right)x^{-\frac{1}{2}} - y^{\frac{1}{2}}\left(-\frac{1}{2}x^{-\frac{3}{2}}\right)$$

$$= -\frac{1}{2}y^{-\frac{1}{2}}x^{-\frac{1}{2}}\left(-y^{\frac{1}{2}}x^{-\frac{1}{2}}\right) + \frac{1}{2}y^{\frac{1}{2}}x^{-\frac{3}{2}}$$

$$= \frac{1}{2x} + \frac{y^{\frac{1}{2}}}{2x^{\frac{3}{2}}} = \frac{1}{2x}\left(1 + \frac{y^{\frac{1}{2}}}{x^{\frac{1}{2}}}\right)$$

$$= \frac{1}{2x}\left(\frac{\sqrt{x} + \sqrt{y}}{\sqrt{x}}\right) = \frac{\sqrt{a}}{2x^{\frac{3}{2}}}.$$

Hence,

$$\rho = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{\left[1 + \frac{y}{x}\right]^{\frac{3}{2}}}{\frac{\sqrt{a}}{2x^{\frac{3}{2}}}} = \frac{2(x+y)^{\frac{3}{2}}}{\sqrt{a}}.$$

EXAMPLE 3.6

Prove that for the ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, the radius of curvature $\rho = \frac{a^2b^2}{p^3}$, where p is the perpendicular from the center to the tangent at (x,y).

Solution. The equation of the ellipse is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \text{ which implies } b^2x^2 + a^2y^2 = a^2b^2.$$

Differentiating with respect to x, we get

$$\frac{2x}{a^2} + \frac{2y}{b^2}\frac{dy}{dx} = 0$$

or

$$\frac{dy}{dx} = -\frac{b^2}{a^2}\left(\frac{x}{y}\right).$$

Differentiating again with respect to x, we have

$$\frac{d^2y}{dx^2} = -\frac{b^2}{a^2}\left(\frac{y - x\frac{dy}{dx}}{y^2}\right) = -\frac{b^2}{a^2y^2}\left[y - x\left(-\frac{b^2x}{a^2y}\right)\right]$$

$$= -\frac{b^2}{a^2y^2}\left[\frac{a^2y^2 + b^2x^2}{a^2y}\right] = -\frac{b^2}{a^2y^2}\left[\frac{a^2b^2}{a^2y}\right]$$

$$= -\frac{b^4}{a^2y^3}.$$

Therefore ρ at the point (x,y) is

$$\rho = \frac{\left[1 + \left(-\frac{b^2x}{a^2y}\right)^2\right]^{\frac{3}{2}}}{-\frac{b^4}{a^2y^3}}$$

$$= \frac{[a^4y^2 + b^4x^2]^{\frac{3}{2}}}{a^4b^4} \text{ (in magnitude).}$$

The equation of the tangent to the given ellipse at (x, y) is $\frac{Xx}{a^2} + \frac{Yy}{b^2} = 1$. Therefore, $p =$ length of the perpendicular from the center (0,0) to the tangent

$$= \frac{1}{\sqrt{\left(\frac{x}{a^2}\right)^2+\left(\frac{y}{b^2}\right)^2}} = \frac{a^2b^2}{\sqrt{b^4x^2+a^4y^2}}.$$

Thus,

$$p^3 = \frac{a^6b^6}{(b^4x^2+a^4y^2)^{\frac{3}{2}}}$$

so that,

$$(b^4x^2+a^4y^2)^{\frac{3}{2}} = \frac{a^6b^6}{p^3}.$$

Substituting this value in the expression for ρ, we get

$$\rho = \frac{\frac{a^6b^6}{p^3}}{a^4b^4} = \frac{a^2b^2}{p^3}.$$

3.3 RADIUS OF CURVATURE FOR PARAMETRIC CURVES

Let the parametric equation of the curve be

$$x = f(t) \text{ and } y = \phi(t).$$

Then if $x' = \frac{dx}{dt}$ and $y' = \frac{dy}{dt}$, we have

$$\frac{dy}{dx} = \frac{\frac{dy}{dt}}{\frac{dx}{dt}} = \frac{y'}{x'}$$

and

$$\frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d}{dx}\left(\frac{y'}{x'}\right) = \left[\frac{d}{dt}\left(\frac{y'}{x'}\right)\right]\frac{dt}{dx}$$

$$= \frac{x'y''-y'x''}{(x')^2}\cdot\frac{1}{x'} = \frac{x'y''-y'x''}{(x')^3}.$$

Therefore,

$$\rho = \frac{\left[1+\left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}}$$

$$= \frac{\left[1+\left(\frac{y'}{x'}\right)^2\right]^{\frac{3}{2}}}{\frac{x'y''-y'x''}{x'^3}}$$

$$= \frac{(x'^2+y'^2)^{\frac{3}{2}}}{x'y''-y'x''},\ x'y''-y'x'' \neq 0.$$

EXAMPLE 3.7

Solve Example 3.6 using parametric equation of the ellipse.

Solution. Any point on the ellipse $\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$ is $(a\cos\theta, b\sin\theta)$ and the parametric equation of the ellipse is

$$x = a\ \cos\theta \text{ and } y = b\ \sin\theta.$$

Therefore,

$$x' = -a\sin\theta \text{ and } y' = b\cos\theta,$$

$$x'' = -a\cos\theta \text{ and } y'' = -b\sin\theta.$$

Hence, ρ at $(a\cos\theta, b\sin\theta)$ is

$$\rho = \frac{(x'^2+y'^2)^{\frac{3}{2}}}{x'y''-y'x''} = \frac{(a^2\sin^2\theta+b^2\cos^2\theta)^{\frac{3}{2}}}{ab\ \sin^2\theta+ab\ \cos^2\theta}$$

$$= \frac{(a^2\sin^2\theta+b^2\cos^2\theta)^{\frac{3}{2}}}{ab}. \qquad (1)$$

Now the equation of tangent to the ellipse at $(a\cos\theta, b\sin\theta)$ is

$$\frac{xa\cos\theta}{a^2}+\frac{yb\sin\theta}{b^2} = 1 \text{ or } \frac{x}{a}\cos\theta+\frac{y}{b}\sin\theta = 1.$$

Therefore,

p = length of the perpendicular from the center $(0,0)$ on the tangent

$$= \frac{1}{\sqrt{\frac{\cos^2\theta}{a^2}+\frac{\sin^2\theta}{b^2}}} = \frac{ab}{\sqrt{a^2\sin^2\theta+b^2\cos^2\theta}}$$

Thus,

$$p^3 = \frac{a^3b^3}{(a^2\sin^2\theta+b^2\cos^2\theta)^{\frac{3}{2}}}.$$

Putting this value in (1), we get

$$\rho = \frac{a^2b^2}{p^3}.$$

EXAMPLE 3.8

Find the radius of curvature at any point θ of the curve

$$x = a(\theta-\sin\theta) \text{ and } y = a(1-\cos\theta).$$

Solution. The equation of the curve is

$$x = a(\theta-\sin\theta) \text{ and } y = a(1-\cos\theta).$$

Therefore,

$$x' = a(1-\cos\theta) = 2a\sin^2\frac{\theta}{2} \text{ and}$$

$$y' = a\sin\theta = 2a\sin\frac{\theta}{2}\cos\frac{\theta}{2}.$$

Thus,

$$\frac{dy}{dx} = \frac{y'}{x'} = \frac{2a\sin\frac{\theta}{2}\cos\frac{\theta}{2}}{2a\sin^2\frac{\theta}{2}} = \cot\frac{\theta}{2}.$$

Further,

$$\begin{aligned}\frac{d^2y}{dx^2} &= \frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d}{dx}\left(\cot\frac{\theta}{2}\right)\\ &= \frac{d}{d\theta}\left(\cot\frac{\theta}{2}\right)\frac{d\theta}{dx}\\ &= -\frac{1}{2}\operatorname{cosec}^2\frac{\theta}{2}\cdot\frac{1}{2a\sin^2\frac{\theta}{2}}\\ &= -\frac{1}{4a}\operatorname{cosec}^4\frac{\theta}{2}.\end{aligned}$$

Hence,

$$\begin{aligned}\rho &= \frac{\left[1+\left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} = \frac{\left(1+\cot^2\frac{\theta}{2}\right)^{\frac{3}{2}}}{-\frac{1}{4}\operatorname{cosec}^4\frac{\theta}{2}}\\ &= -\frac{4a}{\operatorname{cosec}\frac{\theta}{2}} = 4a\sin\frac{\theta}{2} \text{ (in magnitude).}\end{aligned}$$

EXAMPLE 3.9

Show that the radius of curvature at any point of the cycloid

$x = a\,(t + \sin t)$ and $y = a(1 - \cos t)$ is $4a\cos\frac{t}{2}$.

Solution. The equation of the curve is

$$x = a(t + \sin t) \text{ and } y = a(1 - \cos t).$$

Therefore,

$$\begin{aligned}x' &= a(1+\cos t) \text{ and } y' = a\sin t,\\ x'' &= -a\sin t \text{ and } y'' = a\cos t.\end{aligned}$$

Hence,

$$\begin{aligned}\rho &= \frac{(x'^2+y'^2)^{\frac{3}{2}}}{x'y''-y'x''}\\ &= \frac{[a^2(1+\cos t)^2 + a^2\sin^2 t]^{\frac{3}{2}}}{a(1+\cos t)a\cos t - a\sin t(-a\sin t)}\\ &= \frac{a\,[2\,(1+\cos t)]^{\frac{3}{2}}}{1+\cos t} = (2\sqrt{2})a\,(1+\cos t)^{\frac{1}{2}}\\ &= (2\sqrt{2})a\left(2\cos^2\frac{t}{2}\right)^{\frac{1}{2}} = 4a\cos\frac{t}{2}.\end{aligned}$$

EXAMPLE 3.10

If ρ_1 and ρ_2 are the radii of curvatures at the extremities of a focal chord of the parabola $y^2 = 4ax$, prove that

$$\rho_1^{-\frac{2}{3}} + \rho_2^{-\frac{2}{3}} = (2a)^{-\frac{2}{3}}.$$

Solution. The parametric equation of the parabola $y^2 = 4ax$ is

$$x = at^2 \text{ and } y = 2at.$$

Therefore,

$$\begin{aligned}x' &= 2at \text{ and } y' = 2a,\\ x'' &= 2a \text{ and } y'' = 0.\end{aligned}$$

Therefore, ρ at the point $(at^2, 2at)$ is

$$\begin{aligned}\rho &= \frac{[x'^2+y'^2]^{\frac{3}{2}}}{x'\,y''-y'\,x''} = \frac{[4a^2t^2+4a^2]^{\frac{3}{2}}}{-4a^2}\\ &= \frac{8a^3(t^2+1)^{\frac{3}{2}}}{-4a^2} = 2a(1+t^2)^{\frac{3}{2}} \text{ (in magnitude).}\end{aligned}$$

Let the extremities of the focal chord be

$$P(at_1^2,\ 2at_1) \text{ and } Q\,(at_2^2,\ 2at_2).$$

Then, by the property of focal chord, $t_1t_2 = -1$. Further, by the above-obtained expression for ρ, we have

$$\begin{aligned}\rho_1 &= \text{radius of curvature at } \rho\,(at_1^2,\ 2at_1)\\ &= 2a\left(1+t_1^2\right)^{\frac{3}{2}} \text{ and}\\ \rho_2 &= \text{radius of curvature at } Q\left(at_2^2,\ 2at_2\right)\\ &= 2a\left(1+t_2^2\right)^{\frac{3}{2}}.\end{aligned}$$

Therefore, since $t_1^2\,t_2^2 = 1$, we have

$$\begin{aligned}\rho_1^{-\frac{2}{3}} + \rho_2^{-\frac{2}{3}} &= (2a)^{-\frac{2}{3}}\left[\frac{1}{1-t_1^2} + \frac{1}{1-t_2^2}\right]\\ &= (2a)^{-\frac{2}{3}}\left[\frac{t_1^2+t_2^2+2}{t_1^2+t_2^2+2}\right] = (2a)^{-\frac{2}{3}}.\end{aligned}$$

EXAMPLE 3.11

If ρ_1 and ρ_2 are the radii of curvatures at the extremities of two conjugate semi-diameters of an ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, show that

$$\left(\rho_1^{\frac{2}{3}} + \rho_2^{\frac{2}{3}}\right)(ab)^{\frac{2}{3}} = a^2 + b^2.$$

Solution. The parametric equations of the ellipse are $x = a\cos\theta$ and $y = b\sin\theta$. As in Example 3.7, we have

$$\rho = \frac{(a^2\sin^2\theta + b^2\cos^2\theta)^{\frac{3}{2}}}{ab}$$

and so,

$$\rho ab = (a^2\sin^2\theta + b^2\cos^2\theta)^{\frac{3}{2}}$$

or

$$(ab)^{\frac{2}{3}}\,\rho^{\frac{2}{3}} = a^2\sin^2\theta + b^2\cos^2\theta.$$

If C is the center of the ellipse and CP and CQ be a pair of conjugate semi-diameters of the ellipse, then the eccentric angles of P and Q are θ and $\theta + \frac{\pi}{2}$, respectively. Thus if ρ is the radius of curvature at P $(a\cos\theta, b\sin\theta)$, then the curvature at Q is obtained by replacing θ by $\theta+\frac{\pi}{2}$. Thus, if ρ_1 and ρ_2 are the radii of curvatures at P and Q, then from the above expressions we get

$$\begin{aligned}(ab)^{\frac{2}{3}}\,\rho_1^{\frac{2}{3}} &= a^2\sin^2\theta+b^2\cos^2\theta\\ (ab)^{\frac{2}{3}}\,\rho_2^{\frac{2}{3}} &= a^2\sin^2\left(\theta+\frac{\pi}{2}\right)+b^2\cos^2\left(\theta+\frac{\pi}{2}\right)\\ &= a^2\cos^2\theta+b^2\sin^2\theta.\end{aligned}$$

Adding these two relations, we get

$$\left(\rho_1^{\frac{2}{3}}+\rho_2^{\frac{2}{3}}\right)(ab)^{\frac{2}{3}} = a^2(\sin^2\theta+\cos^2\theta) + b^2(\sin^2\theta+\cos^2\theta) = a^2+b^2.$$

EXAMPLE 3.12

Show that the radius of curvature at a point P on an ellipse $\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$ is given by $\rho=\frac{(CQ)^3}{ab}$, where CQ is the semi-diameter conjugate to CP.

Solution. If $P(a\cos\theta,\ b\sin\theta)$ is the point on the ellipse, then the point Q shall be $Q\left(a\cos\left(\theta+\frac{\pi}{2}\right), b\sin\left(\theta+\frac{\pi}{2}\right)\right)=Q(-a\sin\theta,\ b\cos\theta)$. Therefore,

$$CQ=\sqrt{a^2\sin^2\theta+b^2\cos^2\theta}\quad\text{or}$$

$$(CQ)^3=(a^2\sin^2\theta+b^2\cos^2\theta)^{\frac{3}{2}}.$$

Hence, from Example 3.7, we have

$$\rho=\frac{(a^2\sin^2\theta+b^2\cos^2\theta)^{\frac{3}{2}}}{ab}=\frac{(CQ)^3}{ab}.$$

EXAMPLE 3.13

Show that the radius of curvature at the end of the major axis of the ellipse $\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$ is equal to the semi-latus rectum of the ellipse.

Solution. As in the above examples, we have

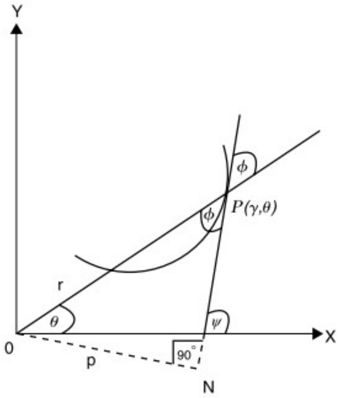
$$\rho=\frac{(a^2\sin^2\theta+b^2\cos^2\theta)^{\frac{3}{2}}}{ab}.$$

Now at the ends of the major axis, $\theta=0$ and π. Therefore, putting $\theta=0$, we get

$$\begin{aligned}\rho&=\frac{(b^2)^{\frac{3}{2}}}{ab}\\ &=\frac{b^2}{a}=\text{Semi-latus rectum of the ellipse.}\end{aligned}$$

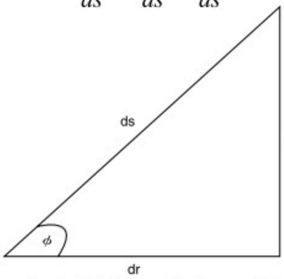
3.4 RADIUS OF CURVATURE FOR PEDAL CURVES

Let $P(r,\theta)$ be a given point on the curve such that the tangent to the curve at P makes an angle ψ with the x-axis. Let ϕ be the angle between the tangent and the radius vector. Then $\psi=\theta+\phi$.



Differentiating with respect to s, we get

$$\frac{d\psi}{ds}=\frac{d\theta}{ds}+\frac{d\phi}{ds}. \tag{1}$$



Also $p=r\sin\phi$. Differentiating with respect to r, we get

$$\begin{aligned}\frac{dp}{dr}&=\sin\phi+r\cos\phi\,\frac{d\phi}{dr}=r\frac{d\theta}{ds}+r\frac{dr}{ds}\cdot\frac{d\phi}{dr}\\ &=r\left[\frac{d\theta}{ds}+\frac{d\phi}{ds}\right]=r\frac{d\psi}{ds}=\frac{r}{\rho},\ \rho=\frac{ds}{d\psi}.\end{aligned}$$

Hence,

$$\rho=r\frac{dr}{dp}.$$

3.5 RADIUS OF CURVATURE FOR POLAR CURVES

From the figure of article 3.4, we have $\psi=\theta+\phi$ and so differentiation yields

$$\frac{d\psi}{ds}=\frac{d\theta}{ds}+\frac{d\phi}{ds}$$

or

$$\frac{1}{\rho}=\frac{d\theta}{ds}+\frac{d\phi}{d\theta}\cdot\frac{d\theta}{ds}. \tag{1}$$

But,

$$\tan\phi = r\frac{d\theta}{dr} = \frac{\frac{r}{dr}}{d\theta} = \frac{r}{r_1}, \text{ where } r_1 = \frac{dr}{d\theta}.$$

Differentiating with respect to θ, we get

$$\sec^2\phi\frac{d\phi}{d\theta} = \frac{r_1 r_1 - r.r_2}{{r_1}^2}, \text{ where } r_2 = \frac{d^2r}{d\theta^2}.$$

Therefore,

$$\frac{d\phi}{d\theta} = \frac{{r_1}^2 - rr_2}{{r_1}^2\sec^2\phi} = \frac{{r_1}^2 - rr_2}{{r_1}^2(1+\tan^2\phi)}$$

$$= \frac{{r_1}^2 - rr_2}{{r_1}^2\left(1+\frac{r^2}{{r_1}^2}\right)}, \text{since}$$

$$\tan\phi = \frac{rd\theta}{dr} = \frac{r}{r_1}.$$

$$= \frac{{r_1}^2 - rr_2}{{r_1}^2 + r^2}.$$

Moreover, since $\sin\phi = r\frac{d\theta}{ds}$, we have

$$\frac{d\theta}{ds} = \frac{\sin\phi}{r} = \frac{1}{r}\cdot\frac{r}{\sqrt{r^2+{r_1}^2}} = \frac{1}{\sqrt{r^2+{r_1}^2}}.$$

Hence from (1), we have

$$\frac{1}{\rho} = \frac{1}{\sqrt{r^2+{r_1}^2}}\left[1+\frac{{r_1}^2-rr_2}{{r_1}^2+r^2}\right] = \frac{r^2-rr_2+2{r_1}^2}{(r^2+{r_1}^2)^{\frac{3}{2}}},$$

which yields

$$\rho = \frac{(r^2+{r_1}^2)^{\frac{3}{2}}}{r^2-rr_2+2{r_1}^2}.$$

3.5.1 Second Method

The relation between p, r, and θ is

$$\frac{1}{p^2} = \frac{1}{r^2} + \frac{1}{r^4}{r_1}^2, \; r_1 = \frac{dr}{d\theta}.$$

Differentiating with respect to r, we get

$$-\frac{2}{p^3}\frac{dp}{dr} = -\frac{2}{r^3} - \frac{4}{r^5}{r_1}^2 + \frac{2}{r^4}r_1\frac{d}{dr}r_1$$

$$= -\frac{2}{r^3} - \frac{4}{r^5}{r_1}^2 + \frac{2}{r^4}r_1\left[\frac{d}{d\theta}\left(\frac{dr}{d\theta}\right)\right]\frac{d\theta}{dr}$$

$$= -\frac{2}{r^3} - \frac{4}{r^5}{r_1}^2 + \frac{2}{r^4}r_1\cdot r_2\cdot\frac{1}{r_1}$$

$$= -\frac{2}{r^3} - \frac{4}{r^5}{r_1}^2 + \frac{2}{r^4}r_2.$$

Therefore,

$$\frac{1}{p^3}\frac{dp}{dr} = \frac{1}{r^3} + \frac{2}{r^5}r_1^2 - \frac{1}{r^4}r_2 = \frac{r^2+2{r_1}^2-rr_2}{r^5}. \quad (1)$$

Since,

$$\frac{1}{p^3} = \left[\left(\frac{1}{r^2}+\frac{1}{r^4}{r_1}^2\right)^2\right]^{\frac{3}{2}} \text{ and } \frac{dp}{dr} = \frac{r}{\rho},$$

we have,

$$\rho = \frac{r^6\left[\left(\frac{1}{r^2}+\frac{1}{r^4}{r_1}^2\right)^2\right]^{\frac{3}{2}}}{r^2+2{r_1}^2-rr_2} == \frac{(r^2+{r_1}^2)^{\frac{3}{2}}}{r^2+2{r_1}^2-rr_2}.$$

Corollary: Let the equation of the curve be $\frac{1}{r} = f(\theta)$. Put $u = \frac{1}{r}$ or $r = \frac{1}{u}$. Then,

$$\frac{dr}{d\theta} = -\frac{1}{u^2}\cdot\frac{du}{d\theta} \quad \text{and}$$

$$\frac{d^2r}{d\theta^2} = -\frac{1}{u^2}\cdot\frac{d^2u}{d\theta^2} + \frac{2}{u^3}\left(\frac{du}{d\theta}\right)^2.$$

Therefore,

$$\rho = \frac{\left[r^2+\left(\frac{dr}{d\theta}\right)^2\right]^{\frac{3}{2}}}{r^2+2\left(\frac{dr}{d\theta}\right)^2 - r\frac{d^2r}{d\theta^2}}$$

$$= \frac{\left[\frac{1}{u^2}+\frac{1}{u^4}\left(\frac{du}{d\theta}\right)^2\right]^{\frac{3}{2}}}{\frac{1}{u^2}+2.\frac{1}{u^4}\left(\frac{du}{d\theta}\right)^2 - \frac{1}{u}\left[-\frac{1}{u^2}\frac{d^2u}{d\theta^2}+\frac{2}{u^3}\left(\frac{du}{d\theta}\right)^2\right]}$$

$$= \frac{\frac{1}{u^6}\left[u^2+\left(\frac{du}{d\theta}\right)^2\right]^{\frac{3}{2}}}{\frac{1}{u^2}+\frac{1}{u^3}\frac{d^2u}{d\theta^2}} = \frac{\left[u^2+\left(\frac{du}{d\theta}\right)^2\right]^{\frac{3}{2}}}{u^2\left(u+\frac{d^2u}{d\theta^2}\right)}$$

$$= \frac{[u^2+u_1^2]^{\frac{3}{2}}}{u^3(u+u_2)},$$

where

$$u_1 = \frac{du}{d\theta} \text{ and } u_2 = \frac{d^2u}{d\theta^2}.$$

EXAMPLE 3.14

Find the radius of curvature at the point (r, θ) of the following curves:

(i) $r^2\cos 2\theta = a^2$.

(ii) $r^n = a^n\sin n\theta$.

(iii) $r = a(1-\cos\theta)$.

Solution.

(i) The equation of the curve is

$$r^2\cos 2\theta = a^2. \quad (1)$$

Taking logarithm, we get

$$2\log r + \log\cos 2\theta = \log a^2. \quad (2)$$

Differentiating (2) with respect to θ, we get

$$\frac{2}{r}\frac{dr}{d\theta} + \frac{-2\sin 2\theta}{\cos 2\theta} = 0 \quad \text{or} \quad r_1 = \frac{dr}{d\theta} = r\tan 2\theta.$$

Differentiating again with respect to θ, we get

$$r_2 = \frac{d^2r}{d\theta^2} = 2r\sec^2 2\theta + \tan 2\theta \frac{dr}{d\theta}$$
$$= 2r\sec^2 2\theta + r\tan^2 2\theta.$$

Hence,

$$\rho = \frac{(r^2 + {r_1}^2)^{\frac{3}{2}}}{r^2 + 2{r_1}^2 - rr_2}$$
$$= \frac{(r^2 + r^2\tan^2 2\theta)^{\frac{3}{2}}}{r^2 + 2r^2\tan^2 2\theta - (2r^2\sec^2\theta + r^2\tan^2 2\theta)}$$
$$= -\frac{r^3\sec^3 2\theta}{r^2\sec^2 2\theta} = -r\sec 2\theta = -r\left(\frac{r^2}{a^2}\right), \text{using}(1)$$
$$= \frac{r^3}{a^2} \text{ (in magnitude)}.$$

(ii) The given curve is

$$r^n = a^n \sin\ n\theta \tag{1}$$

Taking log, we get

$$n\log r = n\log a + \log\sin n\theta.$$

Differentiating with respect to θ, we get

$$\frac{n}{r}\frac{dr}{d\theta} = n\cot n\theta.$$

Therefore,

$$r_1 = \frac{dr}{d\theta} = r\cot n\theta.$$

Differentiating once more, we get

$$r_2 = \frac{d^2r}{d\theta^2} = -nr\,\text{cosec}^2 n\theta + \cot n\theta\frac{dr}{d\theta}$$
$$= -nr\,\text{cosec}^2 n\theta + r\cot^2 n\theta.$$

Hence,

$$\rho = \frac{(r^2 + r_1^2)^{\frac{3}{2}}}{r^2 + 2r_1^2 - rr_2}$$
$$= \frac{(r^2 + r^2\cot^2 n\theta)^{\frac{3}{2}}}{r^2 + 2r^2\cot^2 n\theta - r(-nr\ \text{cosec}^2 n\theta + r\cot^2 n\theta)}$$
$$= \frac{r^3\,\text{cosec}^3 n\theta}{r^2 + r^2\cot^2 n\theta + nr^2\,\text{cosec}^2 n\theta}$$
$$= \frac{r^3\text{cosec}^3 n\theta}{r^2(1 + \cot^2 n\theta) + nr^2\,\text{cosec}^2 n\theta}$$
$$= \frac{r^3\,\text{cosec}^3 n\theta}{r^2\text{cosec}^2 n\theta(1 + n)}$$
$$= \frac{r\,\text{cosec}\ n\theta}{n + 1}$$
$$= \frac{a^n}{(n + 1)r^{n-1}}, \text{using}(1).$$

(iii) The equation of the given curve is

$$r = a(1 - \cos\theta). \tag{1}$$

Differentiating with respect to θ, we get

$$r_1 = \frac{dr}{d\theta} = a\sin\theta \quad \text{and} \quad r_2 = \frac{d^2r}{d\theta^2} = a\cos\theta.$$

Therefore,

$$\rho = \frac{(r^2 + r_1^2)^{\frac{3}{2}}}{r^2 + 2r_1^2 - rr_2}$$
$$= \frac{[a^2(1 - \cos\theta)^2 + a^2\sin^2\theta]^{\frac{3}{2}}}{a^2(1 - \cos\theta)^2 + 2a^2\sin^2\theta - a^2\cos\theta(1 - \cos\theta)},$$
using (1)
$$= \frac{a^3(1 + \cos^2\theta + \sin^2\theta - 2\cos\theta)^{\frac{3}{2}}}{a^2[1 + \cos^2\theta - 2\cos\theta + 2\sin^2\theta - \cos\theta + \cos^2\theta]}$$
$$= \frac{2^{\frac{3}{2}}a(1 - \cos\theta)^{\frac{3}{2}}}{3(1 - \cos\theta)} = \frac{2^{\frac{3}{2}}a\sqrt{r}}{3\sqrt{a}} = \frac{2}{3}\sqrt{2ar}.$$

It also follows that the radius of curvature at any point of the cardioid $r = a(1 - \cos\theta)$ varies as $\sqrt{r}$.

EXAMPLE 3.15

Show that the radius of curvature at any point of the cardioid $r = a(1 + \cos\theta)$ is $\frac{2}{3}\sqrt{2ar}$ and that $\frac{\rho^2}{r}$ is constant.

Solution. The equation of the curve is

$$r = a(1 + \cos\theta).$$

Therefore,

$$r_1 = \frac{dr}{d\theta} = -a\sin\theta \text{ and } r_2 = \frac{d^2r}{d\theta^2} = -a\cos\theta.$$

Therefore,

$$\rho = \frac{(r^2 + r_1^2)^{\frac{3}{2}}}{r^2 + 2r_1^2 - rr_2}$$
$$= \frac{[a^2(1 + \cos\theta)^2 + a^2\sin^2\theta]^{\frac{3}{2}}}{a^2(1 + \cos\theta)^2 + 2a^2\sin^2\theta + a^2\cos\theta(1 + \cos\theta)}$$
$$= \frac{a^3(1 + \cos^2\theta + \sin^2\theta + 2\cos\theta)^{\frac{3}{2}}}{a^2[1 + \cos^2\theta + 2\cos\theta + 2\sin^2\theta + \cos\theta + \cos^2\theta]}$$
$$= \frac{2^{\frac{3}{2}}a(1 + \cos\theta)^{\frac{3}{2}}}{3(1 + \cos\theta)} = \frac{2^{\frac{3}{2}}a\sqrt{r}}{3\sqrt{a}}$$
$$= \frac{2}{3}\sqrt{2ar} = \frac{4a}{3}\cos\frac{\theta}{2} \text{(in terms of } \theta\text{)}.$$

It follows that ρ varies as $\sqrt{r}$. Further,

$$\rho^2 = \frac{8ar}{9} \text{ or } \frac{\rho^2}{r} = \frac{8a}{9} \text{ (constant).}$$

EXAMPLE 3.16

Find the radius of curvature of the curve

$$\frac{l}{r} = 1 + e \cos\theta.$$

Solution. The equation of the given curve is

$$\frac{l}{r} = 1 + e \cos\theta.$$

Let $\frac{1}{r} = u$. Then the equation of the curve becomes

$$u = \frac{1}{l}(1 + e \cos\theta).$$

Therefore,

$$u_1 = \frac{du}{d\theta} = \frac{1}{l}(-e \sin\theta),$$

$$u_2 = \frac{d^2u}{d\theta^2} = \frac{1}{l}(-e \cos\theta).$$

Hence, the radius of curvature is

$$\begin{aligned}\rho &= \frac{(u^2 + u_1^2)}{u^3(u + u_2)}\\ &= \frac{\left(\frac{1}{l^3}\right)\left[(1 + e\cos\theta)^2 + e^2\sin^2\theta\right]^{\frac{3}{2}}}{\left(\frac{1}{l^4}\right)(1 + e\cos\theta)^3\left[(1 + e\cos\theta) - e\cos\theta\right]}\\ &= \frac{l\left[1 + e^2 + 2e\cos\theta\right]^{\frac{3}{2}}}{(1 + e\cos\theta)^3}.\end{aligned}$$

EXAMPLE 3.17

If ρ is the radius of curvature and $\tan\phi = r\frac{d\theta}{dr}$, show that

$$\frac{r}{\rho} = \sin\phi\left(1 + \frac{d\phi}{d\theta}\right) \text{ for any curve.}$$

Solution. We know that

$$\psi = \theta + \phi.$$

Differentiating with respect to s, we get

$$\begin{aligned}\frac{d\psi}{ds} = \frac{d\theta}{ds} + \frac{d\phi}{ds} &= \frac{d\theta}{ds} + \frac{d\phi}{d\theta}\cdot\frac{d\theta}{ds}\\ &= \frac{d\theta}{ds}\left(1 + \frac{d\phi}{d\theta}\right), \text{ that is,}\\ \frac{1}{\rho} &= \frac{\sin\phi}{r}\left(1 + \frac{d\phi}{d\theta}\right), \text{ since}\\ \rho &= \frac{ds}{d\psi} \text{ and } \sin\phi = r\frac{d\theta}{ds}.\end{aligned}$$

Hence,

$$\frac{r}{\rho} = \sin\phi\left(1 + \frac{d\phi}{d\theta}\right) \quad \text{so that} \quad \rho = \frac{r\,\mathrm{cosec}\,\phi}{1 + \frac{d\phi}{d\theta}}.$$

EXAMPLE 3.18

If ρ_1 and ρ_2 are the radii of curvatures at the extremities of any chord of the cardioid $r = a(1 + \cos\theta)$ which passes through the pole, show that

$$\rho_1^2 + \rho_2^2 = \frac{16a^2}{9}.$$

Solution. As in Example 3.15, the radius of curvature at any point of the cardioid $r = a(1 + \cos\theta)$ is

$$\rho = \frac{2}{3}\sqrt{2ar} \quad \text{so that} \quad \rho^2 = \frac{8}{9}ar.$$

If PQ is any chord of the cardioid passing through the pole and if P and Q are the points (r_1, θ_1) and (r_2, θ_2), respectively, then $\theta_2 = \pi + \theta_1$. Hence, if ρ_1 and ρ_2 are the radii of curvatures at P and Q, respectively, then

$$\rho_1{}^2 = \frac{8}{9}ar_1 \quad \text{and} \quad \rho_2{}^2 = \frac{8}{9}ar_2.$$

Therefore,

$$\begin{aligned}\rho_1{}^2 + \rho_2{}^2 &= \frac{8a}{9}[r_1 + r_2]\\ &= \frac{8a}{9}[a(1 + \cos\theta_1) + a(1 + \cos\theta_2)]\\ &= \frac{8a^2}{9}[2 + \cos\theta_1 + \cos\theta_2]\\ &= \frac{8a^2}{9}[2 + \cos\theta_1 + \cos(\pi + \theta_1)]\\ &= \frac{8a^2}{9}[2 + \cos\theta_1 - \cos\theta_1] = \frac{16a^2}{9}.\end{aligned}$$

EXAMPLE 3.19

Find the radius of curvature at any point (p, r) of the following curves:

(i) ellipse $\frac{1}{p^2} = \frac{1}{a^2} + \frac{1}{b^2} - \frac{r^2}{a^2b^2}$.

(ii) $pa^2 = r^3$.

(iii) $pa^n = r^{m+1}$

Solution.

(i) The equation of the ellipse is

$$\frac{1}{p^2} = \frac{1}{a^2} + \frac{1}{b^2} - \frac{r^2}{a^2b^2}.$$

Differentiating with respect to p, we get

$$-\frac{2}{p^3} = -\frac{2r}{a^2b^2}\cdot\frac{dr}{dp} \quad \text{or} \quad r\frac{dr}{dp} = \frac{a^2b^2}{p^3}.$$

Hence,

$$\rho = r\frac{dr}{dp} = \frac{a^2b^2}{p^3}.$$

(ii) The equation of the curve is

$$pa^2 = r^3.$$

Differentiating with respect to p, we have

$$a^2 = 3r^2\frac{dr}{dp} \quad \text{or} \quad r\frac{dr}{dp} = \frac{a^2}{3r}.$$

Hence,

$$\rho = r\frac{dr}{dp} = \frac{a^2}{3r}$$

(iii) The given equation is

$$pa^n = r^{m+1}.$$

Therefore, differentiation with respect to p yields

$$a^n = (m+1)r^m\frac{dr}{dp} \quad \text{or} \quad r\frac{dr}{dp} = \frac{a^n}{(m+1)r^{m-1}}.$$

Hence,

$$\rho = r\frac{dr}{dp} = \frac{a^n}{(m+1)r^{m-1}}.$$

Thus the radius of curvature varies inversely as the $(m-1)$th power of the radius vector.

EXAMPLE 3.20

Show that the radius of curvature of the equiangular spiral $r = ae^{\theta \cot\alpha}$ at any point (r, θ) is $\rho = r \operatorname{cosec} \alpha$.

Solution. The given curve is

$$r = ae^{\theta \cot\alpha}.$$

Differentiating with respect to θ, we have

$$r_1 = \frac{dr}{d\theta} = ae^{\theta\cot\alpha}\cdot\cot\alpha = r\cot\alpha \text{ and}$$

$$r_2 = \frac{d^2r}{d\theta^2} = r\cot^2\alpha.$$

Therefore,

$$\rho = \frac{(r+r_1^2)^{\frac{3}{2}}}{r^2+2r_1^2-rr_2} = \frac{(r^2+r^2\cot^2\alpha)^{\frac{3}{2}}}{r^2+2r^2\cot^2\alpha-r^2\cot^2\alpha}$$

$$= \frac{r^3(1+\cot^2\alpha)^{\frac{3}{2}}}{r^2(1+\cot^2\alpha)} = r(\operatorname{cosec}^2\alpha)^{\frac{1}{2}} = r\operatorname{cosec}\alpha.$$

3.6 RADIUS OF CURVATURE AT THE ORIGIN

The radius of curvature at the origin is determined by the following methods:

1. Newton's Method

Suppose that a curve passes through the origin and the axis of x is tangent at the origin. Then,

$$\text{slope of the tangent at the origin} = \left(\frac{dy}{dx}\right)_{(0,0)}$$
$$= y_1(0,0).$$

Since the tangent at the origin is x-axis, the slope of the tangent should be zero. Therefore $y_1(0,0) = 0$. The radius of curvature at the origin is

$$\rho \text{ at } (0,0) = \frac{[1+y_1{}^2(0,0)]^{\frac{3}{2}}}{y_2(0,0)} = \frac{1}{y_2(0,0)}. \qquad (1)$$

On the other hand,

$$\lim_{\substack{x\to 0\\ y\to 0}}\frac{x^2}{2y} = \lim_{\substack{x\to 0\\ y\to 0}}\frac{2x}{2y_1} \quad \left(\frac{0}{0}\text{ form}\right)$$

$$= \lim_{\substack{x\to 0\\ y\to 0}}\frac{1}{y_2} = \frac{1}{y_2(0,0)}. \qquad (2)$$

From (1) and (2), it follows that

$$\rho \; at \; (0,0) = \lim_{\substack{x\to 0\\ y\to 0}}\frac{x^2}{2y}.$$

Similarly, if the curve passes through the origin and y-axis is tangent to it at the origin, then

$$\rho \text{ at } (0,0) = \lim_{\substack{x\to 0\\ y\to 0}}\frac{y^2}{2x}.$$

If the initial line is tangent at the pole (origin), then

$$\rho = \lim_{\substack{x\to 0\\ y\to 0}}\frac{x^2}{2y} = \lim_{\substack{r\to 0\\ \theta\to 0}}\frac{r^2\cos^2\theta}{2r\sin\theta}$$

$$= \lim_{\substack{r\to 0\\ \theta\to 0}}\frac{r}{2\theta}\cdot\frac{\theta}{\sin\theta}\cdot\cos^2\theta = \lim_{\substack{r\to 0\\ \theta\to 0}}\frac{r}{2\theta}\left(\frac{0}{0}\text{form}\right)$$

$$= \lim_{\substack{r\to 0\\ \theta\to 0}}\frac{\frac{dr}{d\theta}}{2} = \frac{1}{2}\cdot\frac{dr}{d\theta}.$$

2. Method of Expansion

This method is used when neither x- nor y-axis is tangent to the curve at the origin. Suppose that the equation of the curve is $y = f(x)$. Since the curve passes through the origin, $f(0) = 0$. By Maclaurin's expansion, we have

$$y = f(0) + xf'(0) + \frac{x^2}{2!}f''(0) + \frac{x^3}{3!}f'''(0) + \ldots$$

$$= xf'(0) + \frac{x^2}{2!}f''(0) + \frac{x^3}{3!}f'''(0) + \ldots$$

$$= px + \frac{1}{2!}qx^2 + \frac{1}{3!}rx^3 + \ldots \qquad (1)$$

where,

$$p = f'(0) = y_1(0),$$
$$q = f''(0) = y_2(0),$$
$$r = f'''(0) = y_3(0), \text{ and so on.}$$

Differentiating (1) with respect to x, we get

$$y_1 = p + qx + \frac{1}{2}rx^2 + \dots \text{ and}$$
$$y_2 = q + rx + \dots .$$

Thus,

$$y_1(0,0) = p,\ y_2(0,0) = q.$$

Hence,

$$\rho \text{ at the origin} = \frac{[1 + y_1{}^2(0,0)]^{\frac{3}{2}}}{y_2(0)} = \frac{(1+p^2)^{\frac{3}{2}}}{q}.$$

EXAMPLE 3.21

Find the radius of curvature at the origin for the curve

$5x^3 + 7y^2x^2 + 4x^2y + xy^2 + 2x^2 + 3xy + y^2 + 4x = 0.$

Solution. The given curve passes through the origin. The lowest-degree term in the given equation is 4x. Therefore, the tangent at the origin is $4x = 0$ or $x = 0$, that is, the y-axis. Therefore, by Newton's Method,

$$\rho \text{ at the origin} = \lim_{\substack{x\to 0\\ y\to 0}} \frac{y^2}{2x}.$$

Dividing the equation of the curve throughout by $2x$, we get

$$\frac{5}{2}x^2 + \frac{7y^2x^2}{2x} + 2xy + \frac{y^2}{2} + x + \frac{3}{2}y + \frac{y^2}{2x} + 2 = 0.$$

Taking limit as $x \to 0$ and $y \to 0$, we get

$$\lim_{\substack{x\to 0\\ y\to 0}} \frac{y^2}{2x} + 2 = 0$$

or

$$\rho = -2 = 2\,(\text{numerically}).$$

EXAMPLE 3.22

Show that the radii of curvatures at the origin on the curve $x^3 + y^3 = 3axy$ is each equal to $\frac{3a}{2}$.

Solution. The equation of the given curve is

$$x^3 + y^3 = 3axy.$$

The curve passes through the origin. Further, the tangent at the origin is given by $3axy = 0$. Thus, $x = 0$ and $y = 0$ are the tangents at the origin. Therefore, the radii of curvatures are given by

$$\rho_1 \text{ at the origin } = \lim_{\substack{x\to 0\\ y\to 0}} \frac{x^2}{2y}.$$

and

$$\rho_2 \text{ at the origin } = \lim_{\substack{x\to 0\\ y\to 0}} \frac{y^2}{2x}.$$

Dividing the given equation throughout by 2xy, we get

$$\frac{x^2}{2y} + \frac{y^2}{2x} = \frac{3a}{2}.$$

Taking limit as $x \to 0$ and $y \to 0$, we have

$$\lim_{\substack{x\to 0\\ y\to 0}} \frac{x^2}{2y} + \lim_{\substack{x\to 0\\ y\to 0}} \frac{y^2}{2x} = \frac{3a}{2}$$

or

$$\lim_{\substack{x\to 0\\ y\to 0}} \frac{x^2}{2y} + \lim_{\substack{x\to 0\\ y\to 0}} \frac{1}{4}xy\frac{2y}{x^2} = \frac{3a}{2}$$

or

$$\rho_1 + 0\frac{1}{\rho_1} = \frac{3a}{2} \quad \text{or} \quad \rho_1 = \frac{3a}{2}.$$

Similarly, we can show that $\rho_2 = \frac{3a}{2}$.

EXAMPLE 3.23

Show that the radius of curvature of the curve

$$y^2 = x^2\frac{a+x}{a-x}$$

is $\pm a\sqrt{2}$ (or $a\sqrt{2}$ in magnitude).

Solution. The curve is

$$y^2(a-x) = x^2(a+x).$$

Obviously, the curve passes through the origin. But equating to zero the lowest-degree terms, we get

$$a(y^2 - x^2) = 0.$$

Therefore $y = \pm x$ is the tangent at the origin. Hence Newton's method cannot be applied to this curve. So let

$$y = px + \frac{1}{2!}qx^2 + \frac{1}{3!}rx^3 + \dots$$

Substituting this value of y in the given equation of the curve, we get

$$\left(px + \frac{1}{2}qx^2 + \frac{1}{3!}rx^3 + \dots\right)^2 (a-x) = x^2(a+x).$$

Equating coefficients of x^2 and x^3 on both sides, we get

$$ap^2 = a \text{ and } -p^2 + apq = 1,$$

which yield

$$p = 1, q = \frac{2}{a} \text{ and } p = -1, q = \frac{-2}{a}.$$

Therefore,

$$\rho_1 = \frac{(1+p^2)^{\frac{3}{2}}}{q} = \frac{2^{\frac{3}{2}}}{\frac{2}{a}} = \sqrt{2}a$$

and

$$\rho_2 = \frac{(1+1)^{\frac{3}{2}}}{-\frac{2}{a}} = -\sqrt{2}a = \sqrt{2}a \text{ (in magnitude).}$$

EXAMPLE 3.24

Find the radius of curvature at the origin of the cycloid

$$x = a(\theta + \sin\theta) \text{ and } y = a(1-\cos\theta).$$

Solution. The given curve is

$$x = a(\theta + \sin\theta) \text{ and } y = a(1-\cos\theta).$$

Therefore, differentiation with respect to θ yields

$$\frac{dx}{d\theta} = a(1+\cos\theta) \text{ and } \frac{dy}{d\theta} = a\sin\theta.$$

Then,

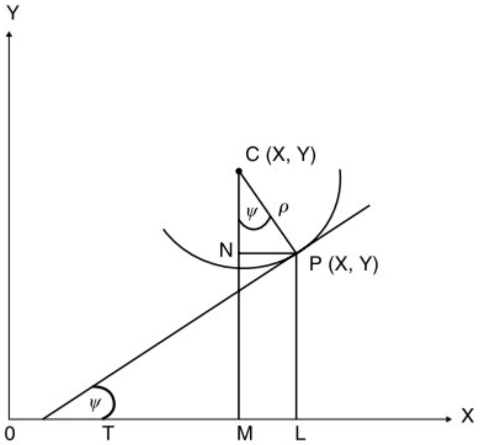
$$\frac{dy}{dx} = \frac{dy/d\theta}{dx/d\theta} = \frac{a\sin\theta}{a(1+\cos\theta)} = \frac{2\sin\frac{\theta}{2}\cos\frac{\theta}{2}}{2\cos^2\frac{\theta}{2}}$$
$$= \tan\frac{\theta}{2}.$$

Since $\theta = 0$ at $(0,0)$, we have $\left(\frac{dy}{dx}\right)_{(0,0)} = 0$. Therefore, x-axis is tangent to the curve at the origin and so, the Newton's method is applicable. Therefore, ρ at the origin is given by

$$\rho(0,0) = \lim_{\substack{x\to 0\\ y\to 0}} \frac{x^2}{2y}$$
$$= \lim_{\theta\to 0}\left[\frac{a^2(\theta+\sin\theta)^2}{2a(1-\cos\theta)}\right] \quad \left(\frac{0}{0}\text{form}\right)$$
$$= \lim_{\theta\to 0}\left[\frac{a\{2(\theta+\sin\theta)(1+\cos\theta)\}}{2\sin\theta}\right] \quad \left(\frac{0}{0}\text{form}\right)$$
$$= \lim_{\theta\to 0}\left[a\frac{(\theta+\sin\theta)(-\sin\theta)+(1+\cos\theta)^2}{\cos\theta}\right]$$
$$= 4a.$$

3.7 CENTRE OF CURVATURE

Let P(x, y) be any point on the curve and let PT be the tangent at P making an angle ψ with the positive direction of x-axis. Let $C(X, Y)$ be the center of curvature corresponding to P(x, y).



Draw PL and CM perpendicular to the x-axis from P and C, respectively. Draw PN ⊥ CM. Then

$$X = OM = OL - ML = OL - NP = x - \rho\sin\psi \quad (1)$$

and

$$Y = CM = NM + CN = \text{NM} + \rho\cos\psi$$
$$= y + \rho\cos\psi \quad (2)$$

But,

$$\tan\psi = \frac{dy}{dx} = y_1.$$

Therefore,

$$\sec\psi = \sqrt{1+\tan^2\psi}$$
$$= \sqrt{1+y_1^2} \text{ or}$$
$$\cos\psi = \frac{1}{\sqrt{1+y_1^2}}$$

and so,

$$\sin\psi = \sqrt{1-\cos^2\psi} = \sqrt{1-\frac{1}{1+y_1^2}} = \frac{y_1}{\sqrt{1+y_1^2}}.$$

Also,

$$\rho = \frac{(1+y_1^2)^{\frac{3}{2}}}{y_2}.$$

Hence (1) yields

$$X = x - \frac{(1+y_1^2)^{\frac{3}{2}}}{y_2}.\frac{y_1}{\sqrt{1+y_1^2}} = x - \frac{y_1(1+y_1^2)}{y_2}$$

and

$$Y = y + \frac{(1+y_1^2)^{\frac{3}{2}}}{y_2}.\frac{1}{\sqrt{1+y_1^2}} = y + \frac{1+y_1^2}{y_2}.$$

Also (1) and (2) can be expressed as

$$X = x - \rho \sin \psi = x - \frac{ds}{d\psi} \cdot \frac{dy}{ds} = x - \frac{dy}{d\psi} \text{ and}$$

$$Y = y + \rho \cos \psi = y + \frac{ds}{d\psi} \cdot \frac{dx}{ds} = y + \frac{dx}{d\psi}.$$

3.8 EVOLUTES AND INVOLUTES

The locus of the center of curvature for a curve is called the *evolute* of the curve and the curve itself is called the *involute* of its evolute.

3.9 EQUATION OF THE CIRCLE OF CURVATURE

Let (X,Y) be the coordinates of the center of curvature and ρ the radius of curvature at any point (x, y) of the curve. Then the equation of the circle of curvature is

$$(x - X)^2 + (y - Y)^2 = \rho^2.$$

EXAMPLE 3.25

Find the center of curvature of the following curves:

(i) $y = x^3 - 6x^2 + 3x + 1$ at (1,−1).

(ii) the parabola $y^2 = 4ax$ at (x, y). Also find the equation of the evolute of the given parabola.

(iii) the ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$ at (x, y). Also find the evolute.

Solution.

(i) The given curve is

$$y = x^3 - 6x^2 + 3x + 1.$$

Therefore,

$$y_1 = \frac{dy}{dx} = 3x^2 - 12x + 3 \text{ and so } y_1(1, -1) = -6,$$

$$y_2 = \frac{d^2y}{dx^2} = 6x - 12 \text{ and so } y_2(1, -1) = -6,$$

$$X = x - \frac{y_1(1 + y_1^2)}{y_2}$$

$$= 1 - \frac{(-6)[1 + (-6)^2]}{-6} = -36, \text{ and}$$

$$Y = -1 + \frac{1 + (-6)^2}{-6} = -\frac{43}{6}.$$

Hence, the centre of curvature is

$$(X, Y) = \left(-36, -\frac{43}{6}\right).$$

(ii) The equation of the given parabola is $y^2 = 4ax$. Therefore,

$$y_1 = \frac{2a}{y} = \frac{2a}{\sqrt{4ax}} = \sqrt{\frac{a}{x}} \text{ and } y_2 = -\frac{1}{2}\sqrt{a}\, x^{-\frac{3}{2}}.$$

Therefore,

$$X = x - \frac{\sqrt{\frac{a}{x}}\left(1 + \frac{a}{x}\right)}{-\frac{1}{2}\sqrt{a}\, x^{-\frac{3}{2}}}$$

$$= x + 2(x + a)$$

$$= 3x + 2a \tag{1}$$

and

$$Y = y + \frac{1 + \frac{a}{x}}{-\frac{1}{2}\sqrt{a}\, x^{-\frac{3}{2}}}$$

$$= 2\sqrt{a}\sqrt{x} - \frac{2(x + a)}{\sqrt{a}\, x^{-\frac{1}{2}}}$$

$$= 2\sqrt{a}\sqrt{x}\left(1 - \frac{x + a}{a}\right)$$

$$= -2\frac{x^{\frac{3}{2}}}{\sqrt{a}}. \tag{2}$$

Hence, the center of curvature of the given parabola is

$$(X, Y) = \left(3x + 2a, -\frac{2x^{\frac{3}{2}}}{\sqrt{a}}\right).$$

From (1), we have $x = \frac{X - 2a}{3}$. Putting this value in (2), we get

$$Y = -\frac{2(X - 2a)^{\frac{3}{2}}}{\sqrt{a}} \text{ or } aY^2 = 4\left(\frac{X - 2a}{3}\right)^3$$

or

$$27aY^2 = 4(X - 2a)^3.$$

Therefore, the locus of the center of curvature (X, Y) is

$$27ay^2 = 4(x - 2a)^3,$$

which is the required evolute.

(iii) The equation of the ellipse is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1.$$

Therefore,

$$y_1 = -\frac{b^2x}{a^2y} \text{ and } y_2 = -\frac{b^4}{a^2y^3}.$$

Therefore,

$$X = x - \frac{y_1(1 + y_1^2)}{y_2} = x - \frac{b^4x^2 + a^4y^2}{a^4b^2} \text{ and}$$

$$Y = y + \frac{1 + y_1^2}{y_2} = y + \frac{b^4x^2 + a^4y^2}{a^2b^4}.$$

Second Method

Equations of the ellipse are

$$x = a\cos\theta \text{ and } y = b\sin\theta.$$

Therefore,

$$\frac{dx}{d\theta} = -a\sin\theta \text{ and } \frac{dy}{d\theta} = b\cos\theta$$

and so,

$$y_1 = \frac{dy}{dx} = \frac{\frac{dy}{d\theta}}{\frac{dx}{d\theta}} = -\frac{b}{a}\cot\theta \text{ and}$$

$$y_2 = \frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{dy}{dx}\right) = \left[\frac{d}{d\theta}\left(-\frac{b}{a}\cot\theta\right)\right]\frac{d\theta}{dx}$$

$$= \frac{b}{a}\operatorname{cosec}^2\theta\left(\frac{1}{-a\sin\theta}\right) = -\frac{b}{a^2}\operatorname{cosec}^3\theta.$$

Therefore,

$$X = x - \frac{y_1(1+y_1^2)}{y_2}$$

$$= x - \frac{-\frac{b}{a}\cot\theta\left(1+\frac{b^2}{a^2}\cot^2\theta\right)}{-\frac{b}{a^2}\operatorname{cosec}^3\theta}$$

$$= a\cos\theta - \frac{(a^2\sin^2\theta + b^2\cos^2\theta)}{a}\cos\theta$$

$$= \frac{a^2-b^2}{a}\cos^3\theta \qquad (1)$$

and

$$Y = y + \frac{1+y_1^2}{y_2} = y + \frac{1+\frac{b^2}{a^2}\cot^2\theta}{-\frac{b}{a^2}\operatorname{cosec}^3\theta}$$

$$= b\sin\theta - \frac{\sin\theta}{b}(a^2\sin^2\theta + b^2\cos^2\theta)$$

$$= \frac{1}{b}\sin\theta\,[b^2 - a^2\sin^2\theta - b^2\cos^2\theta]$$

$$= \frac{b^2-a^2}{b}\sin^3\theta = -\frac{a^2-b^2}{b}\sin^3\theta \qquad (2)$$

Hence the center of curvature is

$$(X, Y) = \left(\frac{a^2-b^2}{a}\cos^3\theta,\ -\frac{a^2-b^2}{b}\sin^3 t\right).$$

From (1) and (2), we have

$$aX = (a^2-b^2)\cos^3\theta \quad \text{or}$$

$$(aX)^{\frac{2}{3}} = (a^2-b^2)^{\frac{2}{3}}\cos^2\theta$$

and

$$bY = -(a^2-b^2)\sin^3\theta \quad \text{or}$$

$$(bY)^{\frac{2}{3}} = -(a^2-b^2)^{\frac{2}{3}}\sin^3\theta.$$

Adding both we get

$$(aX)^{\frac{2}{3}} + (bY)^{\frac{2}{3}} = (a^2-b^2)^{\frac{2}{3}}.$$

Therefore, the evolute of the ellipse is

$$(ax)^{\frac{2}{3}} + (by)^{\frac{2}{3}} = (a^2-b^2)^{\frac{2}{3}}.$$

EXAMPLE 3.26

Show that the evolute of the cycloid $x = a(\theta - \sin\theta)$ and $y = a(1-\cos\theta)$ lies on an equal cycloid.

Solution. For the given cycloid, we have

$$\frac{dx}{x\theta} = a\,(1-\cos\theta) \text{ and } \frac{dy}{d\theta} = a\sin\theta.$$

Therefore,

$$y_1 = \frac{dy}{dx} = \frac{\frac{dy}{d\theta}}{\frac{dx}{d\theta}} = \frac{a\sin\theta}{a(1-\cos\theta)} = \cot\frac{\theta}{2}$$

and

$$y_2 = \frac{d}{dx}(y_1) = \frac{d}{d\theta}(y_1)\frac{d\theta}{dx}$$

$$= -\frac{1}{2}\operatorname{cosec}^2\frac{\theta}{2}\cdot\frac{1}{a(1-\cos\theta)} = \frac{-1}{4a\sin^4\frac{\theta}{2}}.$$

Therefore,

$$X = x - \frac{y_1(1+y_1^2)}{y_2}$$

$$= a(\theta-\sin\theta) - \frac{\cot\frac{\theta}{2}\left[1+\cot^2\frac{\theta}{2}\right]}{-\frac{1}{4}\operatorname{cosec}^4\frac{\theta}{2}}$$

$$= a(\theta-\sin\theta) + 4a\cos\frac{\theta}{2}\sin\frac{\theta}{2}$$

$$= a\theta - a\sin\theta + 2a\sin\theta = a(\theta+\sin\theta) \qquad (1)$$

and

$$Y = y + \frac{1+y_1^2}{y_2}$$

$$= a(1-\cos\theta) - 4a\sin^2\frac{\theta}{2}$$

$$= a - a\cos\theta - 2a + 2a\cos\theta$$

$$= -a(1-\cos\theta). \qquad (2)$$

Hence, the center of curvature of the given cycloid is

$$(X, Y) = (a(\theta+\sin\theta) \text{ and } -a(1-\cos\theta)).$$

The locus of (*X*, *Y*) is

$$x = a(\theta+\sin\theta) \text{ and } y = -a(1-\cos\theta),$$

which is another equal cycloid.

EXAMPLE 3.27

Show that the evolute of the rectangular hyperbola $xy = c^2$ is the curve

$$(x+y)^{\frac{2}{3}} - (x-y)^{\frac{2}{3}} = (4c)^{\frac{2}{3}}.$$

Solution. We have

$$xy = c^2 \quad \text{or} \quad y = \frac{c^2}{x}.$$

Therefore,

$$y_1 = \frac{dy}{dx} = -\frac{c^2}{x^2} \text{ and } y_2 = \frac{d^2y}{dx^2} = \frac{2c^2}{x^3}.$$

Let (X, Y) be the coordinate of the center of curvature. Then,

$$\begin{aligned} X &= x - \frac{y_1(1+y_1^2)}{y_2} = x - \frac{\frac{-c^2}{x^2}\left(1+\frac{c^4}{x^4}\right)}{\frac{2c^2}{x^3}} \\ &= x + \frac{x^4+c^4}{2x^3} = \frac{2x^4+x^4+c^4}{2x^3} \\ &= \frac{3x^4+x^2y^2}{2x^3}, \text{ since } xy = c^2 \\ &= \frac{3x}{2} + \frac{y^2}{2x} \quad \text{and} \end{aligned}$$

$$\begin{aligned} Y &= y + \frac{1+y_1^2}{y_2} = y + \frac{1+\frac{c^4}{x^4}}{\frac{2c^2}{x^3}} = y + \frac{x^4+c^4}{2c^2x} \\ &= y + \frac{x^4+x^2y^2}{2x^2y}, \text{ since } xy = c^2 \\ &= y + \frac{x^2+y^2}{2y} = \frac{3y^2+x^2}{2y} = \frac{3}{2}y + \frac{x^2}{2y}. \end{aligned}$$

Hence, the center of curvature is

$$(X, Y) = \left(\frac{3x}{2} + \frac{y^2}{2x}, \frac{3y}{2} + \frac{x^2}{2y}\right).$$

Further, we note that

$$X + Y = \frac{1}{2xy}[x^3 + y^3 + 3x^2y + 3xy^2] = \frac{1}{2c^2}(x+y)^3$$

and so,

$$(X+Y)^{\frac{2}{3}} = \frac{1}{(2c^2)^{\frac{2}{3}}}(x+y)^2.$$

Similarly,

$$(X-Y)^{\frac{2}{3}} = -\frac{1}{(2c^2)^{\frac{2}{3}}}(x-y)^2.$$

Therefore,

$$\begin{aligned} (X+Y)^{\frac{2}{3}} - (X-Y)^{\frac{2}{3}} &= \frac{1}{(2c^2)^{\frac{2}{3}}}[(x+y)^2 + (x-y)^2] \\ &= \frac{1}{(2c^2)^{\frac{2}{3}}}(4xy) = \frac{1}{(2c^2)^{\frac{2}{3}}}(4c^2) \\ &= (4c)^{\frac{2}{3}}. \end{aligned}$$

The locus of (X, Y) is therefore,

$$(x+y)^{\frac{2}{3}} - (x-y)^{\frac{2}{3}} = (4c)^{\frac{2}{3}}.$$

Remark 3.2. The question can also be solved by taking a parametric equation of the curve as $x = ct$ and $y = \frac{c}{t}$, and then eliminating t from the expression for X and Y.

EXAMPLE 3.28

Show that the circle of curvature at the origin of the parabola $y = mx + \frac{x^2}{a}$ is $x^2 + y^2 = a(1 + m^2)(y - mx)$.

Solution. The equation of the given parabola is

$$y = mx + \frac{x^2}{a}.$$

Therefore,

$$y_1 = m + \frac{2x}{a} = \frac{am+2x}{a}$$

so that $y_1(0,0) = m$ and

$$y_2 = \frac{2}{a} \text{ so that } y_2(0,0) = \frac{2}{a}.$$

Let (X, Y) be the center of curvature at the origin. Then,

$$X = x - \frac{y_1(1+y_1^2)}{y_2} = 0 - \frac{m(1+m^2)}{\frac{2}{a}} = \frac{-am(1+m^2)}{2}$$

and

$$Y = y + \frac{1+y_1^2}{y_2} = 0 + \frac{1+m^2}{\frac{2}{a}} = \frac{a(1+m^2)}{2}.$$

Also,

$$\rho \text{ at } (0,0) = \frac{(1+y_1^2)^{\frac{3}{2}}}{y_2} = \frac{(1+m^2)^{\frac{3}{2}}}{\frac{2}{a}} = \frac{a(1+m^2)^{\frac{3}{2}}}{2}$$

Therefore, the equation of the circle of curvature is

$$(x-X)^2 + (y-Y)^2 = \rho^2$$

or

$$\left[x + \frac{am(1+m^2)}{2}\right]^2 + \left[y - \frac{a(1+m^2)}{2}\right]^2 = \frac{a^2(1+m^2)^3}{4}$$

or

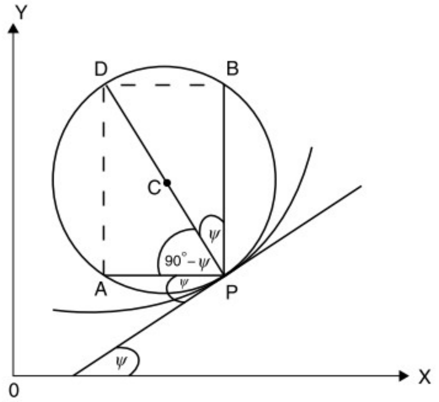
$$\begin{aligned} 4x^2 + 4y^2 &= a(1+m^2)[a(1+m^2)^2 - am^2(1+m^2) \\ &\quad - a(1+m^2) + 4(y-mx)] \\ &= 4a(1+m^2)(y-mx), \end{aligned}$$

which yields

$$x^2 + y^2 = a(1+m^2)(y-mx).$$

3.10 CHORDS OF CURVATURE PARALLEL TO THE COORDINATE AXES

Let P(X, Y) be a point on the curve and let the tangent at P make an angle ψ with the positive direction of x-axis. Then $CP = \rho$ and $PD = 2\rho$. Let PA and PB be the chords of curvature parallel to the x- and y-axis, respectively.



The chord PA makes an angle $\frac{\pi}{2} - \psi$ with CP and the chord PB makes an angle ψ with CP. Let C_x denote the length of PA and C_y denote the length of the chord PB. Then

$$C_x = PD\cos\left(\frac{\pi}{2} - \psi\right) = 2\rho\sin\psi$$

$$= 2\frac{(1+y_1^2)^{\frac{3}{2}}}{y_2}\cdot\frac{y_1}{\sqrt{1+y_1^2}} = \frac{2y_1(1+y_1^2)}{y_2}$$

and

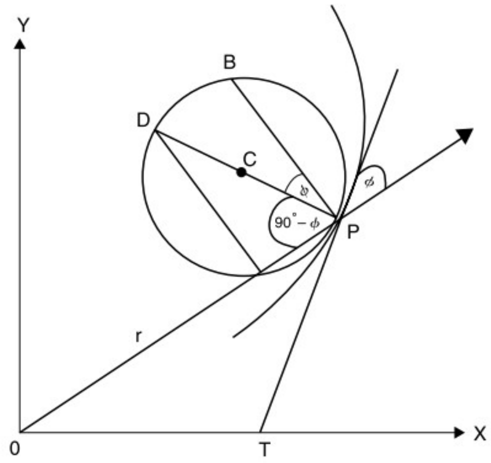
$$C_y = PD\cos\psi = 2\rho\cos\psi$$

$$= 2\frac{(1+y_1^2)^{\frac{3}{2}}}{y_2}\cdot\frac{1}{\sqrt{1+y_1^2}} = \frac{2(1+y_1^2)}{y_2}.$$

3.11 CHORD OF CURVATURE IN POLAR COORDINATES

1. Chord of Curvature Through the Pole (Origin)

Let P(X, Y) be a point on the curve and let the tangent at P make an angle ϕ with the radius vector OP. Then PA, the chord of curvature through the pole O makes an angle $\frac{\pi}{2} - \phi$ with CP, the radius of curvature.



If C_o denotes the length of the chord of curvature through the pole, then

$$C_o = \text{PA} = \text{PD}\cos\left(\frac{\pi}{2} - \phi\right) = 2\rho\sin\phi$$

$$= 2\frac{(r^2+r_1^2)^{\frac{3}{2}}}{r^2+2r_1^2-rr_2}\cdot\frac{r}{\sqrt{r^2+r_1^2}}, \text{ since } \tan\phi = \frac{r}{r_1}$$

$$= \frac{2r(r^2+r_1^2)}{r^2+2r_1^2-rr_2}.$$

2. Chord of Curvature Perpendicular to the Radius Vector

The chord PB of curvature perpendicular to the radius vector makes an angle ϕ with CP. Therefore, the length C_p of this chord is given by

$$C_p = \text{PB} = \text{PD}\cos\varphi = 2\rho\sin\phi$$

$$= 2\frac{(r^2+r_1^2)^{\frac{3}{2}}}{r^2+2r_1^2-rr_2}\cdot\frac{r_1}{\sqrt{r^2+r_1^2}}$$

$$= \frac{2r_1(r^2+r_1^2)}{r^2+2r_1^2-rr_2}.$$

EXAMPLE 3.29

Show that in the curve $y = a\log\sec\frac{x}{a}$, the chord of curvature parallel to the axis of y is of constant length.

Solution. The equation of the curve is

$$y = a\log\sec\frac{x}{a}.$$

Therefore,

$$y_1 = \frac{dy}{dx} = a\frac{1}{\sec\frac{x}{a}}\sec\frac{x}{a}\tan\frac{x}{a}.\frac{1}{a} = \tan\frac{x}{a},$$

$$y_2 = \frac{d^2y}{dx^2} = \frac{1}{a}\sec^2\frac{x}{a}.$$

Therefore, the length of chord of curvature parallel to the y-axis is

$$C_y = \frac{2(1+y_1^2)}{y_2} = \frac{2\left(1+\tan^2\frac{x}{a}\right)}{\frac{1}{a}\sec^2\frac{x}{a}} = 2a \quad \text{(constant)}.$$

EXAMPLE 3.30

Find the length of the chord of curvature through the pole of the cardioid $r = a\,(1 + \cos\,\theta)$.

Solution. The cardioid is $r = a\,(1 + \cos\theta)$. Therefore,

$$r_1 = \frac{dr}{d\theta} = -a\sin\theta \text{ and } r_2 = \frac{d^2r}{d\theta^2} = -a\cos\theta.$$

Hence,

$$\begin{aligned} C_o &= \frac{2r(r^2+r_1^2)}{r^2+2r_1^2-rr_2} \\ &= \frac{2r[a^2(1+\cos\theta)^2+a^2\sin^2\theta]}{a^2(1+\cos\theta)^2+2a^2\sin^2\theta+a^2(1+\cos\theta)\cos\theta} \\ &= \frac{2r(a^2+a^2\cos^2\theta+2a^2\cos\theta+a^2\sin^2\theta)}{3a^2+3a^2\cos\theta} \\ &= \frac{2r[2a^2+2a^2\cos\theta]}{3a^2(1+\cos\theta)} = \frac{4r^2a}{3ar} = \frac{4r}{3}. \end{aligned}$$

EXAMPLE 3.31

If C_x and C_y are the chords of curvature parallel to the axes at any point of the curve $y = ae^{\frac{x}{a}}$, show that

$$\frac{1}{C_x^2} + \frac{1}{C_y^2} = \frac{1}{2aC_x}.$$

Solution. We know that

$$C_x = \frac{2y_1(1+y_1^2)}{y_2} \text{ and } C_y = \frac{2(1+y_1^2)}{y_2}.$$

The given curve is $y = \text{a}e^{\frac{x}{a}}$. Therefore,

$$y_1 = \frac{dy}{dx} = \text{a}e^{\frac{x}{a}}\cdot\frac{1}{a} = e^{\frac{x}{a}} \text{ and } y_2 = \frac{d^2y}{dx^2} = e^{\frac{x}{a}}\cdot\frac{1}{a}.$$

Hence,

$$C_x = \frac{2e^{\frac{x}{a}}\left(1+e^{\frac{2x}{a}}\right)}{\frac{1}{a}e^{\frac{x}{a}}} = 2a\left(1+e^{\frac{2x}{a}}\right)$$

and

$$C_y = \frac{2\left(1+e^{\frac{2x}{a}}\right)}{\frac{1}{a}\;e^{\frac{x}{a}}} = \frac{2a}{e^{\frac{x}{a}}}\left(1+e^{\frac{2x}{a}}\right).$$

Then,

$$\begin{aligned} \frac{1}{C_x^2}+\frac{1}{C_y^2} &= \frac{1}{4a^2\left(1+e^{\frac{2x}{a}}\right)^2}+\frac{1}{\frac{4a^2}{e^{\frac{2x}{a}}}\left(1+e^{\frac{2x}{a}}\right)^2} \\ &= \frac{1}{4a^2\left(1+e^{\frac{2a}{x}}\right)^2}\left(1+e^{\frac{2x}{a}}\right) = \frac{1}{4a^2\left(1+e^{\frac{2x}{a}}\right)} = \frac{1}{2aC_x}. \end{aligned}$$

EXAMPLE 3.32

Find the length of the chord of curvature through the pole of the curve $r^n = a^n\cos n\theta$.

Solution. The equation of the given curve is $r^n = a^n \cos n\theta$. Differentiating with respect to θ, we have

$$nr^{n-1}\frac{dr}{d\theta} = -na^n\sin\;n\theta$$

or

$$\begin{aligned} r_1 &= \frac{dr}{d\theta} = -\frac{a^n\sin\;n\theta}{r^{n-1}} = -r\frac{a^n\sin\;n\theta}{r^n} \\ &= -r\frac{a^n\sin\;n\theta}{a^n\cos n\theta} = -r\tan\;n\theta \quad \text{and} \\ r_2 &= -r_1\tan\;n\theta - rn\sec^2 n\theta \\ &= r\tan^2\;n\theta - rn\sec^2 n\theta. \end{aligned}$$

Therefore,

$$\begin{aligned} C_o &= \frac{2r(r^2+r_1^2)}{r^2-rr_2+2r_1^2} \\ &= \frac{2r(r^2+r^2\tan\;n\theta)}{r^2-r(r\tan^2 n\theta-r\,n\sec^2 n\theta)+2r^2\tan^2\theta} \\ &= \frac{2r^3\sec^2 n\theta}{r^2[1-\tan^2 n\theta+n\sec^2 n\theta+2\tan^2 n\theta]} \\ &= \frac{2r\sec^2 n\theta}{1+\tan^2 n\theta+n\sec^2 n\theta} \\ &= \frac{2r\sec^2 n\theta}{\sec^2 n\theta+n\sec^2 n\theta} = \frac{2r}{n+1}. \end{aligned}$$

EXAMPLE 3.33

If C_o and C_p denote the length of the chords of curvature of the cardioid $r = a(1 + \cos\theta)$, along and perpendicular to the radius vector through any point, show that

$$3(C_o^2 + C_p^2) = 8aC_o.$$

Solution. From Example 3.30, we note that

$$r_1 = \frac{dr}{d\theta} = -a\sin\theta,$$

$$r_2 = \frac{d^2r}{d\theta^2} = -a\cos\theta, \text{ and } C_o = \frac{4r}{3}.$$

Further,

$$C_p = \frac{2r_1(r^2 + r_1^2)}{r^2 - rr_2 + 2r_1^2} = -\frac{2a\sin\theta(2a^2 + 2a^2\cos\theta)}{3a^2(1+\cos\theta)}$$

$$= -\frac{4a^2\sin\theta(1+\cos\theta)}{3a^2(1+\cos\theta)} = -\frac{4a\sin\theta}{3}.$$

Therefore,

$$3(C_o^2 + C_p^2) = 3\left[\frac{16r^2}{9} + \frac{16a^2}{9}\sin^2\theta\right]$$

$$= \frac{16}{3}[r^2 + a^2\sin^2\theta]$$

$$= \frac{16}{3}[a^2(1+\cos^2\theta + 2\cos\theta) + a^2\sin^2\theta]$$

$$= \frac{16}{3}[2a^2(1+\cos\theta)] = \frac{32ra}{3} = 8aC_o.$$

EXAMPLE 3.34

Prove that the points on the curve $r = f(\theta)$, is the circle of curvature at which it passes through the origin (pole) are given by the equation

$$f(\theta) + f''(\theta) = 0.$$

Solution. Since the circle of curvature passes through the pole, the chord of curvature through the pole is r. But the chord of curvature C_o is given by

$$C_o = \frac{2r(r^2 + r_1^2)}{r^2 - rr_2 + 2r_1^2}.$$

Therefore,

$$r = \frac{2r(r^2 + r_1^2)}{r^2 - rr_2 + 2r_1^2}$$

or

$$r^2 - rr_2 + 2r_1^2 = 2(r^2 + r_1^2)$$

or

$$r^2 + rr_2 = 0 \text{ or } r(r + r_2) = 0$$

and so, $r + r_2 = 0$. Hence,

$$f(\theta) + f''(\theta) = 0.$$

EXAMPLE 3.35

Show that in any curve the chord of curvature perpendicular to the radius vector is

$$\frac{2\rho}{r}\sqrt{r^2 - p^2}.$$

Solution. The chord of curvature perpendicular to the radius victor is

$$C_p = 2\rho\cos\phi = 2\rho\sqrt{1 - \sin^2\phi}$$

$$= 2\rho\sqrt{1 - \left(\frac{p}{r}\right)^2}, \text{ since } p = r\sin\phi$$

$$= \frac{2\rho}{r}\sqrt{r^2 - p^2}.$$

EXERCISES

1. Find the radius of curvature at any point (x, y) of the following curves:

   (i) $ay^2 = x^3$ **Ans.** (i) $\frac{\sqrt{x}(4a+9x)^{\frac{3}{2}}}{6a}$.

   (ii) $xy = c^2$ **Ans.** (ii) $\frac{x^2+y^2}{2c^2}$.

2. Find the radius of curvature at a given point of the following curves:

   (i) $y = e^x$ at the point where it cross the y-axis.
   Hint: The point is $x = 0$ and $y = e^0 = 1$.

   (ii) $y = \frac{c}{2}\left(e^{\frac{x}{c}} + e^{-\frac{x}{c}}\right)$ at (x, y).
   Hint: The curve is $y = c\cosh\frac{x}{c}$.

   (iii) $\sqrt{x} + \sqrt{y} = \sqrt{a}$ at $\left(\frac{a}{4}, \frac{a}{4}\right)$.

   (iv) $y^2 = \frac{a^2(a-x)}{x}$ at $(a, 0)$.

   Ans. (i) $2\sqrt{2}$ (ii) $\frac{y^2}{c}$ (iii) $\frac{a}{\sqrt{2}}$ (iv) $\frac{a}{2}$.

3. Show that the radius of curvature at any point of the astroid $x^{\frac{2}{3}} + y^{\frac{2}{3}} = a^{\frac{2}{3}}$ is three times the length of the perpendicular from the origin to the tangent at that point.
   Hint: If parametric equations are $x = a\cos^2 t$ and $y = a\sin^3 t$, then $\rho = 3a\sin t\ \cos t$, tangent is $y - a\sin^3 t = \frac{dy}{dx}(x - a\cos^3 t)$, and length of perpendicular from (0,0) on tangent is $\sin t \cos t$.

4. If ρ is the radius of curvature of the parabola $y^2 = 4ax$ at a point P, show that ρ^2 varies as $(SP)^3$, where S is the focus.
   Hint: ρ at $(at^2, 2at)$ is $2a(1+t^2)^{\frac{3}{2}}$, $S(a, 0)$ is the focus and so,
   $SP = \sqrt{(at^2 - a)^2 + (2at - 0)^2} = a(1 + t^2)$.
   Then $\rho^2 = \frac{4}{a}(SP)^3$.

5. For the curve $y = \frac{ax}{a+x}$, show that $\left(\frac{2\rho}{a}\right)^{\frac{2}{3}} = \left(\frac{y}{x}\right)^2 + \left(\frac{x}{y}\right)^2$, where ρ is the radius of curvature at (x,y).

6. Show that for the curve $x = a\cos\theta(1+\sin\theta)$ and $y = a\sin\theta\,(1+\cos\theta)$, the radius of curvature at $\theta = -\frac{\pi}{4}$ is a.

7. Prove that for the curve $r = a(\sec^3\psi - 1)$ the radius of curvature is $\rho = 3a\tan\psi\sec^3\psi$ and hence, show that $3a\frac{dy}{dx}\cdot\frac{d^2y}{dx^2} = 1$.

8. Prove that for the curve $4x = \theta + \sin\theta$ and $4y = 1 - \cos\theta$, the radius of curvature is $\rho = \cos\frac{\theta}{2}$.

9. Find the radius of curvature at the point θ of the curve $x = a\left(\cos\theta + \log\tan\frac{\theta}{2}\right)$ and $y = a\sin\theta$.
Hint: $\frac{dx}{d\theta} = \frac{a\cos^2\theta}{\sin\theta}$, $\frac{dy}{d\theta} = a\cos\theta$, $\frac{dy}{dx} = \tan\theta$, and $\frac{d^2y}{dx^2} = \frac{\sin\theta}{a\cos^4\theta}$. **Ans.** $a\cos\theta$.

10. Find the radius of curvature of the point (p,r) of the following curves:

    (i) $r^3 = 2ap^2$.

    (ii) $p^2 = \frac{r^4}{r^2+a^2}$. **Ans**. (i) $\frac{2}{3}\sqrt{2ar}$ (ii) $\frac{(r^2+a^2)^{\frac{3}{2}}}{r^2+2a^2}$.

11. Find the radius of curvature at any point of the curve $r^n = a^n\cos n\theta$.
Hint: $r_1 = -r\tan n\theta$ and $r_2 = r\tan^2\theta - nr\sec^2 n\theta$. Putting in $\rho = \frac{(r^2+r_1^2)}{r^2+2r_1^2-rr_2}$, we get $\rho = \frac{a^n}{(n+1)r^{n-1}}$.

12. Find the radius of curvature at (r,θ) of the curve $r = 6\left(1-\sin^2\frac{\theta}{2}\right)$.
Ans. $\rho = 4\cos\frac{\theta}{2}$.

13. Show that the radius of curvature at the point (r,θ) on the curve
$\theta = \frac{1}{a}(r^2-a^2)^{\frac{1}{2}} - \cos^{-1}\left(\frac{a}{r}\right)$ is $\rho = (r^2-a^2)^{\frac{1}{2}}$.
Hint: $\frac{d\theta}{dr} = \frac{(r^2-a^2)^{\frac{1}{2}}}{ar}$ and so, $\frac{dr}{d\theta} = \frac{ar}{\sqrt{r^2-a^2}}$.
Also $\frac{1}{p^2} = \frac{1}{r^2} + \frac{1}{r^4}\left(\frac{dr}{d\theta}\right)^2 = \frac{1}{r^2-a^2}$ and so pedal equation is $p^2 = r^2 - a^2$. Differentiating, we get $2p = 2r\frac{dr}{dp}$. Then $\rho = r\frac{dr}{dp} = p = \sqrt{r^2-a^2}$.

14. Show that the curvatures of the curves $r = a\theta$ and $r\theta = a$ at their common point are in the ratio 3:1.
Hint: Eliminating r between the two equations, we get $\theta^2 = 1$. Thus, at the common point $\theta^2 = 1$, for the first curve $r_1 = a$ and $r_2 = 0$ and so, $\rho_1(at\ \theta^2 = 1) = \frac{2a\sqrt{2}}{3}$. For the second curve $r_1 = -\frac{a}{\theta^2}$ and $r_2 = \frac{2a}{\theta^3}$ and so, $\rho_2(at\ \theta^2 = 1) = 2a\sqrt{2}$.

15. Prove that for any curve $\frac{d^2r}{ds^2} = \frac{\sin^2\phi}{r} - \frac{\sin\phi}{\rho}$
Hint: $\frac{dr}{ds} = \cos\phi$, $\rho = \frac{ds}{d\psi}$, $\phi = \psi - \theta$, and $\sin\phi = r\frac{d\theta}{ds}$.

16. Find the radius of curvature for the curve
$x = c\log\left\{s + \sqrt{s^2+c^2}\right\}$ and $y = \sqrt{s^2+c^2}$.
Hint: $\frac{dx}{ds} = -\frac{c}{\sqrt{s^2+c^2}}$ and $\frac{dy}{ds} = \frac{s}{s^2+c^2}\ \frac{d^2y}{ds^2} = \frac{d}{ds}\left(\frac{dy}{ds}\right) = \frac{c^2}{(s^2+c^2)^{\frac{3}{2}}}$ and so, $\rho = \frac{\frac{dx}{ds}}{\frac{d^2y}{ds^2}} = \frac{y^2}{c}$.

17. Find the radius of curvature at the origin of the following curves:

    (i) $x^3 - y^3 - 2x^2 + 6y = 0$.

    (ii) $x^3 - 2x^2y + 3xy^2 - 4y^3 + 5x^2 - 6xy + 7y^2 - 8y = 0$.

    Ans. (i) $\rho(0,0) = \frac{3}{2}$ (ii) $\rho(0,0) = \frac{4}{5}$.

18. Find the radius of curvature at the pole for the curve $r = a\sin n\theta$.
Ans. $\rho = \frac{1}{2}\frac{dr}{d\theta} = \frac{na}{2}$.

19. Find the radius of curvature at the origin for the curve $a(y^2 - x^2) = x^3$.
Ans. $2\sqrt{2}a$.

20. Find the coordinates of the center of curvature for the curve $a^2y = x^3$.
Ans. $\left(\frac{x}{2}\left(1 - \frac{9x^4}{a^4}\right), \left(\frac{5x^3}{2a^3} + \frac{a^2}{6x}\right)\right)$.

21. Show that the evolute of the tractrix $x = c\cos t + c\log\tan\frac{t}{2}$ and $y = c\sin t$ is the catenary $y = c\cosh\frac{x}{c}$.

22. Find the circle of curvature for the curve $x^3 + y^3 = 3xy$ at the point $\left(\frac{3}{2}, \frac{3}{2}\right)$.
Ans. $8(x^2 + y^2) - 21(x + \mathrm{y}) + 27 = 0$.

23. Find the length of the chord of curvature through the pole for the curves $r = \mathrm{a}e^{m\theta}$.
Ans. $2r$.

24. Find the coordinates of the center of curvature at $(at^2, 2at)$ on the parabola $y^2 = 4ax$.
Ans. $(2a + 3at^2, -2at^3)$.

25. Show that in the curve $y = a\cosh\left(\frac{x}{a}\right)$, the chord of curvature parallel to the axis of x is of length $a\sinh\left(\frac{2x}{a}\right)$.
Hint: $y_1 = \sinh\frac{x}{a}$ and $y_2 = \frac{1}{a}\cosh\frac{x}{a}$. Therefore, $C_x = \frac{2y_1(1+y_1^2)}{y_2} = a\sinh\frac{2x}{a}$.

26. If C_x and C_y are the chords of curvature parallel to the axis of x and y, respectively, at any point of the curve $y = a\cosh\frac{x}{a}$, show that

$$4a^2(C_x^2 + C_y^2) = C_y^4.$$

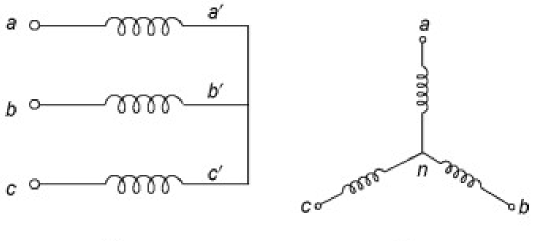
STAR AND DELTA CONNECTIONS

The *three armature conductors* in a three-phase generator are not generally interconnected. They may be connected in the star (*Y*) or delta (Δ) form. The star connection of the three-armature conductors is shown in Figure 25 where all the similar ends a', b' and c' are at the starting point. The terminals a', b' and c' are joined to form the neutral terminal (*N*). In a star connection, similar ends are connected (the '*s*' in star indicates similar ends). The neutral conductor may or may not be present. If it is present, it is called a three-phase four-wire system. Otherwise, it is a three-phase three-wire system. The delta connection of the three-armature conductor is shown in Figure 26. In a delta connection (the *'d'* in delta indicates dissimilar ends), dissimilar ends are interconnected.



(a) (b)

Figure 25 Star Connection

Figure 26 Delta Connection

VOLTAGES, CURRENTS AND POWER IN STAR CONNECTIONS

Figure 27 shows the three-phase three-wire system. The voltages V_{an}, V_{bn} and V_{cn} are called phase voltages, whereas the voltages V_{ab}, V_{bc} and V_{ca} are called line voltages, and the phase current (I_p) in each phase is equal to the line current in each line because each line is in series with its individual phase winding.

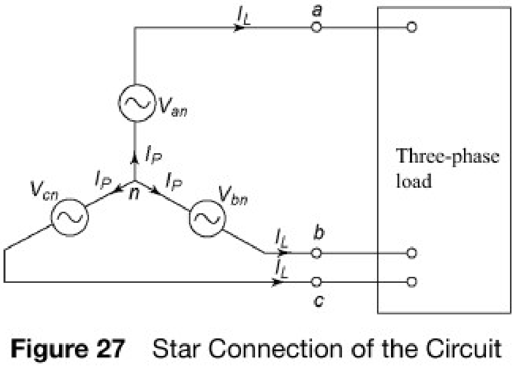

Figure 27 Star Connection of the Circuit

Let
$$\begin{aligned} V_{an} &= V_P \angle 0^\circ \\ V_{bn} &= V_P \angle -120^\circ \\ V_{cn} &= V_P \angle -240^\circ \end{aligned}$$

V_p indicates the magnitude of phase voltage.

Now,
$$\begin{aligned} V_{ab} &= V_{an} + V_{nb} = V_{an} - V_{bn} \\ &= V_P \angle 0^\circ - V_P \angle -120^\circ \\ &= V_P (\cos 0^\circ + j \sin 0^\circ) - V_P [\cos(-120^\circ) + j \sin(-120^\circ)] \\ &= V_P - V_P (\cos 120^\circ - j \sin 120^\circ) \\ &= V_P - V_P \left(-\frac{1}{2} - j\frac{\sqrt{3}}{2} \right) = V_P \left(1 + \frac{1}{2} + j\frac{\sqrt{3}}{2} \right) \\ &= V_P \left(\frac{3}{2} + j\frac{\sqrt{3}}{2} \right) = \sqrt{3}\, V_P \left(\frac{\sqrt{3}}{2} + j\frac{1}{2} \right) \\ &= \sqrt{3}\, V_P (\cos 30^\circ + j \sin 30^\circ) = \sqrt{3}\, V_P \angle 30^\circ \end{aligned}$$

Similarly,
$$\begin{aligned} V_{bc} &= V_{bn} + V_{nc} = V_{bn} - V_{cn} \\ &= V_P \angle -120^\circ - V_P \angle -240^\circ = V_P \angle -90^\circ \end{aligned}$$

and
$$\begin{aligned} V_{ca} &= V_{cn} + V_{na} = V_{cn} - V_{an} = V_P \angle -240^\circ - V_P \angle 0^\circ \\ &= \sqrt{3}\, V_P \angle -210^\circ \end{aligned}$$

Figure 28 shows the phasor diagram.

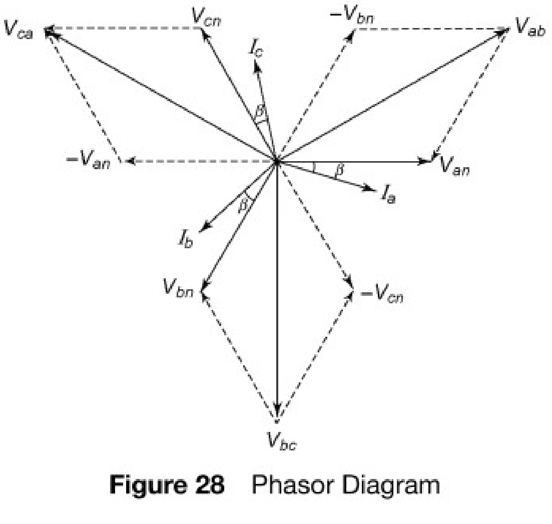

Figure 28 Phasor Diagram

So the magnitude of line voltage is $\sqrt{3}$ times the magnitude of phase voltage. In this case, $I_P = I_L$. The active or true power in each phase of the circuit is given by $V_P I_P \cos\beta$, where β is the angle between each phase voltage and its corresponding phase current. The total three-phase power (P) is expressed as

$$P = 3V_P I_P \cos\beta = 3\left(\frac{V_L}{\sqrt{3}}\right) I_L \cos\beta$$

i.e.,

$$P = \sqrt{3}V_L I_L \cos\beta \tag{29}$$

Similarly, total reactive power (Q) is expressed as

$$Q = 3V_P I_P \sin\beta = 3\left(\frac{V_L}{\sqrt{3}}\right) I_L \sin\beta$$

i.e.,

$$Q = \sqrt{3}V_L I_L \sin\beta \tag{30}$$

Q is positive when the load is of the inductive type, and it is negative when the load is of the capacitive type.

The total apparent power of the three phases (S) = $\sqrt{3}V_L I_L$.

VOLTAGES, CURRENTS AND POWER IN DELTA CONNECTIONS

Figure 29 shows three voltage sources connected in delta. In Figure 29, the phase voltages and line voltages are identical, but the line currents and phase currents are not identical.

Here, taking I_{ab} as reference, we have

$$\begin{aligned}
I_{ab} &= I_P \angle 0^\circ \\
I_{bc} &= I_P \angle -120^\circ \\
I_{ca} &= I_P \angle -240^\circ \\
I_a &= I_{ca} - I_{ab} = I_P \angle -240^\circ - I_P \angle 0^\circ \\
&= I_P(\cos 240^\circ - j\sin 240^\circ) - I_P(\cos 0^\circ + j\sin 0^\circ) \\
&= I_P\left(-\frac{1}{2} + j\frac{\sqrt{3}}{2}\right) - I_P = I_P\left(-\frac{3}{2} + j\frac{\sqrt{3}}{2}\right) \\
&= \sqrt{3}\,I_P\left(-\frac{\sqrt{3}}{2} + j\frac{1}{2}\right) = \sqrt{3}\,I_P(\cos 150^\circ + j\sin 150^\circ) \\
&= \sqrt{3}\,I_P \angle 150^\circ
\end{aligned}$$

100. Applications of the Integral Curve of the Reciprocal Curve.

Fig. 2 shows an **acceleration-velocity** curve, the scales being marked. The integral curve of its reciprocal, drawn in the direct manner described above, is shown below OX. The scale and units for ordinates of the integral curve, from the above reasoning, are:

$$1'' = \frac{20 \text{ feet}}{\text{secs.}} \div \text{NO} \, . \, \frac{\cdot 02 \text{ feet}}{(\text{secs.})^2} = \frac{20}{\cdot 75 \times \cdot 02} \, . \, \frac{\text{feet secs.}^2}{\text{secs. feet}} = 1333\tfrac{1}{3} \text{ seconds.}$$

The integral curve is therefore a **velocity-time** curve; a space-time curve may be obtained from it as on page 78.

If the given curve is a **velocity-space** curve (space along OX) the integral of the reciprocal will give a **space-time** curve.

EXAMPLES

(1) Plot the graph $y = \cdot 1x^2 + 3$ from $x = 0$ to 6. Scales: values of x, $1'' = 1$; values of y, $1'' = 2$. Draw the reciprocal curve using a pole distance of $2''$. Deduce the scale and read off the value of $1/y$ when $x = 3$. Check by calculation.

(2) The following table shows the relation between acceleration α and velocity v for a body, starting from rest.

α, ft./sec.^{2}	·6	·55	·45	·34	·246	·19	·16
v, ft./sec.	0	10	20	30	40	50	60

Plot the acceleration-velocity graph and obtain from it a velocity-time curve. What times have elapsed when the body has velocities of (*a*) 35 f.s., (*b*) 60 f.s.? Through what distance has the body moved when the velocity is 60 f.s.? Ans. (*a*) 80 sec., (*b*) 205 sec.; 7655 ft.

Note.—An additional example (No. 3) is given on page 86

Problem 99. To construct the Reciprocal Curve of a given Curve, and the Integral Curve of the Reciprocal.

Let $y = f(x)$, fig. 1, be any given curve. The reciprocal of this curve is one which will give values of $1/y$ for values of x.

Draw a succession of ordinates, produce them below OX, and mark the mid-points on the curve. Consider the mid-point p. Draw pA par¹ to OX to intersect OY in A, and join A to any pole N, on XO produced. From N draw NB perp. to NA to intersect OY in B. Draw Bp_1 par¹ to OX to intersect in p_1 the mid-ordinate from p: p_1 is a point on the required reciprocal curve. Obtain other points in the same way and draw the complete reciprocal curve.

To construct the integral curve of the reciprocal, make use of the radials below OX, from the pole N. Beginning at O draw through each ordinate space a line par¹ to the corresponding radial. The construction is similar to that given on page 76

It will be seen that this integral curve may be drawn *without first constructing the reciprocal*, the first segment of the integral curve, from O, being perp. to the first radial, as indicated by the dotted line; and so on.

Scales. (1) Reciprocal Curve. Let the scales be as marked: to determine n[C] in terms of h[A], m[B], and d.

From the figure, $po = \text{AO}$ and $p_1o = \text{BO}$.

By similar △s, AO : NO :: NO : BO, i.e. $\text{AO} \,.\, \text{BO} = (\text{NO})^2$ . . . (1)

$$\text{i.e. BO} = \frac{1}{\text{AO}} \,.\, (\text{NO})^2 = \frac{1}{\text{AO}} \,.\, \text{constant.}$$

Because ordinates of the reciprocal curve are to represent values of $\frac{1}{y}$, then

$$\text{BO}'' \,.\, n[\text{C}] = \frac{1}{\text{AO}'' \,.\, m[\text{B}]}; \text{ i.e. } n[\text{C}] = \frac{1}{\text{AO}'' \,.\, \text{BO}'' \,.\, m[\text{B}]}.$$

Substituting from (1), $n[\text{C}] = \dfrac{1}{(\text{NO}'')^2 \,.\, m[\text{B}]}$; i.e. $\boldsymbol{n[\text{C}] = \dfrac{1}{d^2 \,.\, m[\text{B}]}}$

(2) Integral Curve. The ordinate scale for this curve, $1'' = o[\text{D}]$, is deduced as on page 76 and is $1'' = n[\text{C}] \,.\, h[\text{A}] \,.\, d = \dfrac{1}{d^2 \,.\, m[\text{B}]} \,.\, h[\text{A}] \,.\, d$.

$$\therefore\ \boldsymbol{o[\text{D}] = \frac{h[\text{A}]}{d \,.\, m[\text{B}]}}.$$

100. Applications of the Integral Curve of the Reciprocal Curve.

Fig. 2 shows an **acceleration-velocity** curve, the scales being marked. The integral curve of its reciprocal, drawn in the direct manner described above, is shown below OX. The scale and units for ordinates of the integral curve, from the above reasoning, are:

$$1'' = \frac{20 \text{ feet}}{\text{secs.}} \div \text{NO} \,.\, \frac{\cdot 02 \text{ feet}}{(\text{secs.})^2} = \frac{20}{\cdot 75 \times \cdot 02} \,.\, \frac{\text{feet secs.}^2}{\text{secs. feet}} = 1333\tfrac{1}{3} \text{ seconds.}$$

The integral curve is therefore a **velocity-time** curve; a space-time curve may be obtained from it as on page 78.

If the given curve is a **velocity-space** curve (space along OX) the integral of the reciprocal will give a **space-time** curve.

EXAMPLES

(1) Plot the graph $y = \cdot 1x^2 + 3$ from $x = 0$ to 6. Scales: values of x, $1'' = 1$; values of y, $1'' = 2$. Draw the reciprocal curve using a pole distance of 2″. Deduce the scale and read off the value of $1/y$ when $x = 3$. Check by calculation.

(2) The following table shows the relation between acceleration α and velocity v for a body, starting from rest.

α, ft./sec.²	·6	·55	·45	·34	·246	·19	·16
v, ft./sec.	0	10	20	30	40	50	60

Plot the acceleration-velocity graph and obtain from it a velocity-time curve. What times have elapsed when the body has velocities of (*a*) 35 f.s., (*b*) 60 f.s.? Through what distance has the body moved when the velocity is 60 f.s.? Ans. (*a*) 80 sec., (*b*) 205 sec.; 7655 ft.

Note.—An additional example (No. 3) is given on page 86

6.9 Equilateral triangles

Explicit formulas for the equilateral triangle are developed in this section, thus allowing the qualitative max/min theorems in this chapter for triangles to be rephrased as computable estimates. For example, the maximality of $\mu_2 A$ for the equilateral triangle (as stated in Theorem 6.33) is equivalent to saying

$$\mu_2 A \le \frac{4\pi^2}{3\sqrt{3}},$$

as one sees by evaluating $\mu_2 A$ for the equilateral using the values stated below.

The modes and frequencies of the equilateral triangle were derived roughly 150 years ago by Lamé. For a modern treatment of the Dirichlet case, see Mathews and Walker's text [695, pp. 237–239], and for a comprehensive treatment under all boundary conditions see McCartin's monograph [701] or his earlier papers upon which the monograph is based.

Consider now the equilateral triangle with vertices at $(0,0)$, $(\sqrt{3}/2, 1/2)$ and $(\sqrt{3}/2, -1/2)$. This triangle has sidelength 1, and

$$A = \sqrt{3}/4, \qquad D = 1, \qquad L = 3, \qquad S^2 = 3.$$

We state below the Dirichlet and Neumann spectra for this triangle.

6.9.1 Dirichlet spectrum of equilateral triangle with unit sidelength

The first three eigenvalues are

$$\lambda_1 = \frac{3 \cdot 16\pi^2}{9}, \qquad \lambda_2 = \lambda_3 = \frac{7 \cdot 16\pi^2}{9}$$

with eigenfunctions

$$u_1(x,y) = \sin\left(\frac{4}{\sqrt{3}}\pi x\right) - 2\cos(2\pi y)\sin\left(\frac{2}{\sqrt{3}}\pi x\right) \tag{6.13}$$

$$u_2(x,y) = \sin\left(\frac{6}{\sqrt{3}}\pi x\right)\cos\left(\frac{2}{3}\pi y\right) - \sin\left(\frac{4}{\sqrt{3}}\pi x\right)\cos\left(\frac{8}{3}\pi y\right) - \sin\left(\frac{2}{\sqrt{3}}\pi x\right)\cos\left(\frac{10}{3}\pi y\right) \tag{6.14}$$

$$u_3(x,y) = \sin\left(\frac{6}{\sqrt{3}}\pi x\right)\sin\left(\frac{2}{3}\pi y\right) - \sin\left(\frac{4}{\sqrt{3}}\pi x\right)\sin\left(\frac{8}{3}\pi y\right) + \sin\left(\frac{2}{\sqrt{3}}\pi x\right)\sin\left(\frac{10}{3}\pi y\right) \tag{6.15}$$

Figure 6.11 displays the nodal patterns of these first three Dirichlet eigenfunctions of the equilateral triangle, extended by odd reflection across the sides of the triangle.

The higher eigenfunctions are more complicated, although the corresponding eigenvalues retain a simple form:

$$\frac{16\pi^2}{9}(j_1^2 + j_1 j_2 + j_2^2), \qquad j_1, j_2 \ge 1. \tag{6.16}$$

Choosing $(j_1, j_2) = (1,1)$ gives the first eigenvalue $48\pi^2/9$ stated above. Note that modes $(j_1, j_2) = (5,6)$ and $(j_1, j_2) = (1,9)$ belong to the same eigenvalue (see Figure 6.11 for some linear combinations).

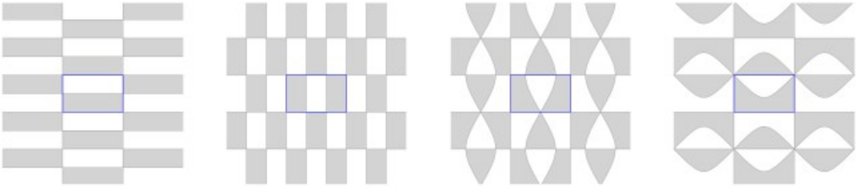

Fig. 6.9. Nodal patterns for the smallest multiple eigenvalue on a rectangle with $a/b = \sqrt{8/3}$.

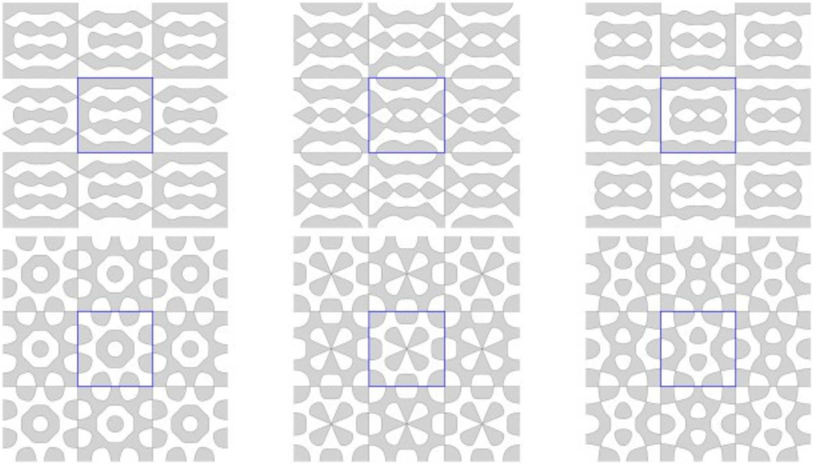

Fig. 6.10. Various nodal patterns belonging to the 31st Dirichlet eigenvalue of a square. This eigenvalue has multiplicity three, with pure modes (1, 7), (7, 1) and (5, 5). Different linear combinations of these modes generate rather diverse nodal domains, including the ones shown here.

multiplicity can arise in interesting ways, such as for $(0, 5)$ and $(3, 4)$ in the Neumann case, or $(1, 7)$ and $(5, 5)$ in the Dirichlet case (which in fact gives triple multiplicity). In Section 6.13 we describe nodal problems that have been solved recently in a few special cases, including squares.

6.9 Equilateral triangles

Explicit formulas for the equilateral triangle are developed in this section, thus allowing the qualitative max/min theorems in this chapter for triangles to be rephrased as computable estimates. For example, the maximality of $\mu_2 A$ for the equilateral triangle (as stated in Theorem 6.33) is equivalent to saying

$$\mu_2 A \leq \frac{4\pi^2}{3\sqrt{3}},$$

as one sees by evaluating $\mu_2 A$ for the equilateral using the values stated below.

The modes and frequencies of the equilateral triangle were derived roughly 150 years ago by Lamé. For a modern treatment of the Dirichlet case, see Mathews and Walker's text [695, pp. 237–239], and for a comprehensive treatment under all boundary conditions see McCartin's monograph [701] or his earlier papers upon which the monograph is based.

Consider now the equilateral triangle with vertices at $(0,0)$, $(\sqrt{3}/2, 1/2)$ and $(\sqrt{3}/2, -1/2)$. This triangle has sidelength 1, and

$$A = \sqrt{3}/4, \qquad D = 1, \qquad L = 3, \qquad S^2 = 3.$$

We state below the Dirichlet and Neumann spectra for this triangle.

6.9.1 Dirichlet spectrum of equilateral triangle with unit sidelength

The first three eigenvalues are

$$\lambda_1 = \frac{3 \cdot 16\pi^2}{9}, \qquad \lambda_2 = \lambda_3 = \frac{7 \cdot 16\pi^2}{9}$$

with eigenfunctions

$$u_1(x,y) = \sin\left(\frac{4}{\sqrt{3}}\pi x\right) - 2\cos(2\pi y)\sin\left(\frac{2}{\sqrt{3}}\pi x\right) \tag{6.13}$$

$$u_2(x,y) = \sin\left(\frac{6}{\sqrt{3}}\pi x\right)\cos\left(\frac{2}{3}\pi y\right) - \sin\left(\frac{4}{\sqrt{3}}\pi x\right)\cos\left(\frac{8}{3}\pi y\right) - \sin\left(\frac{2}{\sqrt{3}}\pi x\right)\cos\left(\frac{10}{3}\pi y\right) \tag{6.14}$$

$$u_3(x,y) = \sin\left(\frac{6}{\sqrt{3}}\pi x\right)\sin\left(\frac{2}{3}\pi y\right) - \sin\left(\frac{4}{\sqrt{3}}\pi x\right)\sin\left(\frac{8}{3}\pi y\right) + \sin\left(\frac{2}{\sqrt{3}}\pi x\right)\sin\left(\frac{10}{3}\pi y\right) \tag{6.15}$$

Figure 6.11 displays the nodal patterns of these first three Dirichlet eigenfunctions of the equilateral triangle, extended by odd reflection across the sides of the triangle.

The higher eigenfunctions are more complicated, although the corresponding eigenvalues retain a simple form:

$$\frac{16\pi^2}{9}(j_1^2 + j_1 j_2 + j_2^2), \qquad j_1, j_2 \geq 1. \tag{6.16}$$

Choosing $(j_1, j_2) = (1,1)$ gives the first eigenvalue $48\pi^2/9$ stated above. Note that modes $(j_1, j_2) = (5,6)$ and $(j_1, j_2) = (1,9)$ belong to the same eigenvalue (see Figure 6.11 for some linear combinations).

6.9.2 Neumann spectrum of equilateral triangle with unit sidelength

We have $\mu_1 = 0$, with eigenfunction $u_0 \equiv 1$, and

$$\mu_2 = \mu_3 = \frac{16\pi^2}{9}$$

5. Let ℓ, m, n be three *mutually skew* lines (i.e. no two of the lines intersect) of a projective space S_3 of dimension 3. Show that through each point of ℓ, there exists a unique line r which intersects both m and n.
   Such a line r is called an (ℓ, m, n)**-transversal**. The set $\mathfrak{R}$ of all (ℓ, m, n)-transversals is called a **regulus**, and is sometimes denoted by $\mathfrak{R}(\ell, m, n)$. Prove that no two distinct (ℓ, m, n)-transversals intersect in a point.
6. Show that if p, q are two skew lines in a projective space S_4 of dimension 4, then there exists a unique hyperplane of S_4 containing them. Deduce that *in general* there exists a unique line of S_4 intersecting three given lines which are pairwise non-intersecting.
7. Show that if S_r, S_n are two given projective spaces, then the points of $S_r \oplus S_n$ are those (and only those) on all the lines joining any point of S_r to any point of S_n.

Projective planes

A projective space of dimension 2 is called a projective plane. In that case, the set of axioms reduces to the following:

Definition 3.11 *A* **projective plane** π *is a set* $\mathcal{P}$ *of points and a set* $\mathcal{L}$ *of subsets of* $\mathcal{P}$*, called lines, satisfying the following:*

P1. There exists a unique line joining two distinct points.

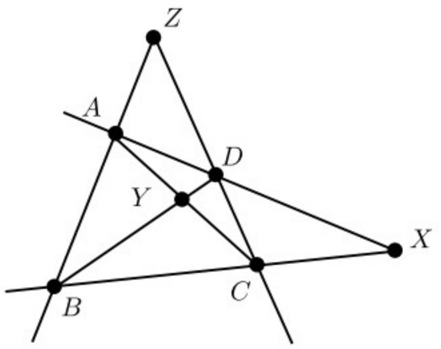
P2. There exists a unique point of intersection of two distinct lines.

P3. There exist at least three non-collinear points.

P4. There exist at least three points on each line.

Example 3.12 The EEP is a projective plane since all the axioms are satisfied. However the Euclidean plane is not a projective plane, since axiom P2 is not satisfied by any pair of parallel lines.

Definition 3.13 *In a projective plane, a set of four points* $A, B, C, D,$ no three collinear *is called a* **quadrangle**. *A set of four lines* $a, b, c, d,$ no three concurrent *is called a* **quadrilateral**.



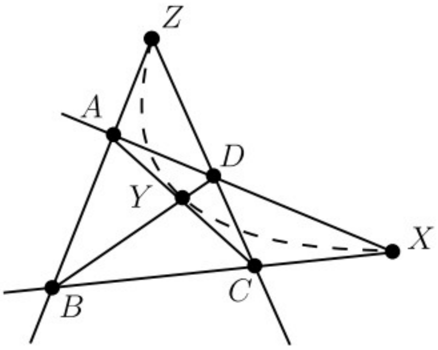
Example 3.14 Let π be a projective plane. Prove that π has a quadrangle

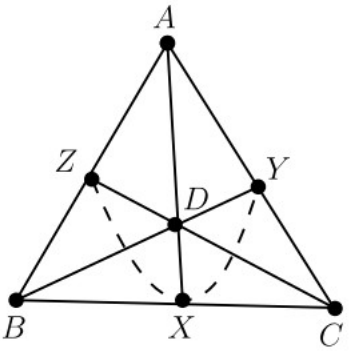
Solution. By Axiom P3, there exist three non-collinear points A, B, and X of π. Axiom P1 gives the lines AB, AX, and BX. By Axiom P4, there exist points $C \in BX$, $D \in AX$, distinct from A, B, and X. By Axioms P1 and P2, the line DC intersects the line AB in a point Z, which is distinct from A,B,C,D, and X. Thus $ABCD$ is a quadrangle. □

Note 6 *In the last example, BD, AC intersect in a point Y, which is distinct from the points A, B, C, D, X, and Z. There may be no other point in π, in which case the points X, Y, Z lie on a line.*

Definition 3.15 *This plane of seven points and seven lines is called the* **Fano** *plane.*

Either of the following two diagrams represents the Fano plane!





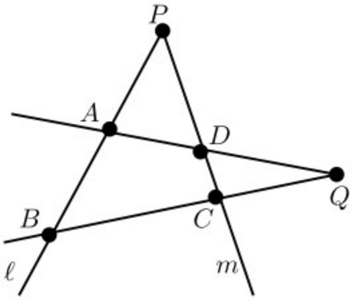
The Fano plane has exactly *three* points on *each* line, and *three* lines through *each* point. We now prove that this is a consequence of the Fano plane being a projective plane with a *finite* number of points.

Theorem 3.16 *Let π be a projective plane which has a finite number N_2 of points. Then*

1. *Every line of π has the same number $N_1 = q + 1$ of points. The number q is called the* **order** *of the plane π.*
2. *The number N_2 of points in π is $q^2 + q + 1 = (q^3 - 1)/(q - 1)$.*

Proof.

1. Let ℓ, m be any two distinct lines of π. Let $P = \ell \cap m$. On ℓ, there exist at least two points A, B, other than P. On m, there exist two points C, D, other than P.
   Let $AD \cap BC = Q$. Then $Q \notin \ell$, and $Q \notin m$. For each $P_i \in \ell$, the line QP_i intersects m in a point. Hence m has at least as many points as ℓ. Similarly, ℓ has at least as many points as m. Hence ℓ and m have the same number N_1 of points. Put $N_1 = q + 1$.



2. Let ℓ be any line of π. Take a point $P \notin \ell$. Then the points of π lie on the lines joining P to the $q+1$ points of ℓ. There are $q+1$ such lines, and each line contains q points, other than P. Hence

$$\begin{aligned} N_2 &= q(q+1) + 1 \\ &= q^2 + q + 1 \\ &= \frac{q^3 - 1}{q - 1}. \end{aligned}$$

□

Exercise 3.2 Let π be a projective plane. Use Definition 3.11 to prove:

P3'. There exist at least three non-concurrent lines in π.

P4'. There exist at least three lines through each point in π.

Deduce that the *Principle of Duality is valid in a projective plane.*

Order of a finite projective space

In Theorem 3.16, we proved that every line of a finite projective plane π has the same number of points. We next show that this is also true of a finite projective space.

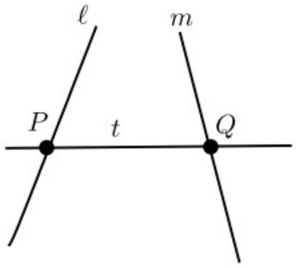
Theorem 3.17 *Let $S_r, r \geq 2$, be an r-dimensional projective space which has a finite number N_r of points. Then*

1. *Every line of S_r has the same number $q+1$ of points. The number q is called the* **order** *of the space S_r.*

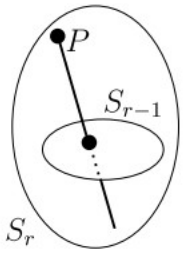
2. $N_r = q^r + q^{r-1} + \cdots + q + 1 = (q^{r+1} - 1)/(q - 1)$.

Proof.

1. Let ℓ, m be any two lines of S_r. Two cases are to be considered.
   Case 1: Suppose ℓ and m are coplanar. By Theorem 3.16, ℓ and m have the same number of points.
   Case 2: Suppose ℓ and m are not coplanar. Take a point P on ℓ, and a point Q on m. Then the line PQ is coplanar with, but distinct from, both ℓ and m. From Case 1, ℓ has the same number of points as PQ, and PQ has the same number of points as m. Hence ℓ and m have the same number N_1 of points.



2. Put $N_1 = q + 1$. We use induction to find N_r. Assume that the result is true for S_{r-1}. Take a point $P \notin S_{r-1}$. Then $P \oplus S_{r-1}$ is a projective space S_r of dimension r. (See Example 3.10.) The points of S_r lie on the lines joining P to the points of S_{r-1}. There are N_{r-1} such lines, and each line contains q points, other than P. Hence



$$\begin{aligned} N_r &= qN_{r-1} + 1 \\ &= q(q^{r-1} + q^{r-2} + \cdots + q + 1) + 1 \\ &= q^r + q^{r-1} + \cdots + q + 1 \\ &= \frac{q^{r+1} - 1}{q - 1}. \end{aligned}$$ □

Example 3.18 The Fano plane is of order 2, since it has $2 + 1$ points on each line. In fact, it has $7 = 2^2 + 2 + 1$ points and $7 = 2^2 + 2 + 1$ lines.

Note 7 1. *By the principle of duality in the plane:*

$$\begin{aligned} \textit{number of points on a line} &= \textit{number of lines through a point} \\ &= q + 1, \\ \textit{number of points in the plane} &= \textit{number of lines in the plane} \\ &= q^2 + q + 1. \end{aligned}$$

2. *A careful investigation reveals that the principle of duality is valid in a projective space S_r of dimension r. In S_r, for all n, with $0 \leq n \leq r$, a subspace S_n of dimension n is dual to a subspace S_{r-n-1} of dimension $r - n - 1$.*

   In the plane ($r = 2$), S_0 and S_1 are dual spaces.

   In the projective space S_3 of dimension 3,

   - *a point (of dimension 0) is dual to a plane (of dimension $2 = 3 - 0 - 1$),*
   - *a line (of dimension 1) is dual to a line (of dimension $1 = 3 - 1 - 1$).*

Example 3.19 Let S_3 be a three-dimensional projective space of order q. By the principle of duality (a point is dual to a plane, and a line is dual to a line), we have:

$$\begin{aligned}\text{Number of points} &= q^3+q^2+q+1\\ &= \text{number of planes.}\end{aligned}$$

$$\begin{aligned}\text{Number of planes containing a line } \ell &= \text{number of points on a line } \ell\\ &= q+1.\end{aligned}$$

$$\begin{aligned}\text{Number of lines through a point} &= \text{number of lines in a plane}\\ &= q^2+q+1.\end{aligned}$$

Now, let N be the number of lines in S_3. We count the number M of pairs (ℓ, P), where P is a point lying on the line ℓ. On each of the N lines of S_3 there are $q+1$ points. Thus,

$$M = N(q+1).$$

Further, through each of the q^3+q^2+q+1 points of S_3, there pass q^2+q+1 lines. Therefore,

$$M = (q^2+q+1)(q^3+q^2+q+1).$$

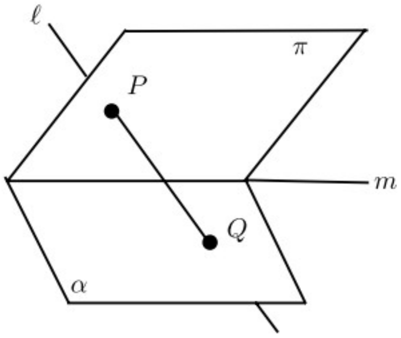
Hence

$$\begin{aligned}N = \frac{M}{(q+1)} &= (q^2+q+1)\frac{(q^3+q^2+q+1)}{(q+1)}\\ &= (q^2+q+1)(q^2+1)\\ &= q^4+q^3+2q^2+q+1.\end{aligned}$$

□

In the next two examples, we use different techniques to find again the number of lines in a three-dimensional projective space S_3 of order q; the rationale of this repetition is to expose the reader to combinatorial arguments which are typical of what one encounters in Finite Geometry.

Example 3.20 Let π and α be two distinct planes of a three-dimensional projective space S_3 of order q. Find the number N of lines in S_3 by investigating how a line intersects π and α.



Solution. In S_3, the planes π and α necessarily intersect in a line; let m denote the line $\pi \cap \alpha$. A line ℓ of S_3 is one of three types:

Type I: $\ell = PQ$, with $P \in \pi \backslash m$ and $Q \in \alpha \backslash m$.

Type II: $\ell = m$.

Type III: ℓ intersects m in a point.

There are q^2 choices for P, and q^2 choices for Q; therefore there are $q^2 \times q^2$ lines of Type I. There is one line of Type II, namely m. Through each of the $q+1$ points of m, there pass q^2+q lines of Type III. Therefore, there are $(q^2+q)(q+1)$ lines of Type III. Hence,

$$N = q^4 + 1 + (q^2+q)(q+1) = q^4 + q^3 + 2q^2 + q + 1.$$

□

Example 3.21 Find the number N of lines in a three-dimensional projective space S_3 of order q by counting the number of ways of choosing two distinct points from the points of S_3.

Solution. Since each pair of the q^3+q^2+q+1 points of S_3 gives rise to a line, and any line is specified by a pair of its $q+1$ points, the number of lines of S_3 is

$$\begin{aligned} N &= \frac{\binom{q^3+q^2+q+1}{2}}{\binom{q+1}{2}} \\ &= \frac{(q^3+q^2+q+1)(q^3+q^2+q)}{(q+1)q} \\ &= \frac{(q^2+1)(q+1)q(q^2+q+1)}{(q+1)q} \\ &= (q^2+1)(q^2+q+1) \\ &= q^4+q^3+2q^2+q+1. \end{aligned}$$

□

Exercise 3.3

1. Consider the triple $(\mathcal{P}, \mathcal{L}, \mathcal{I})$ with $\mathcal{P} = \{1,2,3,4\}$, $\mathcal{L} = \{a, b, c, d, e, f\}$, and $\mathcal{I} = \{(1,a), (2,a), (3,b), (4,b), (1,c), (3,c), (2,d), (4,d), (1,e), (4,e), (2,f), (3,f)\}$.
   (a) Draw a diagram of this triple.
   (b) Verify that it satisfies only two of the axioms of a projective plane.

2. Using your knowledge of the Euclidean three-dimensional space $\mathbb{R}^3$, show that the following triple $(\mathcal{P}, \mathcal{L}, \mathcal{I})$ is a projective plane where:
   $\mathcal{P}$ is the set of lines passing through the origin $O = (0,0,0)$;
   $\mathcal{L}$ is the set of planes passing through O;
   $\mathcal{I} = \{(\ell, \alpha) \mid \ell \text{ is a line in the plane } \alpha;\ \ell \in \mathcal{P},\ \alpha \in \mathcal{L}\}$.

3. Prove that the dual of a projective plane is a projective plane.

4. Show that a finite projective plane has an odd number of points. Can there exist a projective plane with 23 points? What about 111 points?

5. Let π be a projective plane. Show that there exists lines ℓ, m in π and a point P not on ℓ or m.

6. Assume that Desargues' Theorem is valid in a given projective plane. Prove its converse, *without appealing to the Principle of Duality.*

   (*Hint:* Draw carefully the configuration of the converse of Desargues' Theorem; find, in the configuration, triangles in perspective from a point and apply Desargues' Theorem.)

7. Recall that in a two-dimensional projective space, (see Exercise 2.1(3)), the dual of Desargues' Theorem is its converse. Thus, by the principle of duality, Desargues' Theorem implies its converse.

   State, for the three-dimensional case: Desargues' Theorem, its dual, and its converse. Comment.

8. Consider the following

   as configurations, first, in a plane, and second, in a three-dimensional projective space. In each case, draw the dual configuration.

9. Let $\pi_1, \pi_2, \pi_3, \pi_4, \pi_5, \pi_6$ be six planes in three-dimensional projective space such that each of the following sets of three planes have a common line of intersection

$$\{\pi_1, \pi_2, \pi_3\}, \{\pi_1, \pi_4, \pi_5\}, \{\pi_3, \pi_5, \pi_6\}, \{\pi_2, \pi_4, \pi_6\}.$$

   Further, no four planes have a common line of intersection.

   Prove that the six planes have a common point.

   (*Hint:* Solve the dual problem.)

10. Count all the incidences in S_4, a four-dimensional projective space of order q. That is, determine the number of
    (a) points and hyperplanes in S_4;
    (b) lines and planes in S_4;
    (c) points in each of a line, a plane and a hyperplane;
    (d) lines in each of a plane and a hyperplane;
    (e) lines through a point;
    (f) planes in a hyperplane;

(g) planes through a point;

(h) planes containing a line;

(i) hyperplanes through each of a point, a line, and a plane.

11. Let π be a projective plane of order q.

    Definition: A **k-arc** K is a set of k points of π, *no three collinear*. A line ℓ of π is a **chord**, a **tangent**, or an **external line** to K depending on whether $|\ell \cap K|$ is $2, 1$, or 0, respectively.

    (a) By considering the lines of π through a point P of a k-arc K, show that the number t of tangents through each point of K is
    $$t = q - k + 2.$$
    Deduce that
    $$k \leq q + 2$$
    and that a $(q+2)$-arc has no tangents.

    (b) Let K be a k-arc of π, where k is an odd number. By considering the lines of π through a point P not on K, show that there pass an odd number of tangents through P. Deduce that if q is odd,
    $$k \leq q + 1.$$

    (c) Let K be a $(q+1)$-arc of π, where q is *even*. Let P, Q be any two distinct points of K. Show that through each point of PQ there passes at least one tangent. Deduce that through each point of PQ there passes exactly one tangent. Deduce also that the $q+1$ tangents of K meet in a point N, and that $K \cup \{N\}$ is a $(q+2)$-arc. The point N is called the **nucleus** of the $(q+1)$-arc K.

12. **Definition**: An **affine plane** $\mathcal{A}$ is a triple $(\mathcal{P}, \mathcal{L}, \mathcal{I})$ with points $\mathcal{P}$, lines $\mathcal{L}$, and incidence $\mathcal{I}$, satisfying the following axioms:

    A1. Every pair of points lies on a unique line.

    A2. Given any line ℓ and any point P not on ℓ, there is a unique line m such that P lies on m, and ℓ and m have no common point.

    A3. There are three non-collinear points.

    We call two lines of $\mathcal{A}$ *parallel* if they coincide or have no common point.

    (a) Let π be a projective plane and let ℓ_∞ be a line of π. Let π^{ℓ_∞} denote the triple obtained from π by deleting the line ℓ_∞ and all the points on ℓ_∞.
        (i) Show that π^{ℓ_∞} is an affine plane.
        (ii) Deduce that the Euclidean plane is an affine plane.

    (b) Show that parallelism in an affine plane $\mathcal{A}$ is an equivalence relation and that each point of $\mathcal{A}$ lies on exactly one line from each class of parallel lines.

    (c) Prove that the dual of an affine plane is not an affine plane.

13. **Definition**: Let $(\mathcal{P}, \mathcal{B}, \mathcal{I})$ be a triple with points $\mathcal{P}$, lines $\mathcal{B}$, and incidence $\mathcal{I}$, satisfying the following axioms:

    A1. Each point is incident with $t+1$ distinct lines.
    Two distinct points are incident with *at most one* line.

A2. Each line is incident with $s+1$ distinct points.
Two distinct lines are incident with *at most one* point.

A3. If ℓ is a line and P a point not incident with ℓ, then there exists a *unique* point Q and a *unique* line m such that $m = PQ$ and $\ell \cap m = Q$.

Then $(\mathcal{P}, \mathcal{B}, \mathcal{I})$ is called a **Generalised Quadrangle** with parameters s and t and is denoted $\mathrm{GQ}(s,t)$.

Note: There is a point–line duality for $\mathrm{GQ}(s,t)$ which interchanges points and lines (and so interchanges s and t) in any definition or theorem.

(a) Let ℓ be a given line of $\mathrm{GQ}(s,t)$. Label the $s+1$ points on ℓ by $P_1, P_2, \ldots, P_{s+1}$. Let the set of t lines through P_i distinct from ℓ be $\ell_{i1}, \ldots, \ell_{it}$ for $i = 1, \ldots, s+1$. Let C^* be the configuration made up of the lines ℓ, ℓ_{ij} ($i = 1, \ldots, s+1$, $j = 1, \ldots, t$), and the points incident with them.

  (i) Show that if $i \neq k$, $(1 \leq i, k \leq s+1)$, then $\ell_{ij} \cap \ell_{km} = \phi$ for any j, m such that $1 \leq j, m \leq t$.

  (ii) Using (i), deduce that C^* has $(1+s)(1+st)$ points.

  (iii) Show that each point of the $\mathrm{GQ}(s,t)$ lies on a line of C^*.

  (iv) Using (ii) and (iii), deduce that the $\mathrm{GQ}(s,t)$ also has $(1+s)(1+st)$ points.

  (v) Using duality, write down the number of lines of the $\mathrm{GQ}(s,t)$.

(b) Let $q = 2^h$, where h is some positive integer. Let $\mathrm{PG}(3,q)$ denote a projective space of dimension 3 and of order q. Let α be a plane of $\mathrm{PG}(3,q)$. Assume that there exists a set $\mathcal{K}$ of $q+2$ points in α such that no three points of $\mathcal{K}$ are collinear. (Note that any line of α meets $\mathcal{K}$ in 0 or 2 points.) Consider the following triple $(\mathcal{P}, \mathcal{B}, \mathcal{I})$:

  - $\mathcal{P}$ is the set of points in $\mathrm{PG}(3,q)\backslash\alpha$.
  - $\mathcal{B}$ is the set of lines of $\mathrm{PG}(3,q)$ which do not lie in α and which contain exactly one point of $\mathcal{K}$.
  - $\mathcal{I}$ is the natural incidence between points and lines.

  (i) Show that $\mathcal{P}$ has q^3 points.

  (ii) Let P be a point of $\mathcal{K}$. Show that there are q^2 distinct lines of $\mathcal{B}$ passing through P and deduce that $\mathcal{B}$ has $q^2(q+2)$ lines.

  (iii) Show that each point in $\mathcal{P}$ lies on $q+2$ distinct lines in $\mathcal{B}$.
  Prove that each line in $\mathcal{B}$ contains q distinct points of $\mathcal{P}$.

  (iv) Let ℓ be a line in $\mathcal{B}$ and let P be a point in $\mathcal{P}$ not incident with ℓ.

    A. *Existence:* Show that there exists a point Q in $\mathcal{P}$ and a line m in $\mathcal{B}$ such that $m = PQ$ and $\ell \cap m = Q$.
    (*Hint:* Consider the plane β containing P and ℓ and investigate $\beta \cap \alpha$. Also, use the fact that any line in α intersects $\mathcal{K}$ in either 0 or 2 points.)

    B. *Uniqueness:* Show that the point–line pair obtained above is unique.
    (*Hint:* Suppose that (Q_1, m_1) and (Q_2, m_2) are two such pairs. Consider the points $\ell \cap \mathcal{K}$, $m_1 \cap \mathcal{K}$, and $m_2 \cap \mathcal{K}$.)

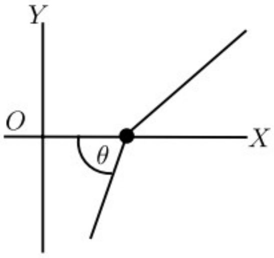
  (v) Deduce that $(\mathcal{P}, \mathcal{B}, \mathcal{I})$ is a generalised quadrangle and determine the parameters s and t.

Desargues' Theorem and non-Desarguesian planes

Desargues' Theorem plays a central role in the study of projective planes. But the theorem is not a consequence of the axioms, as we will soon see.

Definition 3.22 *A projective plane π is* **Desarguesian** *if Desargues' Theorem is valid in π for any pair of triangles which have distinct vertices, and are in perspective from a point.*

Example 3.23 As will be proved later, the EEP is Desarguesian.



Example 3.24 (**A non-Desarguesian projective plane**) Consider the following triple $\pi = (\mathcal{P}, \mathcal{L}, \mathcal{I})$:

1. The *points* of π are the points of the extended Euclidean plane.
2. The *lines* of π are
   (a) the Euclidean lines perpendicular to the x-axis;
   (b) the Euclidean lines parallel to the x-axis;
   (c) the Euclidean lines with negative slopes;
   (d) the 'refracted' Euclidean lines given by:

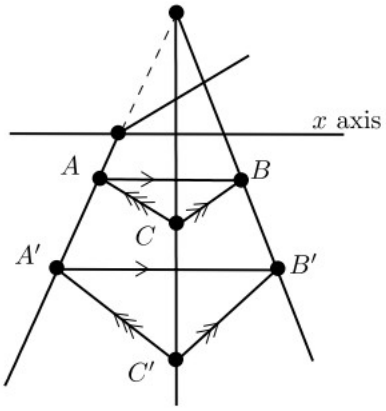
$$y = \begin{cases} \frac{1}{2}(x-a)\tan\theta & y \geq 0, \\ (x-a)\tan\theta & y < 0, \end{cases}$$

   where $a \in \mathbb{R}$ and $0 < \theta < 90$;

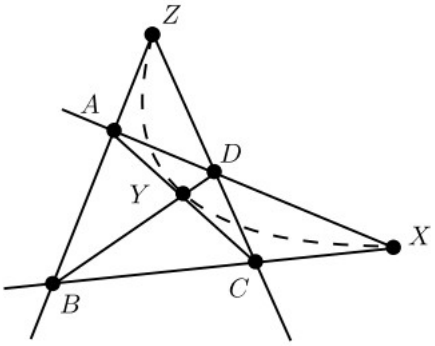
   (e) the line at infinity of the extended Euclidean plane.
3. *Incidence* $\mathcal{I}$ in π is as follows:
   Incidence of the extended Euclidean plane and
   - parallel Euclidean lines of type (a), (b), or (c) intersect in their point at infinity of the extended Euclidean plane.
   - two lines of type (d) that do not intersect in the Euclidean plane, intersect in the point at infinity of their 'upper halves'.

The proof that π *is a projective plane* is left as an exercise for the reader.

Theorem: *π is non-Desarguesian.*
Sketch of Proof. In the diagram, the corresponding sides of triangles ABC and $A'B'C'$ are parallel, and therefore their intersections lie on the line at infinity, but the join of corresponding vertices are not concurrent. Hence the converse of Desargues' Theorem (and so Desargues' Theorem) is not valid in π. □



Note 8 *The Desargues' configuration requires* 10 *points, namely one vertex, two triangles, and three points of intersection of corresponding sides. The Fano plane has only seven points, and therefore Desargues' Theorem is meaningless in the Fano plane. In fact, if a quadrangle is chosen in the Fano plane to play the role of a vertex and a triangle, the remaining three points are collinear!*



Theorem 3.25 *Let π be a finite projective plane of order $q \geq 4$. Then π contains 'many' Desarguesian configurations.*

Proof. Take any point V, any line ℓ with $V \notin \ell$. Take p, q, r, any three lines through V, and let

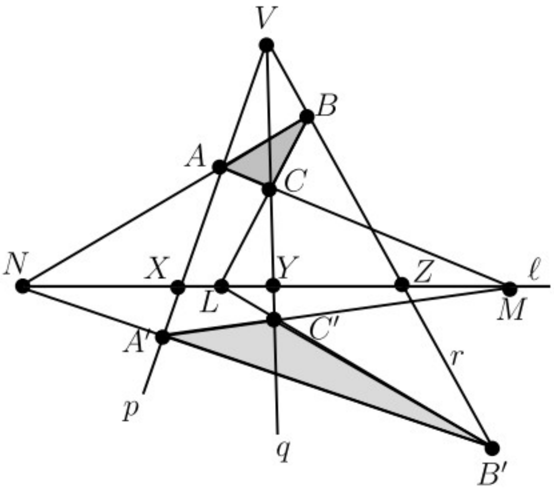
$$p \cap \ell = X, \quad q \cap \ell = Y, \quad r \cap \ell = Z.$$

Let N, L be points of ℓ, distinct from X, Y, and Z. This is possible since ℓ has at least five points.

Define a map $\sigma\colon \mathcal{A} \to \mathcal{L}$, where

$$\mathcal{A} = p \backslash \{V, X\}, \mathcal{L} = \ell \backslash \{N, L, Y, X\},$$

as follows:



- Let $A \in \mathcal{A}$, and let $NA \cap VZ = B$. Thus $B \neq V, Z$.
- Join BL and let $BL \cap q = C$. Thus $C \neq Y$.
- Let $AC \cap \ell = M$. Thus $M \notin \{N, L, Y, X\}$.
- Define $\sigma \colon \mathcal{A} \to \mathcal{L}$ by $A^\sigma = M$.

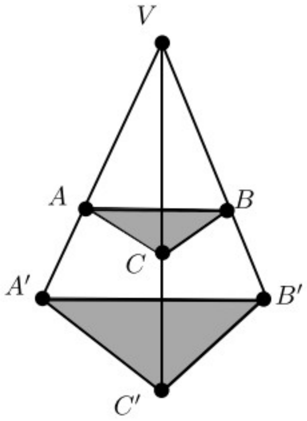
Now $\mathcal{A}$ has $q-1$ elements, while $\mathcal{L}$ has $q-3$ elements. Therefore, σ is not one-to-one. Thus, there exist distinct points $A, A' \in \mathcal{A}$, with $\sigma(A) = \sigma(A')$. Let $B' = NA' \cap r$ and $C' = LB' \cap q$. Then, we have: triangles $ABC, A'B'C'$ are in perspective, with vertex V and axis ℓ. □

Note 9 *The word 'many' in the above theorem is justified by the fact that*

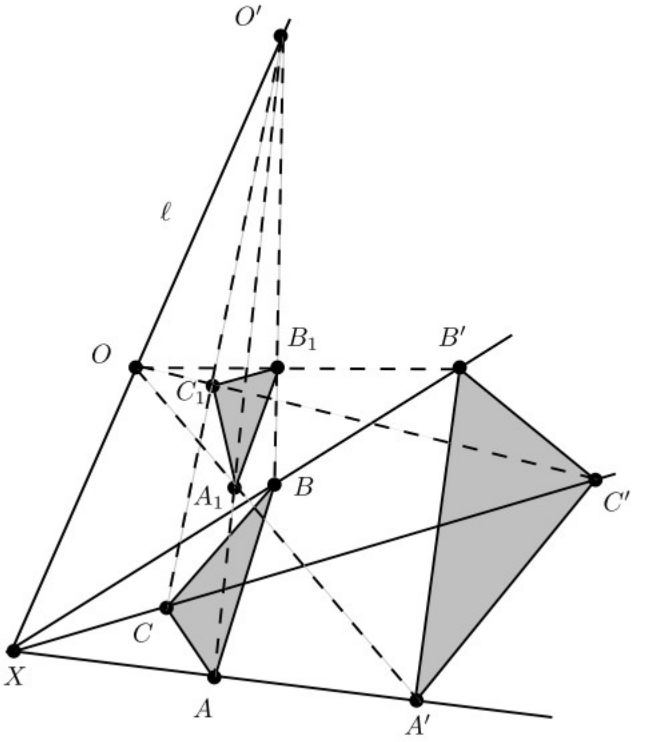
1. V *is any point.*
2. ℓ *is any line,* $V \notin \ell$.
3. p, q, r, *are any three lines through* V.
4. N, L *are any two points of* ℓ, *distinct from* X, Y, Z.

Theorem 3.26 *Desargues' Theorem is valid in a projective space of dimension* n, $n \geq 3$, *for any two non-coplanar triangles* $ABC, A'B'C'$, *in perspective from a point* V.

Proof. Let triangles $ABC, A'B'C'$ belong to the distinct planes π, α, respectively. We first note that the two triangles $ABC, A'B'C'$ belong to a space Σ of dimension 3 because $\Sigma = \pi \oplus V = \alpha \oplus V$. Therefore, $\pi \cap \alpha$ is a line. Now, AB and $A'B'$ are lines of the plane VAB, and therefore they intersect in a point. Similarly, BC and $B'C'$ intersect in a point; so also do the lines $AC, A'C'$. It follows that the points $AB \cap A'B'$, $BC \cap B'C'$, $CA \cap C'A'$ belong to the line $\pi \cap \alpha$. ☐



Theorem 3.27 *Let π be a projective plane, of order greater than two, immersed in a projective space S_n, of dimension $n \geq 3$. Then π is Desarguesian.*



Proof. Let π be a plane (of order greater than two) of a projective space S_n, of dimension $n \geq 3$. Let $ABC, A'B'C'$ be two triangles of π, in perspective from a point X. Take any line $\ell \notin \pi$, through X. There are at least two other points (distinct from X) on ℓ. Let O, O' be two such points. Now $A'O, O'A$ intersect in a point since they are distinct lines of the plane OXA. Let $A'O \cap O'A = A_1$. Similarly, define the points B_1 and C_1. Note that the points A_1, B_1, and $C_1 \notin \pi$, and are not collinear.

Denote the plane $A_1B_1C_1$ by π_1. Thus $\pi \neq \pi_1$. Since triangles $ABC, A_1B_1C_1$ are in perspective from O', from the proof of Theorem 3.26, $A_1C_1 \cap AC \in \pi \cap \pi_1$. Let $A_1C_1 \cap \pi = P$. Similarly, triangles $A'B'C'$ and $A_1B_1C_1$ are in perspective from O; hence $A_1C_1 \cap A'C' \in \pi \cap \pi_1$. Hence $AC \cap A'C' = P$ lies on the line $\pi \cap \pi_1$. Similarly, $BC \cap B'C'$ and $AB \cap A'B'$ lie on the line $\pi \cap \pi_1$. In other words, the line $\pi \cap \pi_1$ is the axis of the perspectivity. ☐

Note 10 1. *A projective plane π need not be Desarguesian, although it could have many Desargues' configurations. Thus, it is not a consequence of the axioms that π is Desarguesian or not.*

2. *In Exercise 3.4(2b), it is proved that if Pappus' Theorem holds for any pair of lines of a projective plane π, (π is said to be* **Pappian***) then π is Desarguesian. The converse of this is not true for infinite planes.*

3. *It will be shown that any projective plane π can be coordinatised by means of a set $\mathcal{S}$ which has (as a consequence of the axioms of a projective plane only) an addition $+$ and a multiplication $\cdot$. But, unless π is assumed to have additional geometrical properties, $\{\mathcal{S}, +, \cdot\}$ has few algebraic properties; in fact, as will be indicated later, if the order of π is greater than two, then π is Desarguesian if and only if it can be coordinatised by a* skew field, *and Pappian if and only if it can be coordinatised by a field.*

   By definition, a **skew field** *has all the properties of a field, except that multiplication is not prescribed to be commutative. There exist infinite skew-fields which are not fields, the* quaternions *for example. However, Wedderburn's Theorem states that a finite skew-field is a field. Therefore,* a finite Desarguesian plane is Pappian.

   Since any plane of a projective space S_r, of dimension $r, r \geq 3$, is Desarguesian (Theorem 3.27), it follows that a non-Desarguesian plane cannot be embedded in a three-dimensional projective space.

Exercise 3.4

1. Consider three triangles in the Euclidean plane which have their corresponding sides parallel. Assume that the EEP is Desarguesian, and prove:
   (a) The three triangles are pairwise in perspective. That is, for each pair of triangles, the joins of corresponding vertices are concurrent.
   (b) If the vertices of the three perspectivities are distinct, then these vertices are collinear.

2. Let π be a given Pappian plane (i.e. a projective plane in which Pappus' Theorem is valid).

(a) Let ABC, DEF be two triangles in π such that lines AD, BE, CF meet in a point O *and* the lines AE, BF, CD meet in a point O'. Prove that AF, BD, CE meet in a point.
(*Hint:* Dualise.)

(b) Prove that π is Desarguesian.
(*Hint:* Let triangles $ABC, A'B'C'$ be in perspective from V. Let

$$\begin{aligned} B'C' \cap AC &= S, & B'A \cap CC' &= T, \\ B'A' \cap VS &= P, & BA \cap VS &= U, \\ BC \cap B'C' &= L, & CA \cap C'A' &= M, \\ AB \cap A'B' &= N. \end{aligned}$$

Use Pappus' Theorem to show that

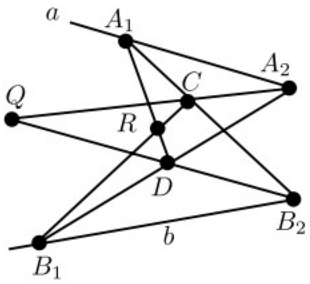
(i) the points U, T, L are collinear by considering the lines $BB'V$ and SCA,

(ii) the points P, M, T are collinear by considering the lines $AA'V$ and $C'SB'$,

(iii) the points L, M, N are collinear by considering the lines $B'AT$ and UPS.

This question is hard unless you draw the three diagrams suggested by the hint separately (i.e. do not crowd any one diagram).)

3. Consider the following diagram and suppose the points and lines are those of a Pappian plane π. By considering the two triads of points $\{A_2, D, B_1\}$ and $\{B_2, C, A_1\}$, prove that the line QR passes though the point $a \cap b$.



4. Let π be a Desarguesian plane. In π, let A, B, C lie on a line m and A', B', C' lie on a line n such that AA', BB', and CC' are concurrent in a point V. Prove that the points $AB' \cap A'B$, $AC' \cap A'C$, and $BC' \cap B'C$ lie on a line passing through the point of intersection of m and n.

(*Hint:* Identify triangles in perspective from the point V, and apply Desargues' Theorem.)

5. Prove that if the lines joining corresponding vertices of two tetrahedra in a three-dimensional projective space S_3 are concurrent, then the intersection of corresponding faces are coplanar. (A tetrahedron is a set of four non-coplanar points; the points are called vertices of the tetrahedron, the plane spanned by any three vertices is called a face, and the line joining two vertices is called an edge.)

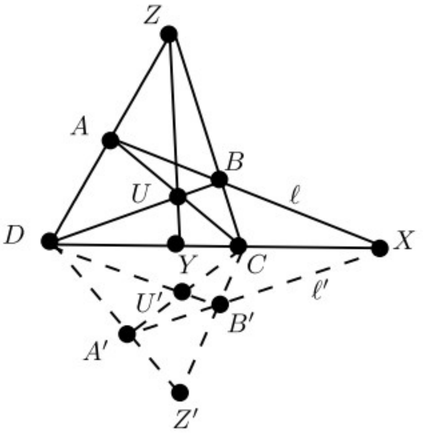
(*Hint:* Desargues' Theorem is valid for non-coplanar triangles. Therefore, corresponding edges intersect in collinear points.)

6. Let π be a projective plane. Let D, C, X be points on a given line m of π. Let ℓ be any line through X, $\ell \neq m$. Let A, B be two points, distinct from X, on ℓ. Let $DA \cap CB = Z$, $BD \cap AC = U$.

   Define $Y = ZU \cap DC$ as a **harmonic conjugate** of X with respect to D, C. *Prove:* If π is Desarguesian, then the construction for a harmonic conjugate is unique.

   (*Hint:* Take another line ℓ' through X. Get Z', A', B', U'. You have to prove: $Z'U'$ passes through Y.
   Apply Desargues' Theorem or its converse to:

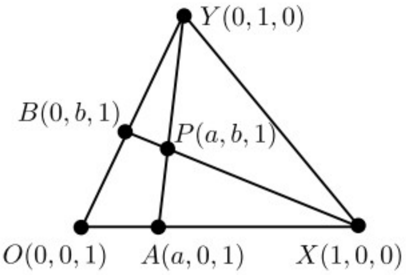
   (a) triangles ZAB and $Z'A'B'$;
   (b) triangles UAB and $U'A'B'$;
   (c) triangles AZU and $A'Z'U'$.)



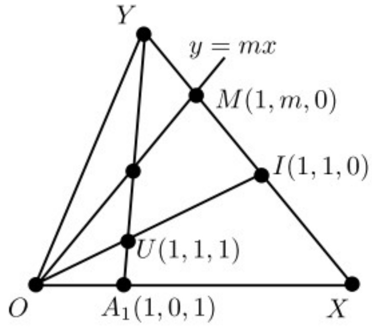
5 Coordinatising a projective plane

Preliminaries

There are many ways to coordinatise a projective plane. The most popular one is to attempt to make the plane look as close to a field plane as possible.



Consider the plane PG$(2,F)$. Let O, X, and Y be any three non-collinear points of PG$(2,F)$. Without loss of generality, we may take the homogeneous coordinates of O, X, and Y to be $(0,0,1)$, $(1,0,0)$, and $(0,1,0)$, respectively. Any point A on OX, with $A \neq X$, has homogeneous coordinates $(a,0,1)$, $a \in F$. Similarly, let $B=(0,b,1)$ be any point of OY, distinct from Y. Then $P = AY \cap XB$ has homogeneous coordinates $(a,b,1)$. Thus, any point P not on XY has non-homogeneous coordinates of type (a,b), with $a,b \in F$.



The line $y=mx$ intersects XY in the point $M=(1,m,0)$. We call (m) the non-homogeneous coordinate of M.

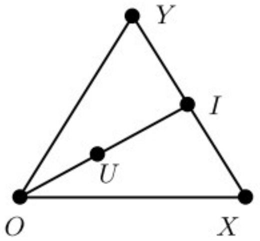
If U is the point $(1,1,1)$, then any point on OU, distinct from $I = OU \cap XY$, has non-homogeneous coordinates of type (a,a), $a \in F$.

The *coordinatisation* of a projective plane, which is introduced in the next section, retains the above-mentioned features.

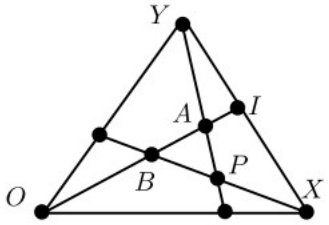
Introducing coordinates

Let π be any projective plane. Let OXY be a triangle in π, and let I be any point on XY, with I distinct from X and Y. Let U be any point of OI, with U

distinct from O and I. Define γ to be an abstract set of elements in one-to-one correspondence with the points of OI distinct from I. Denote by 0 and 1 the elements of γ corresponding to O and U, respectively. Let $c \in \gamma$ correspond to the point C of OI, $C \neq I$. The *coordinates* of C are defined to be (c, c). Thus, O has coordinates $(0, 0)$, and U has coordinates $(1, 1)$.



Let P be any point of π, not on XY. Let $A = YP \cap OI$ and $B = XP \cap OI$ have coordinates (a, a) and (b, b), respectively. *Define (a, b) to be the coordinates of P.* Thus, if $P \in OX$, its coordinates are of type $(a, 0)$; if $P \in OY$, its coordinates are of type $(0, b)$.

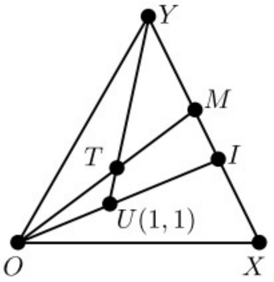


Note 29 *No two points of $\pi \backslash XY$ have the same coordinates.*

Note 30 *Two points have the same 'x' coordinate if and only if they are collinear with Y; two points have the same 'y' coordinates if and only if they are collinear with X.*

Let M be any point of XY, distinct from Y. Let $T = YU \cap OM$ have coordinates $(1, m)$, $m \in \gamma$. *Define (m) to be the coordinates of M.* Lastly, let ∞ be an abstract element. *Define (∞) to be the coordinates of Y.*

The coordinatisation of the projective plane π is now complete.



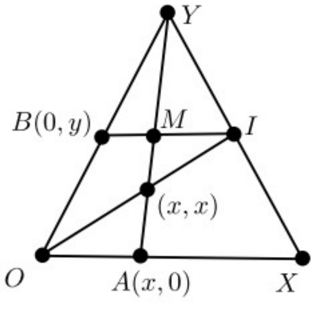
Addition in γ

The aim is to discover any algebraic structure that γ inherits from the fact that π is a projective plane.

Let $A = (x, 0)$ and $B = (0, y)$ be points on OX, OY, respectively. Let $M = YA \cap IB$. Let coordinates of M be (x, m). In γ we define the operation + (to be called **addition**) by

$$x + y = m.$$

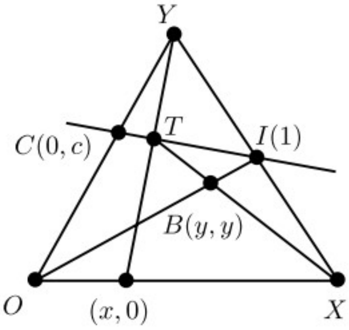
Thus, M has coordinates $(x, x + y)$.



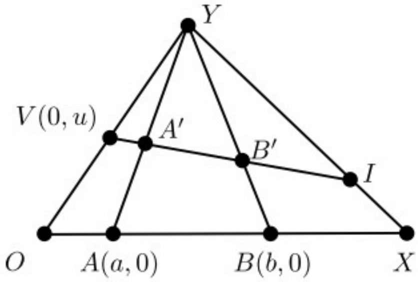
Example 5.1
1. If $M \in OI$, $M \neq I$, we have $m = x$, $y = 0$ and therefore $x + 0 = x$ for all $x \in \gamma$.
2. If $x = 0$, we have $0 + y = y$, for all $y \in \gamma$.
3. If any two of x, c, y are given, the third can be determined by the equation

$$x + c = y.$$

For example, suppose c and y are given. Let C be the point of coordinates $(0, c)$; let B be the point (y, y). Let $T = CI \cap BX$. Then the coordinates of T are $(x, y) = (x, x + c)$.



4. Suppose $a, b, u \in \gamma$ and $a \neq b$. Then the points $V = (0, u)$, $A' = (a, a + u)$, $B' = (b, b + u)$, and I are collinear. Suppose $a + u = b + u$. Then, the points $(a, a + u)$, $(b, b + u)$, having the same 'y' coordinates are collinear with X. This is a contradiction. Therefore, $a + u = b + u$ if and only if $a = b$, for all $u \in \gamma$.



□

Definition 5.2 *A* **loop** $(H, \circ)$ *is a set* H *on which is defined a binary operation* $\circ$*, such that*

1. *For all* $x, y \in H$, $x \circ y \in H$.
2. *Given* $a, b \in H$*, each of the equations* $a \circ x = b$*, and* $y \circ a = b$ *has a unique solution in* H.
3. *There exists an element* $e \in H$*, such that* $e \circ x = x \circ e = x$*, for all* $x \in H$.

Theorem 5.3 $(\gamma, +)$ *is a loop.*

Exercise 5.1

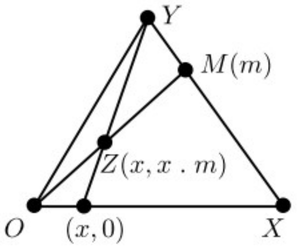
1. Show that loops of orders $1, 2, 3, 4$ are groups.
   (*Hint:* Construct a multiplication table for a loop $(H, \circ)$ of order $2, 3$, or 4. In each case, a multiplication table for a group is obtained.)

2. The following multiplication table is that of a loop of order 5.

	1	a	b	ab	ba
1	1	a	b	ab	ba
a	a	1	ab	ba	b
b	b	ba	1	a	ab
ab	ab	b	ba	1	a
ba	ba	ab	a	b	1

Justify the statement: 'This loop is not a group'.

Multiplication in γ



Let M be a point of XY, distinct from Y. Let its coordinate be (m). Let (x, y) be the coordinates of a point Z on OM, distinct from M. In γ, define the operation '$\cdot$' (to be called **multiplication**) by

$$z = x \cdot m$$

Example 5.4 Prove the following:

1. For all $a \in \gamma$, $a \cdot 0 = 0$ and $0 \cdot a = 0$.
2. If $m \neq 0$, then for all $a, b \in \gamma$

$$\begin{aligned} a \cdot m = b \cdot m &\Leftrightarrow a = b \\ m \cdot a = m \cdot b &\Leftrightarrow a = b \end{aligned}$$

   In particular, $a \cdot b = 0 \Leftrightarrow a = 0$ or $b = 0$.

3. If any two of x, m, c are given, the third can be uniquely determined by the equation

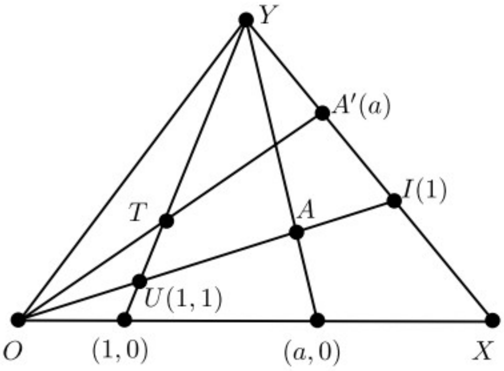
$$x \cdot m = c.$$

4. $a \cdot 1 = 1 \cdot a = a$ for all $a \in \gamma$.

Solution.

1. By definition of '$\cdot$', the point $(x, x \cdot 0)$ is the point $(x, 0)$, and the point $(0, 0 \cdot a)$ is the point $(0, 0)$.
2. Suppose $m \neq 0$ and $a \neq b$. Then the points $O = (0, 0)$, $P = (a, a \cdot m)$, $Q = (b, b \cdot m)$, and $M = (m)$ are collinear. Suppose also that $a \cdot m = b \cdot m$. Then the points P, Q, X are collinear; this is a contradiction. Hence $a \cdot m = b \cdot m$ if and only if $a = b$. The other parts are similarly proved.

3. Suppose m and c are given. Let M, C be points with coordinates (m) and (c, c), respectively. Let $P = OM \cap XC$. Then P has coordinates $(x, x \cdot m) = (x, c)$.
4. Let A', A be points of coordinates (a), and (a, a), respectively. Then $T = YU \cap OA'$ has coordinates $(1, a)$ and also $(1, 1 \cdot a)$. Also, A has coordinates $(a, a \cdot 1)$. Thus,



$$1 \cdot a = a \cdot 1 = a$$

for all $a \in \gamma$. □

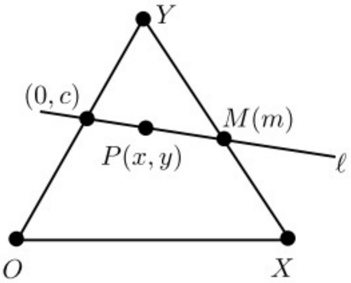
Theorem 5.5 $(\gamma \backslash \{0\}, \cdot)$ *is a loop.*

Proof. This follows from Example 5.4(iii) and (iv). □

Hall Ternary Ring

Our definitions of '$\cdot$' and of '$+$' do not allow us to say that the point (x, y) of a line satisfies an equation of type $y = x \cdot m + c$.

Let ℓ be a line. Let (m) and $(0, c)$ be the coordinates of $M = \ell \cap XY$ and $C = \ell \cap OY$, respectively. Let $P = (x, y)$ be a point of ℓ. This incidence is expressed with the help of a ternary operation $(\circ, *)$ as follows:



$$x \circ m * c = y.$$

Example 5.6 Show that in $[\gamma, \cdot, +, (\circ, *)]$,

1. $x \circ 1 * c = x + c$.
2. $x \circ m * 0 = x \cdot m$.
3. $0 \circ m * c = x \circ 0 * c = c$.
4. $1 \circ m * 0 = m \circ 1 * 0 = m$.
5. Given x, m, y, then there exists a unique c such that

$$x \circ m * c = y.$$

6. If $m_1 \neq m_2$, $c_1 \neq c_2$ are given, then there exists a unique x such that
$$x \circ m_1 * c_1 = x \circ m_2 * c_2.$$
7. If x_1, x_2, y_1, y_2 are given, then there exists a unique (m, c) such that
$$x_1 \circ m * c = y_1 \quad \text{and} \quad x_2 \circ m * c = y_2.$$

Solution. The reader will find the solutions easier if the corresponding diagrams are drawn.

1. $x \circ 1 * c = y$ if and only if $P = (x, y)$ lies on the line joining $C = (0, c)$ to $I = (1)$, if and only if $y = x + c$ by definition of $+$.
2. Let $P = YA \cap OM$, where $A = (x, 0)$, $M = (m)$. Then $x \circ m * 0 = x \cdot m$, since the coordinates of P are $(x, x \cdot m)$ by definition of $\cdot$, and $(x, x \circ m * 0)$, by definition of $(\circ, *)$.
3. The point P on CM has coordinates $(x, x \circ m * c)$. When P is at C, the coordinates of $C = (0, c) = (0, 0 \circ m * c)$. When $m = 0$, P has coordinates $(x, x \circ m * c)$ and also (x, c). Hence $0 \circ m * c = x \circ 0 * c = c$.
4. We have
$$\begin{aligned} 1 \circ m * 0 &= 1 \cdot m \quad \text{by (2).} \\ &= m \quad \text{by Example 5.4(4).} \end{aligned}$$
5. There exists a unique line joining the points $P = (x, y)$ and $M = (m)$. This line intersects OY in a unique point.
6. The line joining the points (m_1) and $(0, c_1)$ intersects the line joining (m_2) and $(0, c_2)$ in a unique point $(x, y) = (x, x \circ m_1 * c_1) = (x, x \circ m_2 * c_2)$.
7. There exists a unique line joining the points (x_1, y_1) and (x_2, y_2). Hence, there exists a unique (m, c) such that
$$x_1 \circ m * c = y_1 \quad \text{and} \quad x_2 \circ m * c = y_2. \qquad \square$$

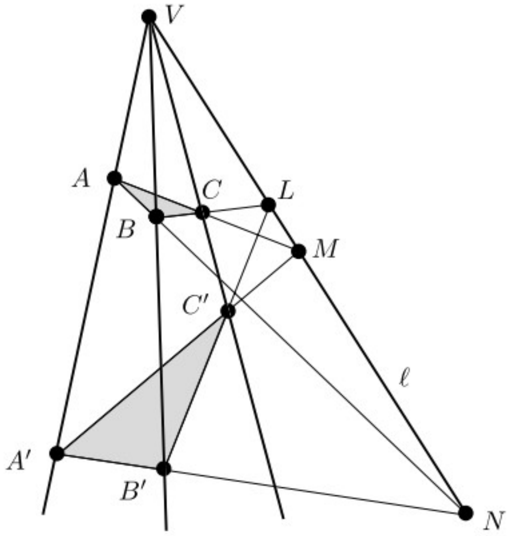
Definition 5.7 1. *The system* $[\gamma, \cdot, +, (\circ, *)]$ *is called* **Hall's ternary ring**.

2. *If* $x \circ m * c = x \cdot m + c$, *Hall's Ternary Ring is said to be* **linear**.

The Veblen–Wedderburn Ring

It is a consequence of π being a projective plane that $(\gamma, +)$ and $(\gamma \backslash \{0\}, \cdot)$ are loops. Any further algebraic relation which γ may be made to satisfy causes the closure of some geometrical configuration.

Definition 5.8 *Let π be a projective plane. Let ABC, $A'B'C'$ be two triangles with distinct vertices such that AA', BB', CC' pass through a point V. Let ℓ be a line through V such that ℓ contains two of the points $L = BC \cap B'C'$, $M = AC \cap A'C'$, and $N = AB \cap A'B'$.*



Then π is said to satisfy the Little Desargues Axiom with respect to triangles ABC, $A'B'C'$ in perspective from the vertex V with ℓ as axis*, if all three points L, M, N necessarily lie on ℓ.*

Example 5.9 A field plane $\mathrm{PG}(2, F)$ satisfies the Little Desargues Axiom with respect to any pair of triangles in perspective from any point V, and any axis ℓ, $V \in \ell$.

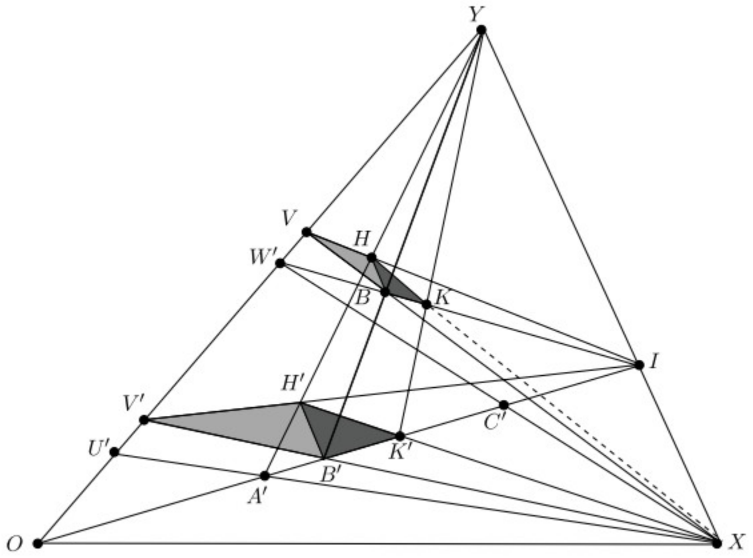
Theorem 5.10 *Let π be a projective plane which satisfies the Little Desargues Axiom with respect to triangles in perspective from Y and with YX as axis, then*

1. $[\gamma, +]$ *is a group.*
2. $x \circ m * c = x \cdot m + c$ *(i.e. γ is linear).*

Proof.

1. We have to prove that for all $a, b, c \in \gamma$,

$$a + (b + c) = (a + b) + c.$$



To do this, we construct two points H, K of coordinates $(a, a+(b+c))$ and $(a+b, (a+b)+c)$, respectively, and show that the Little Desargues Axiom implies that H, K, X are collinear. Since points collinear with X have the same 'y' coordinate, the result follows.

Let $A' = (a,a)$, $B' = (b,b)$, $C' = (c,c)$ be three distinct points of the line OI, distinct from I. The following points are successively constructed, and their coordinates are identified:

$$\begin{aligned}
U' &= OY \cap XA' &&= (0,a),\\
V' &= OY \cap XB' &&= (0,b),\\
W' &= OY \cap XC' &&= (0,c),\\
H' &= YA' \cap V'I &&= (a, a+b),\\
B &= YB' \cap W'I &&= (b, b+c),\\
V &= XB \cap OY &&= (0, b+c),\\
H &= YA' \cap VI &&= (a, a+(b+c)),\\
K' &= H'X \cap OI &&= (a+b, a+b),\\
K &= W'I \cap YK' &&= (a+b, (a+b)+c).
\end{aligned}$$

Consider triangles VHB and $V'H'B'$. They are in perspective from Y, and

$$\begin{aligned}
VH \cap V'H' &= I \in XY,\\
VB \cap V'B' &= X \in XY.
\end{aligned}$$

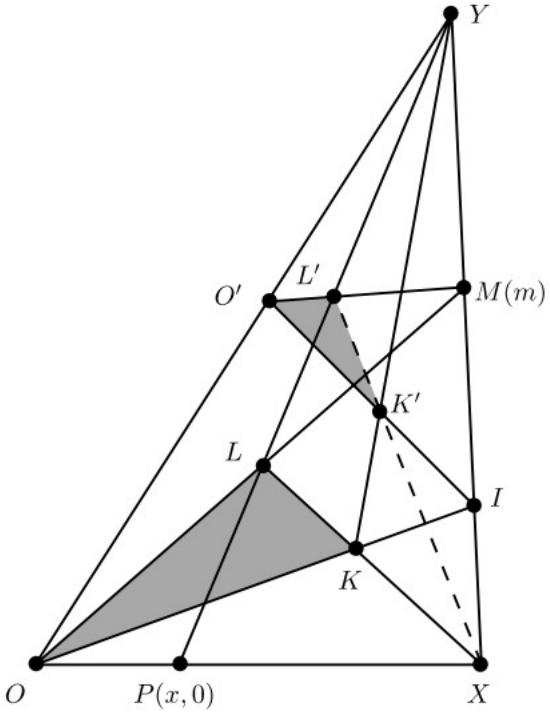
By the Little Desargues Axiom, we have

$$HB \cap H'B' \in XY.$$

Next, consider triangles HBK and $H'B'K'$. They are in perspective from Y and both $HB \cap H'B'$ and $BK \cap B'K' = I$ belong to XY. By the Little Desargues Axiom,

$$HK \cap H'K' \in XY.$$

Since $H'K' \cap XY = X$, it follows that $HK \cap H'K' = X$. In other words, H, K, X are collinear.



2. Starting with the points $P = (x, 0)$, $O' = (0, c)$, and $M = (m)$, the following points are successively constructed, and their coordinates are identified:

$$\begin{aligned} L &= YP \cap OM = (x, x \cdot m), \\ K &= LX \cap OI = (x \cdot m, x \cdot m), \\ K' &= O'I \cap YK = (x \cdot m, x \cdot m + c), \\ L' &= YP \cap O'M = (x, x \circ m * c). \end{aligned}$$

Now triangles OLK, $O'L'K'$ are in perspective from Y, and

$$\begin{aligned} OL \cap O'L' &= M \in YX, \\ OK \cap O'K' &= I \in YX. \end{aligned}$$

By the Little Desargues Axiom, we have

$$LK \cap L'K' \in YX.$$

Since $LK \cap YX = X$, it follows that $L'K' \cap YX = X$. Hence L', K', being collinear with X, have the same 'y' coordinate; and so

$$x \circ m * c = x \cdot m + c. \qquad \square$$

The following theorem is stated without proof. The rationale is to indicate the improvements in the algebraic properties of γ as a result of assuming certain geometrical properties of the projective plane π.

Theorem 5.11 *If the Little Desargues Axiom holds for triangles in perspective from any point* P *of* XY*, with* XY *as axis, then* $[\gamma, +, \cdot, (\circ, *)]$ *is such that*

1. $[\gamma, +]$ *is an abelian group.*
2. $x \circ m * c = x \cdot m + c$*, for all* $x, m, c \in \gamma$*.*
3. $[\gamma \backslash \{0\}, \cdot]$ *is a loop with 1 as unity.*
4. $(a + b) \cdot m = a \cdot m + b \cdot m$ *for all* $a, b, m \in \gamma$*.*
5. *If* $a \neq b$*, then the equation* $x \cdot a = x \cdot b + c$ *has a unique solution* x*, for all* $a, b, c \in \gamma$*.*

Note 31 *We shall, from now on, write* ab *instead of* $a \cdot b$*.*

Definition 5.12

1. *If the Hall Ternary Ring* $\gamma = (\gamma, +, \cdot)$ *has the properties described in Theorem 5.11, then it is called a* **Veblen–Wedderburn Ring** *or a* **quasifield***.*
2. *A quasifield with an associative multiplication is called a* **nearfield***.*
3. *A quasifield with the left distributive law is called a* **semifield***.*
4. *A* **skew field** *has all the properties of a field, except that multiplication is not prescribed to be commutative. Thus a skew field is both a semifield and a nearfield.*
5. *A semifield* γ *is an* **alternative division ring** *if for all* $a, b \in \gamma$

$$
\begin{aligned}
a(ab) &= (aa)b, \\
(ab)b &= a(bb).
\end{aligned}
$$

We quote, without proof, the following two important theorems:

Theorem 5.13 *(***Wedderburn's Theorem***) A* finite *skew field is a field.*

Theorem 5.14 *(***Artin-Zorn Theorem***) A* finite *alternative division ring is a field.*

For comparison sake, we tabulate some results. [Here $a.b$ is written ab, $\gamma \backslash \{0\}$ is written as γ^*, and Little Desargues' Theorem is denoted by L.D.]

Geometric Properties	Properties of Hall Ternary Ring γ
L.D., vertex Y Axis XY	$x.m * c = xm + c$ $(\gamma, +)$ is a group
L.D., vertex anywhere on axis XY	$(\gamma, +)$ is abelian $(\gamma^*, \cdot)$ is a loop with 1 as unity $(a+b)m = am + bm$ $a \neq b \Rightarrow$ unique solution to $xa = xb + c$
L.D., axis any line through Y, vertex anywhere on this line	$(\gamma^*, \cdot)$ has inverses which are two-sided $a \neq 0 \Rightarrow a^{-1}(ab) = b$ The Moufang Identity $a[c(ab)] = [a(ca)]b$ holds. So does the alternative law $a(ab) = (aa)b$
L.D., any axis, vertex anywhere on such axis	$a \neq 0 \Rightarrow a^{-1}(ab) = b = (ba)a^{-1}$ Moufang Identity is replaced by $a(ab) = (aa)b$ $(ba)a = b(aa)$ The plane is now called a Moufang Plane. [Harmonic construction yields a unique conjugate point (line) provided Ring does not have characteristic 2]
Plane is Desarguesian	γ is a skew field

Note 32 *As we have seen, Pappus' Theorem implies Desargues' Theorem; the converse is not true. (*Hessenberg, 1905.*)*

Exercise 5.2

1. If $[\gamma, +, \cdot]$ is a quasifield, then for all $a, b \in \gamma$
$$-(ab) = (-a)b.$$
2. If $(\gamma, +, \cdot)$ has all the properties of a quasifield, except possibly commutative addition, then γ is a quasifield.
3. Let π be a projective plane, with γ as coordinatising set. Let addition $+$ in γ be defined as in Section 'Addition in γ'. (Recall Theorem 5.10: to be a group, $[\gamma, +]$ requires the validity of the Little Desargues' configuration, vertex Y, axis ℓ_∞.) Display a configuration whose validity in π ensures that
$$(a+a)+b = a+(a+b)$$
for all choices of a, b from γ. Show that the configuration has eleven points and may be regarded as consisting of two quadrilaterals Q, Q' where,
   (a) Q, Q' are in perspective from a point;
   (b) the pairs of opposite sides of each quadrilateral are concurrent.

6 Non-Desarguesian planes

(V,ℓ)-perspectivities

The aim of this chapter is to construct some classes of non-Desarguesian projective planes. The starting point we use here for the construction of such planes is the assumption that the planes have a certain type of collineation group.

We adopt the following notation: If τ and σ are collineations of a projective space Π, and P is any point of Π, then $\tau\sigma(P)$ or $P^{\tau\sigma}$ are used to denote $\tau(\sigma(P))$ (i.e. σ is first applied to P, then τ is applied to $\sigma(P)$.)

Definition 6.1 *Let σ be a collineation of a projective plane π. Then*

1. *A point P is* **fixed** *by σ if and only if $P^\sigma = P$.*
2. *A line ℓ is* **fixed** *by σ if and only if $\ell^\sigma = \ell$.*
3. *A line ℓ is* **fixed pointwise** *by σ if and only if $P^\sigma = P$ for all points $P \in \ell$.*
4. *A point P is* **fixed linewise** *by σ if and only if $\ell^\sigma = \ell$ for all lines ℓ through P.*

Example 6.2 Let σ be the homography of a field plane $\mathrm{PG}(2,F)$ defined by the matrix

$$A = \begin{bmatrix} a & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad a \in F\backslash\{0,1\}.$$

Investigate whether σ has any fixed points or lines.

Solution. A point X is fixed if

$$X \mapsto AX = \lambda X, \text{ for some } \lambda \in F.$$

Thus the fixed points are the eigenvectors of A. Now

$$|\lambda I - A| = \begin{vmatrix} \lambda - a & 0 & 0 \\ 0 & \lambda - 1 & 0 \\ 0 & 0 & \lambda - 1 \end{vmatrix} = (\lambda - a)(\lambda - 1)^2.$$

So A has two eigenvalues $1, a$. Corresponding to the eigenvalue $\lambda = 1$, solving $(I - A)X = 0$ gives the eigenvectors and therefore the fixed points

$$\{(x,y,z) = (0,r,t) \mid r,t \in F, \text{ not both zero}\}.$$

Thus every point on the line ℓ of equation $x = 0$ is fixed. In other words, ℓ is fixed pointwise.

Corresponding to the eigenvalue $\lambda = a$, solving $(aI - A)X = 0$ gives the fixed point $V = (1, 0, 0)$.

By Example 4.30, if $L = [\ell, m, n]$ is a line, then

$$\sigma\colon L \mapsto LA^{-1}.$$

Therefore, a line L is fixed if

$$L \mapsto LA^{-1} = \lambda L, \quad \text{for some } \lambda \in F.$$

Thus L is a fixed line if L^t is an eigenvector of $(A^{-1})^t$. In our example, the matrix A is a diagonal matrix, and therefore $(A^{-1})^t = A^{-1}$. Since A and A^{-1} have the same eigenvectors, the fixed lines of σ are $[1, 0, 0]$, and

$$\{[\ell, m, n] = [0, r, t] \mid r, t \in F, \text{ not both zero}\}.$$

Thus the line $[1, 0, 0]$ is fixed; also, every line through the point $V = (1, 0, 0)$ is fixed, and therefore V is fixed linewise. □

Example 6.3 Recall from Example 4.18 that the collineation $\sigma\colon i \mapsto i + 1$ of the Fano plane has no fixed point. By taking the points $0, 1, 2, 5$ to be the points $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, $(1, 1, 1)$, respectively, then σ is seen to be the homography with matrix

$$A = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}.$$

The characteristic polynomial of A is

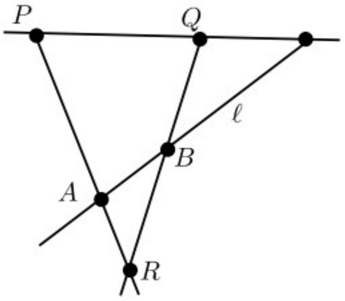
$$|\lambda I - A| = \begin{vmatrix} \lambda & 0 & 1 \\ 1 & \lambda & 1 \\ 0 & 1 & \lambda \end{vmatrix} = \lambda^3 + \lambda + 1.$$

This is irreducible in GF(2). Thus there are no fixed points in PG(2, 2); the fixed points are in the cubic extension PG$(2, 2^3)$.

Exercise 6.1 Let σ be a collineation of a projective plane π. Prove that

1. If the points P and Q are fixed by σ, so is the line PQ.
2. If the lines ℓ and m are fixed by σ, so is the point $\ell \cap m$.
3. If the lines ℓ and m are fixed pointwise by σ, then σ is necessarily the identity collineation i.

   (*Hint:* Let P be any point of π not on ℓ or m. Take two lines a, b through P, but not through $\ell \cap m$. Prove successively that a, b, and P are fixed.)
4. If the points P and Q are fixed linewise by σ, then σ fixes every point of the plane π; σ is the identity collineation i.



Example 6.4 Prove that if a collineation σ of a projective plane π is such that

1. some line ℓ is fixed pointwise;
2. two points $P, Q \notin \ell$ are fixed,

then $\sigma = i$.

Solution. Let R be a point of $\pi\backslash\{\ell, PQ\}$. Let $\ell \cap RP = A$ and $\ell \cap RQ = B$. Since the points P, Q, A, B are fixed, it follows that $R = PA \cap QB$ is fixed. Similarly, every point $S \in PR\backslash\{A, P\}$ is fixed. So the line PR is fixed pointwise. Thus we have two lines (namely ℓ and PR fixed pointwise by σ). Hence by Exercise 6.1(3), $\sigma = i$. □

Exercise 6.2 Let σ be a collineation of a projective plane π. Let $\mathcal{P}$, $\mathcal{L}$ denote the set of all fixed points and fixed lines, respectively, and let $\mathcal{I}$ be the natural incidence. Assume that $(\mathcal{P}, \mathcal{L}, \mathcal{I})$ contains a quadrangle. Prove that $(\mathcal{P}, \mathcal{L}, \mathcal{I})$ is a subplane of π.

Theorem 6.5 *Let σ be a collineation of a projective plane π, $\sigma \neq i$, fixing a line ℓ pointwise. Then there exists a point V fixed linewise by σ.*

Proof. By Example 6.4, σ can fix at most one point P which is not on ℓ.

Case 1: Suppose σ fixes a point $V \notin \ell$. Let P be any point of ℓ. Then $(VP)^\sigma = V^\sigma P^\sigma = VP$. Thus V is fixed linewise.

Case 2: Suppose no point of $\pi\backslash\{\ell\}$ is fixed by σ. Let P be any point of $\pi\backslash\{\ell\}$. Then $P^\sigma \neq P$. Let $V = PP^\sigma \cap \ell$. Now

$$\begin{aligned}(VP)^\sigma &= V^\sigma P^\sigma \\ &= VP^\sigma \\ &= VP, \quad \text{since } V, P, P^\sigma \text{ are collinear.}\end{aligned}$$

Hence $VP = PP^\sigma$ is fixed. Similarly, if Q is any point of $\pi\backslash\{\ell, VP\}$, then QQ^σ is fixed. Therefore, $PP^\sigma \cap QQ^\sigma$ is a fixed point and so lies on ℓ. Hence $PP^\sigma \cap QQ^\sigma = V$. Thus V is fixed linewise. □

Note 33 *Dually we have: if σ fixes a point linewise, then σ fixes a line pointwise.*

Definition 6.6 *Let σ be a collineation of a projective plane π that fixes a line ℓ pointwise and a point V linewise. Then:*

1. *σ is called a* **(V, ℓ)-perspectivity** *or a* **central collineation**.
2. *If $V \in \ell$, σ is called an* **elation**.

3. *If $V \notin \ell$, σ is called a* **homology**.
4. *V is called the* **vertex** *of σ and ℓ is called the* **axis** *of σ.*

Example 6.7 In the homography σ in Example 6.2, $V = (1, 0, 0)$ is the vertex of σ and the line ℓ of equation $x = 0$ is the axis of σ. Also, σ is a homology as $V \notin \ell$.

Example 6.8 Prove that the homography σ of a field plane $\mathrm{PG}(2, F)$ with matrix

$$A = \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix}$$

is an elation. Find the vertex and axis of σ.

Solution. The characteristic polynomial of the matrix A is

$$|\lambda I - A| = \begin{vmatrix} \lambda - 1 & 0 & -1 \\ 0 & \lambda - 1 & -1 \\ 0 & 0 & \lambda - 1 \end{vmatrix} = (\lambda - 1)^3.$$

The fixed points of σ are the solutions of $(I - A)X = 0$, that is,

$$\begin{bmatrix} 0 & 0 & -1 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}.$$

Therefore, the line ℓ of equation $z = 0$ is fixed pointwise by σ, and no point of $\mathrm{PG}(2, F) \backslash \{\ell\}$ is fixed. To find the vertex V, let P be any point of $\mathrm{PG}(2, F) \backslash \{\ell\}$. Then by Case 2 in the proof of Theorem 6.5, $V = \ell \cap PP^\sigma$. Let $P = (0, 0, 1)$. Then P^σ is given by

$$AP = \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}.$$

So $V = PP^\sigma \cap \ell = (1, 1, 0)$. □

Exercise 6.3 Prove that, for a given point V and a given line ℓ of a projective plane π, with respect to composition of functions, the set of all (V, ℓ)-perspectivities of π is a group.

Note 34 *The identity collineation i is considered both as a homology and an elation.*

Example 6.9 Let σ be a (V, ℓ)-perspectivity and τ a collineation of a projective plane π. Prove that $\tau\sigma\tau^{-1}$ is a (V^τ, ℓ^τ)-perspectivity of π.

Solution. Let P be a point of the line ℓ^τ. Let $Q = \tau^{-1}(P)$. Therefore $Q \in \ell$. So,

$$\tau\sigma\tau^{-1}(P) = \tau(\sigma(\tau^{-1}(P))) = \tau(\sigma(Q)) = \tau(Q) = P.$$

Hence ℓ^τ is fixed pointwise by $\tau\sigma\tau^{-1}$. Similarly, V^τ is fixed linewise by $\tau\sigma\tau^{-1}$. □

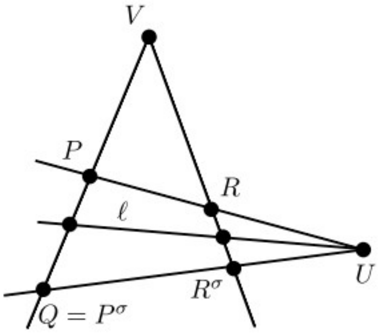
Theorem 6.10 *A (V,ℓ)-perspectivity σ of a projective plane π is uniquely determined by the vertex V, the axis ℓ and the image $Q = P^\sigma$ of* one *point P, $P \notin \ell$, $P \neq V$.*

Proof. Note that as $P \notin \ell$ and $P \neq V$, necessarily $Q \neq V$ and $Q \notin \ell$.

We first prove that such a σ must be unique. Suppose there are two (V,ℓ)-perspectivities σ, τ such that $P^\sigma = P^\tau = Q$. Then $\tau^{-1}\sigma$ fixes P, V and fixes ℓ pointwise.

By Example 6.4, $\tau^{-1}\sigma = i$, and therefore $\tau = \sigma$.

We must now show that we can uniquely find the image R^σ of any point R of $\pi\backslash\{V,\ell\}$. Let R be any point of $\pi\backslash\{V,\ell\}$ not on the line $VPP^\sigma = VPQ$. Let $PR \cap \ell = U$. Then,



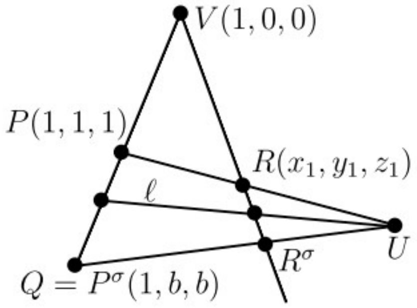
$$\begin{aligned}
R^\sigma &= (PU \cap VR)^\sigma \\
&= (PU)^\sigma \cap (VR)^\sigma \\
&= P^\sigma U^\sigma \cap (VR), \quad \text{as } V \text{ is fixed linewise,} \\
&= QU \cap VR, \quad \text{as } P^\sigma = Q \text{ and } U \in \ell \text{ is fixed.}
\end{aligned}$$

Lastly, if S is a point on the line VPP^σ distinct from V and not in ℓ, then we use R, R^σ in a similar way to find S^σ. □

Example 6.11 Find the equation of the (V,ℓ)-perspectivity σ of a field plane $\mathrm{PG}(2,F)$, where $V = (1,0,0)$, ℓ is the line $x = 0$, $P = (1,1,1)$, $Q = (1,b,b)$, $(b \in F)$, and $P^\sigma = Q$.

Solution. Using the same notation as in the proof of Theorem 6.10, let $R = (x_1, y_1, z_1)$.

Then $U = (0, y_1 - x_1, z_1 - x_1)$. The equation of the line QU is



$$0 = \begin{vmatrix} x & y & z \\ 1 & b & b \\ 0 & y_1 - x_1 & z_1 - x_1 \end{vmatrix}$$

$$\begin{aligned}
&= [b(z_1 - x_1) - b(y_1 - x_1)]x - (z_1 - x_1)y + (y_1 - x_1)z \\
&= b(z_1 - y_1)x - (z_1 - x_1)y + (y_1 - x_1)z.
\end{aligned}$$

The equation of line VR is $z_1y - y_1z = 0$.
The point of intersection of QU and VR is

$$\begin{aligned} R^\sigma &= (y_1(z_1 - x_1) - z_1(y_1 - x_1), by_1(z_1 - y_1), bz_1(z_1 - y_1)) \\ &= (x_1(z_1 - y_1), by_1(z_1 - y_1), bz_1(z_1 - y_1)) \\ &= (x_1, by_1, bz_1). \end{aligned}$$

Thus σ is the homology with matrix

$$A = \begin{bmatrix} 1 & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & b \end{bmatrix}. \qquad \square$$

Example 6.12 Let σ be a (V, ℓ)-perspectivity of $\mathrm{PG}(2, q), q = p^h$. Since σ is a collineation of $\mathrm{PG}(2, q)$, by the fundamental theorem of field planes (see Theorem 4.27), it has an equation of type $\rho X' = AX^\alpha$, where α is an automorphism of $GF(q)$. Recall that every automorphism of $\mathrm{GF}(q)$ is of type $a \mapsto a^{p^i}, i = 0, 1, \ldots, (h-1)$. Show that α is the identity automorphism.

Solution. Without loss of generality, take ℓ to be the line of equation $x = 0$. Let the (V, ℓ)-perspectivity σ have the equation

$$X \mapsto AX^\alpha = \rho X',$$

where α is an automorphism of F and

$$A = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}, \quad a_{ij} \in F,\ |A| \neq 0.$$

Since ℓ is fixed pointwise by σ,

$$(0, 0, 1)^\sigma = (0, 0, 1) \quad \text{and} \quad (0, 1, u)^\sigma = (0, 1, u).$$

Therefore,

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}^\alpha = \rho \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}, \quad \text{for some non-zero } \rho \in F.$$

Since $1^\alpha = 1$, we have $a_{13} = a_{23} = 0$ and $a_{33} \neq 0$.
For all $u \in F$, we have:

$$\begin{bmatrix} a_{11} & a_{12} & 0 \\ a_{21} & a_{22} & 0 \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \begin{bmatrix} 0 \\ 1 \\ u \end{bmatrix}^\alpha = \rho \begin{bmatrix} 0 \\ 1 \\ u \end{bmatrix}, \quad \text{for some non-zero } \rho \in F.$$

Put $u = 0$, and we have $a_{12} = a_{32} = 0$ and $a_{22} \neq 0$.
So, for any non-zero $u \in F$, $a_{22}/(a_{33}u^\alpha) = 1/u$, and therefore $a_{22}u = a_{33}u^\alpha$.

Suppose $\alpha\colon a \mapsto a^{p^i}, i = 1, 2, \ldots,$ or $(h-1)$. Then the polynomial $a_{22}x = a_{33}x^{p^i}$ is of degree at most p^{h-1} but is satisfied by the $p^h - 1$ non-zero elements of GF(q). In other words, the polynomial has more zeros than its degree, making it the zero polynomial. Therefore $a_{33} = a_{22} = 0$, contradicting earlier results. Hence α is the identity automorphism. Moreover, $a_{33} = a_{22}$. □

Note 35 *In the above solution, the matrix A of σ is*

$$A = \begin{bmatrix} a_{11} & 0 & 0 \\ a_{21} & a_{22} & 0 \\ a_{31} & 0 & a_{22} \end{bmatrix}, \quad a_{ij} \in F, \ |A| \neq 0.$$

As noted before, the eigenvectors of A are the fixed points of σ.

Case 1: $a_{11} \neq a_{22}$. *The eigenvalues are a_{11} and a_{22}. The eigenvalue a_{11} gives rise to the axis $x = 0$; the eigenvalue a_{22} gives rise to the vertex $(a_{11} - a_{22}, a_{21}, a_{31})$, which does not lie on the axis since $a_{11} \neq a_{22}$. Thus, σ is a homology.*

Case 2: $a_{11} = a_{22}$. *There is only one eigenvalue, namely a_{11}. The axis ℓ is the line $x = 0$, as in Case 1. To find the vertex V of σ, let m be the line joining $(1, 0, 0)$ to $(1, 0, 0)^\sigma = (a_{11}, a_{21}, a_{31})$. Then, $V = m \cap \ell = (0, a_{21}, a_{31})$. In this case, σ is an elation.*

Exercise 6.4

1. Let σ_1, σ_2 be two homographies of PG$(2, F)$ whose matrices are

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & k \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} 1 & 0 & a \\ 0 & 1 & b \\ 0 & 0 & 1 \end{bmatrix},$$

respectively ($k \neq 0, 1$ and $a, b, k \in F$).

(a) Find their fixed points and their fixed lines.

(b) Verify that σ_1 is a homology and σ_2 is an elation.

2. Let σ be a central collineation with vertex P. Suppose σ also fixes two lines ℓ, m not on P. Show that σ is the identity.

3. Let σ be a homography of the field plane PG$(2, F)$ with matrix

$$A = \begin{bmatrix} 2 & 1 & -2 \\ 0 & 0 & 4 \\ 0 & -1 & 4 \end{bmatrix}.$$

Find the fixed points of σ and hence determine whether σ is a central collineation, and if so whether σ is an elation or a homology.

4. Let σ be a collineation that fixes the point P linewise. Show that if a line ℓ not through P is fixed, then ℓ is fixed pointwise. Hence deduce that if ℓ, m are two lines not through P which are fixed by σ, then σ is the identity.

5. Let σ be a homography of the field plane π_F with matrix A where

$$A = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}.$$

Determine the action of σ on the lines of $\mathrm{PG}(2, F)$. Hence or otherwise determine whether σ is an elation or a homology of $\mathrm{PG}(2, F)$.

6. Let σ be a homography of $\mathrm{PG}(2, F)$. Show that the line $[0, 0, 1]$ is fixed pointwise if and only if σ has matrix

$$A = \begin{bmatrix} 1 & 0 & r \\ 0 & 1 & s \\ 0 & 0 & t \end{bmatrix},$$

for some $r, s, t \in F$ with $t \neq 0$. Find the vertex of σ in the case $t \neq 1$.

7. Let σ be a homography of $\mathrm{PG}(2, F)$. Let the matrix of σ be

$$A = \begin{bmatrix} 1 & a & b \\ 0 & 1 & c \\ 0 & 0 & 1, \end{bmatrix}, \quad a, c \neq 0.$$

Show that σ has exactly one fixed point and one fixed line (and hence σ is not a perspectivity).

8. Let V be the vertex and ℓ the axis of a homology σ of $\mathrm{PG}(2, F)$. Let P be any point not fixed by σ. Let $VP \cap \ell = Q$. Prove that the cross-ratio $(V, Q; P, P^\sigma)$ is constant.

(*Hint:* consider the homology σ_1 of Question 1.)

9. Let Γ be the collineation group of a projective plane π. For points V, P, Q, lines ℓ, k, let

   (a) $\Gamma_{(V,\ell)}$ be the set of all (V, ℓ)-perspectivities of π.

   (b) $\Gamma_{(k,\ell)}$ be the set of all (V, ℓ)-perspectivities of π with $V \in k$.

   (c) $\Gamma_{(P,Q)}$ be the set of all (P, ℓ)-perspectivities of π, for all lines ℓ through Q.

   (d) $\Gamma_{(\ell)}$ be the set of all (V, ℓ)-perspectivities of π, for all points V of π.

   (e) $\Gamma_{(P)}$ be the set of all (P, ℓ)-perspectivities of π, for all lines ℓ of π.

   Show that for all choices of P, Q, ℓ, k

   (i) $\Gamma_{(k,\ell)}, \Gamma_{(P,Q)}, \Gamma_{(\ell)}, \Gamma_{(P)}$ are subgroups of Γ.

   (ii) $\Gamma_{(\ell,\ell)} \lhd \Gamma_{(\ell)}, \Gamma_{(P,P)} \lhd \Gamma_{(P)}$.

   (*Note*: It is sufficient to prove $\Gamma_{(k,\ell)}, \Gamma_{(\ell)}$ are subgroups and $\Gamma_{(\ell,\ell)} \lhd \Gamma_{(\ell)}$. The rest follows by duality.)

(*Hint*: To prove $\Gamma_{(k,\ell)}$ is a group, consider the cases $k = \ell$ and $k \neq \ell$ separately. Take $\alpha, \beta \in \Gamma_{(k,\ell)}$, what can you say about $\alpha\beta^{-1}$? To prove $\Gamma_{(\ell,\ell)} \lhd \Gamma_{(\ell)}$, what can you say about $\gamma^{-1}\Gamma_{(x,\ell)}\gamma$, for $X \in \ell$ and $\gamma \in \Gamma_{(\ell)}$?)

10. Let ℓ be a given line of a projective plane π. Suppose
    (a) A, B are two points on ℓ;
    (b) m is another line through B;
    (c) $|\Gamma_{(A,\ell)}| > 1$ and $|\Gamma_{(B,m)}| > 1$.

    Prove that $|\Gamma_{(B,\ell)}| > 1$.

    (*Hint*: Take $\alpha \in \Gamma_{(A,\ell)}, \beta \in \Gamma_{(B,m)}$ with $\alpha \neq i$ and $\beta \neq i$. Consider the collineation $\beta\alpha\beta^{-1}\alpha^{-1}$ and its effect on a point X of ℓ, and also its effect on a line n through B. You need also to prove that $\beta\alpha\beta^{-1}\alpha^{-1}$ is not the identity i.)

Note 36 *The following theorem also holds: If*

(a) *ℓ is a given line of a projective plane π of order q;*
(b) *$|\Gamma_{(\ell,\ell)}| > q$;*

then

(a) *$|\Gamma_{(A,\ell)}| > 1$ for all points $A \in \ell$;*
(b) *q is a prime power.*

Group of elations

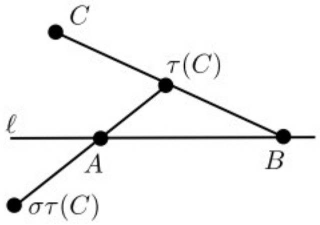
In what follows, an elation which is distinct from the identity i will be referred to as *non-trivial*.

Theorem 6.13 *Let A, B be two distinct points of a line ℓ of a projective plane π. Then*

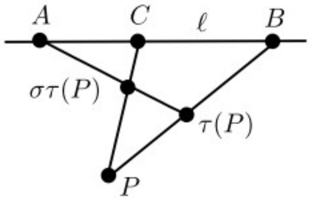
1. *With respect to composition of functions, the set of all (A, ℓ)-elations forms a group G_A.*
2. *If σ is a non-trivial (A, ℓ)-elation and τ is a non-trivial (B, ℓ)-elation then $\sigma\tau$ is a (C, ℓ)-elation with $C \neq A, B$.*
3. *With respect to composition of functions, the set of all elations with ℓ as axis is an Abelian group G called the* **translation group with axis ℓ**.
4. *Every non-trivial element of the above group G is either of infinite order, or of the same prime order.*

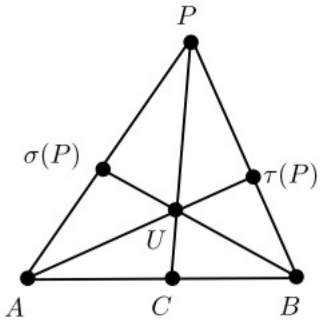
Proof.

1. The proof of 1 is left as an easy exercise for the reader.



2. Let σ be a non-trivial (A, ℓ)-elation and τ a non-trivial (B, ℓ)-elation. Now $\sigma\tau \neq i$ since otherwise $\sigma = \tau^{-1}$ would imply that $A = B$. Also $\sigma\tau$ fixes ℓ pointwise and hence by Theorem 6.5 fixes some point C linewise. Suppose $C \notin \ell$. Then $\tau(C)$ is a point of BC distinct from B and C. Thus $\sigma(\tau(C))$ is a point on the line AC^{τ}. Therefore $\sigma\tau(C) \neq C$. This contradiction shows that $C \in \ell$. Let P be any point of $\pi\backslash\{\ell\}$. Then $\{P, \tau(P), B\}, \{\tau(P), \sigma(\tau(P)), A\}$, and $\{P, \sigma\tau(P), C\}$ are triples of collinear points. Hence $C \neq A, B$.





3. We first prove that $\sigma\tau = \tau\sigma$, where σ is a non-trivial (A, ℓ)-elation and τ is a non-trivial (B, ℓ)-elation. Let P be any point of π. If $P \in \ell$, then $\sigma\tau(P) = \sigma(P) = P$ and $\tau\sigma(P) = \tau(P) = P$. Suppose $P \notin \ell$, then $\{P, \sigma(P), A\}$ and $\{P, \tau(P), B\}$ are two triads of collinear points. Let $U = BP^{\sigma} \cap AP^{\tau}$. Since $\tau(P) = BP \cap AU$, we have

$$\begin{aligned} \sigma\tau(P) &= (BP \cap AU)^{\sigma} \\ &= (BP)^{\sigma} \cap (AU)^{\sigma} \\ &= BP^{\sigma} \cap AU^{\sigma} \\ &= U, \quad \text{since } AU^{\sigma} = AU. \end{aligned}$$

Similarly, $\tau\sigma(P) = U$. Therefore, $\tau\sigma(P) = \sigma\tau(P)$ for all points P in π. Therefore, $\sigma\tau = \tau\sigma$.

We next show that if α_1, α_2 are both non-trivial elations with the same vertex D and axis ℓ, then $\alpha_1\alpha_2 = \alpha_2\alpha_1$. Without loss of generality, suppose $D \neq B$. Then for $j = 1, 2$, $\tau\alpha_j \neq i$ and $\tau\alpha_j$ is a non-trivial (E_j, ℓ)-elation with $E_j \neq D, B$. But then, since non-trivial elations with distinct vertices commute, we have:

$$\begin{aligned} \alpha_1(\tau\alpha_2) &= (\tau\alpha_2)\alpha_1, \\ (\alpha_1\tau)\alpha_2 &= \tau\alpha_2\alpha_1, \\ (\tau\alpha_1)\alpha_2 &= \tau(\alpha_2\alpha_1). \end{aligned}$$

Therefore,

$$\tau(\alpha_1\alpha_2) = \tau(\alpha_2\alpha_1),$$

and so

$$\alpha_1\alpha_2 = \alpha_2\alpha_1, \quad \text{since } \tau \text{ has an inverse.}$$

It now follows that, with respect to composition of functions, the set of all elations with ℓ as axis is an Abelian group G.

4. Suppose there exists an elation of finite order in G. Then by Sylow's Theorem, G contains an element of order p for some prime p. Let β be an (E,ℓ)-elation of order p. Let δ be any non-trivial (X,ℓ)-elation, $E \neq X$. Then $\beta\delta$ is an (F,ℓ)-elation with $F \neq E, X$.

Hence $(\beta\delta)^p$ is an (F,ℓ)-elation. But since G is abelian,

$$\begin{aligned}(\beta\delta)^p &= \beta^p\delta^p \\ &= \delta^p, \quad \text{as } \beta^p = i.\end{aligned}$$

But δ^p is an (X,ℓ)-elation. This is a contradiction unless $\delta^p = i$. □

Exercise 6.5

1. In a projective plane π, let A, B be points on a line ℓ and let m be another line through B. Let α be a non-trivial elation with axis ℓ and vertex A, and let β be a non-trivial elation with axis m and vertex B.
   (a) Prove that $\beta\alpha\beta^{-1}\alpha^{-1}$ is an elation with axis ℓ and vertex B.
   (b) Prove that $\beta\alpha\beta^{-1}\alpha^{-1}$ is not the identity.
   (*Hint:* Consider the effect of $\beta\alpha\beta^{-1}\alpha^{-1}$ on a point $X \in m$.)

(V,ℓ)-transitive and (V,ℓ)-Desarguesian planes

Definition 6.14 1. *Let V be a point and ℓ a line of a projective plane π. Then π is* **(V,ℓ)-transitive** *if given any pair of points A, B of π such that*
   (a) *A, B, V are collinear and distinct;*
   (b) *$A, B \notin \ell$,*

   then there exists a (V,ℓ)-perspectivity σ with $A^\sigma = B$.

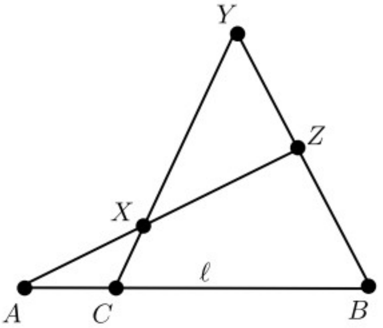
2. *If π is (X,ℓ)-transitive for all points X on a line m, then π is said to be* **(m,ℓ)-transitive**.
3. *If π is* **(ℓ,ℓ)-transitive**, *then π is said to be a* **translation plane** *with respect to ℓ; often we write π^ℓ is a translation plane. The line ℓ is called a* **translation line**.

Example 6.15 A field plane $\mathrm{PG}(2,F)$ is a translation plane with respect to any of its lines.

Definition 6.16 *A* **dual translation plane** *π is a plane π^L with a special point L, such that π^L is (L, m)-transitive for all lines m through the point L (called a* **translation point***). Thus* a dual translation plane may not be a translation plane.

Theorem 6.17 *Let A, B be distinct points of a line ℓ of a projective plane π. If π is (A, ℓ)-transitive and (B, ℓ)-transitive, then π^ℓ is a translation plane.*

Proof. Let C be any point of $\ell = AB$. Let X, Y be two points not on ℓ but collinear with C. We have to show that there exists a (C, ℓ)-elation σ such that $X^\sigma = Y$.
Let $Z = AX \cap BY$. Then $Z \neq X, Y$. Since π is both (A, ℓ)-transitive and (B, ℓ)-transitive, there exists an (A, ℓ)-elation α and a (B, ℓ)-elation β with $X^\alpha = Z$ and $Z^\beta = Y$. Put $\sigma = \beta\alpha$. By Theorem 6.13, σ is a (V, ℓ)-elation. Now



$$X^\sigma = (X^\alpha)^\beta = Z^\beta = Y \quad \text{and} \quad V = XY \cap \ell = C. \qquad \square$$

Example 6.18 Let ℓ be a translation line of a projective plane π and let α be a collineation of π. Prove that ℓ^α is also a translation line of π.

Solution. Let X, Y be any two distinct points of π not on ℓ^α. Let $XY \cap \ell^\alpha = C$. We have to show that there exists a (C, ℓ^α)-elation σ with $X^\sigma = Y$.

Since X, Y, C are collinear, with $C \in \ell^\alpha$, it follows that $X^{\alpha^{-1}}, Y^{\alpha^{-1}}, C^{\alpha^{-1}}$ are collinear, with $C^{\alpha^{-1}} \in \ell$. Since ℓ is a translation line of π, there exists a $(C^{\alpha^{-1}}, \ell)$-elation β such that

$$\beta\alpha^{-1}(X) = \alpha^{-1}(Y).$$

Therefore,

$$\alpha\beta\alpha^{-1}(X) = Y.$$

By Example 6.9, $\sigma = \alpha\beta\alpha^{-1}$ is a $((C^{\alpha^{-1}})^\alpha, \ell^\alpha)$-elation. Thus ℓ^α is a translation line of π. $\square$

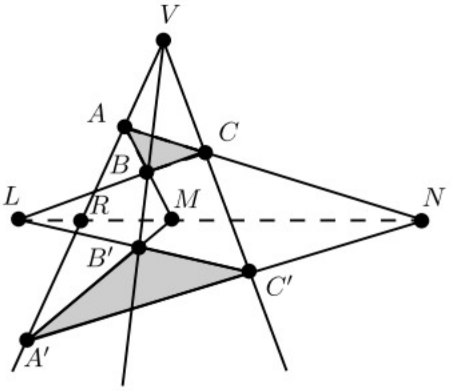
Exercise 6.6 Let π be a projective plane.

1. Prove that if ℓ, m are two translation lines of π, then so is every line through $\ell \cap m$.
2. Prove that if π has three non-concurrent translation lines, then every line of π is a translation line (in which case the plane π is called a **Moufang plane**).

Definition 6.19 *Let V be a point, and ℓ be a line of a projective plane π. Let T, T' be two triangles in perspective from V, with the property that two pairs of corresponding sides of T, T' intersect on ℓ. Then π is said to be* **(V, ℓ)-Desarguesian** *if the third pair of corresponding sides necessarily intersect on ℓ.*

Example 6.20 A field plane is (V, ℓ)-Desarguesian for all points V and all lines ℓ.

Theorem 6.21 *(***Baer***) Let V be a point and ℓ be a line of a projective plane π. Then π is (V, ℓ)-transitive if and only if π is (V, ℓ)-Desarguesian.*



Proof. ($\Longrightarrow$) Suppose π is (V, ℓ)-transitive. Let ABC, $A'B'C'$ be two triangles in perspective from V with $M = AB \cap A'B'$ and $N = AC \cap A'C'$ both on ℓ. Since π is (V, ℓ)-transitive, there exists a (V, ℓ)-perspectivity σ, with $A^\sigma = A'$. Since V is the vertex of σ, B^σ lies on VB. Since ℓ is the axis of σ, $(ABM)^\sigma = A'B^\sigma M$. Therefore, $B^\sigma = VB \cap A'M$. Therefore, $B^\sigma = B'$. Similarly, $C^\sigma = C'$. Let $BC \cap \ell = L$. Since L, B, and C are collinear, their images (under σ) $L^\sigma = L$, $B^\sigma = B'$ and $C^\sigma = C'$ are collinear. Thus $L = BC \cap B'C'$.

($\Longleftarrow$) Suppose π is (V, ℓ)-Desarguesian. Let A, A' be two points collinear with V, but not on ℓ. We need to prove that there exists a (V, ℓ)-perspectivity σ, with $A^\sigma = A'$. Let B be any point not on the lines VAA' and ℓ. Let $M = AB \cap \ell$. Define the permutation α of

$$\pi \backslash AA' \cup \{V, AA' \cap \ell\}$$

by

$$\begin{aligned} \alpha \colon\ & P \mapsto P, \quad \text{if } P = V \text{ or } P \in \ell, \\ & B \mapsto B' = A'M \cap VB, \quad \text{if } B \neq V \text{ or } B \notin \ell. \end{aligned}$$

Having obtained a pair $\{B, B' = B^\alpha\}$, use them to define the permutation β of

$$\pi \backslash BB' \cup \{V, BB' \cap \ell\}$$

by

$$\begin{aligned} \beta\colon\ & P \mapsto P, \quad \text{if } P = V \text{ or } P \in \ell \\ & P \mapsto P' = RB' \cap VP, \quad \text{if } P \neq V \text{ or } P \notin \ell, \text{ where } R = PB \cap \ell. \end{aligned}$$

Thus, α and β agree on V and on points of ℓ.

We next prove that α and β agree on all points not on AA' and BB'. Let C be a point not on AA' and BB'. If $C \in AB$, then $C^\alpha = VC \cap A'B' = C^\beta$. If $C \notin AB$, let $AC \cap \ell = N$ and $BC \cap B'C' = L$. Since π is (V, ℓ)-Desarguesian, we have: $L \in \ell$. Hence, $C^\alpha = C^\beta$.

Define σ to be α on $\pi \backslash \{AA'\}$ and β on $\pi \backslash \{BB'\}$. Thus σ is a well-defined permutation of π.

Lastly, we prove that σ is a (V, ℓ)- perspectivity. By definition, σ leaves ℓ fixed pointwise, and V fixed linewise. Let r be any line not through V, and distinct from ℓ. Without loss of generality, let $r \cap \ell = L$, and B, C be any two points of r distinct from L. Then, $L = L^\sigma, B' = B^\sigma, C' = C^\sigma$ are collinear. Thus σ preserves collinearity. Hence, σ is a (V, ℓ)-perspectivity. □

Note 37 1. *A projective plane π is Desarguesian if and only if it is (V, ℓ)-transitive for all choices of a point V and a line ℓ of π.*

2. *(See Exercise 6.6(2)). A Moufang plane is (V, ℓ)-Desarguesian, for all choices of a point V and a line ℓ, with $V \in \ell$.*

3. *Recall Theorem 5.11. If in a projective plane π, the Little Desargues Axiom holds for triangles in perspective from any point P of a line XY, with XY as axis, then π can be coordinatised by a quasifield γ.*

   Thus π can be coordinatised by a quasifield if and only if the line XY is a translation line of π.

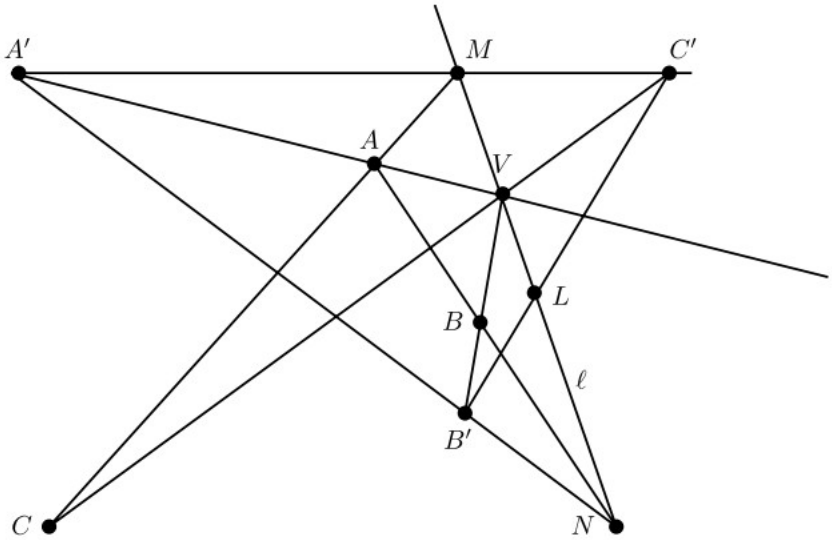
4. *Recall Definition 5.12(2) of a nearfield. It can be proved that a projective plane π can be coordinatised by a nearfield if and only if, in the notation of Chapter 5 and Definition 6.14, (see Theorem 5.11),*
   (a) *π is (XY, XY)-transitive;*
   (b) *π is (V, m)-transitive, with $V = X$, and m is a line through Y* or *$V = Y$, and m contains the point X.*

5. *Let π be a translation plane with $XY = \ell_\infty$ as translation line; let π be coordinatised by a quasifield γ. If two other points of ℓ_∞ are chosen to play the role of X and Y, the coordinatising ternary ring is a quasifield γ', but* γ and γ' need not be isomorphic.

6. A finite Moufang plane is Desarguesian. *This is a consequence of a theorem by Artin and Zorn:* a finite alternative division ring is a field.

Exercise 6.7

1. Let π be a projective plane which is coordinatised by the set γ, as explained in Chapter 5. Prove that π is a translation plane with respect to XY and a dual translation plane with respect to Y if and only if γ is a semifield.
2. Let π be a projective plane which is coordinatised by the set γ, as explained in Chapter 5. Prove that γ is a nearfield if and only if π is (XY, XY)-, (X, Y)-, and (Y, X)-transitive.
3. Use the above two questions to prove: Let π be a projective plane which is coordinatised by the set γ, as explained in Chapter 5. Then π is Desarguesian if and only if γ is a skew field.
4. The points and lines in the following diagram are those of a projective plane π. Assume that π is (V, ℓ)-Desarguesian. Prove that L, B, and C are collinear.



The Hughes plane of order q^2, q an odd prime power

This projective plane was first discovered by Veblen and Wedderburn, in the case $q = 3$. For q any odd prime power, Hughes (1959) defined a nearfield N of order q^2 which has special properties. This nearfield N is then used to construct a projective plane of order q^2. Such a projective plane is called a Hughes plane of order q^2 and is denoted by $\mathcal{H}(q^2)$.

$\mathcal{H}(q^2)$ is given here as an example of a projective plane, which is neither a translation plane nor a dual translation plane. Its construction depends on the following two facts:

1. There exists a 3×3 matrix A over GF(q) such that $A^{q^2+q+1} = kI, k \in$ GF(q), but no smaller power of A has this property. (See Singer's Theorem, Theorem 4.41, where such a matrix is shown to exist.)
2. For all odd prime powers q, there exists a nearfield N of order q^2, which is not a field.

In order to show the existence of such a nearfield N, we need the following lemma.

Lemma 6.22 *Let* $F = GF(q^2), q$ *odd. Then:*

$$f = x^q - \alpha x - \beta \quad \in F[x], \quad \alpha \textit{ a non-square},$$

has precisely one zero in F*, namely* $(-\beta^q - \alpha^q\beta)(\alpha^{q+1} - 1)^{-1}$.

Proof. We first prove that $\alpha^{q+1} \neq 1$. Let ω be a generator of GF(q^2). Then the $(q+1)$th roots of 1 are $1, \omega^{q-1}, \omega^{2(q-1)}, \ldots, \omega^{q(q-1)}$. Since $q-1$ is even, all of these $(q+1)$th roots of 1 are squares, and therefore none of them can be equal to α, as α is a non-square. Therefore, $\alpha^{q+1} \neq 1$. Let $X \in$ GF(q^2) be a zero of f. Then

$$\begin{aligned}
\alpha X + \beta = X^q &\implies \alpha^q X^q + \beta^q = X^{q^2} = X,\\
&\implies \alpha^q(\alpha X + \beta) + \beta^q = X,\\
&\implies (\alpha^{q+1} - 1)X = -\beta^q - \alpha^q\beta,\\
&\implies X = (-\beta^q - \alpha^q\beta)(\alpha^{q+1} - 1)^{-1}, \quad \text{since } \alpha^{q+1} \neq 1. \qquad \square
\end{aligned}$$

Example 6.23 Let $(F, +, .)$ be GF(q^2), q an odd prime power. Define $(N, +, \circ)$ as follows:

1. F, N have the same elements, and same addition.
2. Multiplication $\circ$ in N is given by

$$\begin{aligned}
x \circ y &= x.y, && \text{if } y \text{ is a square in } F,\\
&= \overline{x}.y, && \text{if } y \text{ is not a square in } F, \text{ where } \overline{x} = x^q.
\end{aligned}$$

Prove the following:

(a) N is a nearfield of order q^2.

(b) Every element of N commutes with every element of GF(q) $\subset N$.

(c) N is not a field.

Solution.

(a) (i) $(N,+)=(F,+)$ is an abelian group with 0 as identity.

(ii) $(N\backslash\{0\},\circ)$ is a loop with 1 as identity. We leave this as an exercise for the reader.

(iii) Let $a,b,m\in N$.
If m is a square, then

$$(a+b)\circ m=(a+b).m=a.m+b.m=a\circ m+b\circ m.$$

If m is not a square, then

$$(a+b)\circ m=\overline{(a+b)}.m=(\overline{a}+\overline{b}).m=\overline{a}.m+\overline{b}.m=a\circ m+b\circ m.$$

Thus,

$$(a+b)\circ m=a\circ m+b\circ m,\qquad \text{for all } a,b,m\in N.$$

(iv) Suppose $a\neq b$. We need to show that the equation

$$x\circ a=x\circ b+c$$

has unique solution x, for all $a,b,c\in N$.
If both a and b are squares, the unique solution is $c(a-b)^{-1}$.
If both a and b are non-squares, then

$$\begin{aligned} x\circ a=x\circ b+c &\implies \overline{x}.a=\overline{x}.b+c\\ &\implies \overline{x}.(a-b)=c\\ &\implies x=\overline{c}.(\overline{a}-\overline{b})^{-1}.\end{aligned}$$

If one of a or b is a square, and the other a non-square, we need to solve either $ax^q=bx+c$ or $ax=bx^q+c$. In both cases, we need to solve an equation of type

$$f=x^q-\alpha x-\beta=0,$$

where α, being either $a^{-1}b$ or $b^{-1}a$, is a non-square. By Lemma 6.22, there exists a unique solution.

(v) N has associative multiplication. We leave this as an exercise for the reader.

(b) We next prove that $a\circ x=x\circ a$, for all $x\in \mathrm{GF}(q)$, for all $a\in N$. For all $x\in\mathrm{GF}(q)\subset\mathrm{GF}(q^2)$, we have $\overline{x}=x$, and x is a square. Therefore, for all $a\in N, x\in\mathrm{GF}(q)\subset N$,

$$\begin{aligned} a\circ x&=a.x\\ x\circ a&=x.a, \qquad \text{whether } a \text{ is a square or not, as } \overline{x}=x.\\ &=a.x\\ &=a\circ x.\end{aligned}$$

(c) Let ω be a generator of $\mathrm{GF}(q^2)$. Then ω is a non-square and ω^2 is a square. Then, $\omega \circ \omega^2 = \omega^3$ and $\omega^2 \circ \omega = \omega^{2q+1} \neq \omega^3 = \omega \circ \omega^2$. Thus N is not a field. □

From now till the end of this section, we write xy for $x \circ y$.

Exercise 6.8 Let N be the nearfield of order q^2 as defined in Example 6.23. Prove that if $a, b, a', b' \in K = GF(q)$, and $n \in N \backslash K$, then

1. $a + bn = a' + b'n \iff a = a', b = b'$.
2. $a + nb = 0 \iff a = b = 0$.

Construction of the Hughes plane. Let N be the nearfield of order q^2, as constructed in Example 6.23. Let A be a 3×3 matrix over $\mathrm{GF}(q)$ such that $A^{q^2+q+1} = kI$, $k \in \mathrm{GF}(q)$, but no smaller power of A has this property. Let $V = \{(x, y, z) \mid x, y, z \in N\}$. On V, define addition and right scalar multiplication by: for all (x, y, z), $(a, b, c) \in V$, and for all $k \in N$

$$(x, y, z) + (a, b, c) = (x + a, y + b, z + c),$$
$$(x, y, z)k = (xk, yk, zk).$$

Definition 6.24 *Let N be the nearfield of order q^2, as constructed in Example 6.23. The* **Hughes plane** *$\mathcal{H}(q^2)$ is the triple $(\mathcal{P}, \mathcal{L}, \mathcal{I})$, (where the elements of $\mathcal{P}$ are called* points, *the elements of $\mathcal{L}$, are subsets of $\mathcal{P}$ to be called* lines, *and $\mathcal{I}$ is an incidence relation), defined as follows:*

1. *The set of* **points** *of $\mathcal{H}(q^2)$ is*

$$\mathcal{P} = \{(x, y, z) \mid x, y, z \in N, \text{ not all zero}\},$$

with the proviso that

$$\text{for all } k \in N\backslash\{0\}, (x, y, z)k \text{ refers to the same point.}$$

2. *Let $\alpha = 1$, or $\alpha \in N \backslash GF(q)$. For each α, let $L(\alpha)$ (to be called a* **line** *of $\mathcal{L}$) be the set of points (x, y, z) satisfying $x + \alpha y + z = 0$. Then the set of* **lines** *of $\mathcal{H}(q^2)$ is*

$$\mathcal{L} = \{A^n L(\alpha) \mid 0 \leq n \leq q^2 + q\},$$

where for each n, $A^n L(\alpha)$ is the set of points $v(A^n)^t$ with $v \in L(\alpha)$.

3. *$\mathcal{I}$: the point $v = (x, y, z)$ is incident with the line $A^n L(\alpha)$ if and only if $v = w(A^n)^t$, for some $w \in L(\alpha)$.*

Example 6.25 Find the number of points and lines in $\mathcal{H}(q^2)$. Show that each line of $\mathcal{H}(q^2)$ has $q^2 + 1$ points.

Solution.

1. $|\mathcal{P}| = \dfrac{|V|-1}{q^2-1} = \dfrac{q^6-1}{q^2-1} = q^4+q^2+1.$

2. As $0 \le n \le q^2+q$, $\alpha = 1$, or $\alpha \in N \backslash F$, there are q^2+q+1 choices for n, and q^2-q+1 choices for α. Hence
$$|\mathcal{L}| = (q^2+q+1)(q^2-q+1) = q^4+q^2+1.$$

3. For given α, if any two of x, y, z are given, the third can be uniquely determined by the equation $x+\alpha y+z=0$. Therefore, the number of non-zero solutions of this equation is $(q^2)^2-1$. Since $(x,y,z) \equiv (x,y,z)k, k \in N\backslash\{0\}$, the number of points on line $L(\alpha)$ is $(q^4-1)/(q^2-1) = q^2+1$. Thus, each line of $\mathcal{H}(q^2)$ has q^2+1 points. □

Theorem 6.26 *$\mathcal{H}(q^2)$ is a projective plane of order q^2.*

Proof. In view of Example 6.25, we need only show that every pair of lines of $\mathcal{H}(q^2)$ intersect in a point. This is left as an exercise for the reader. □

Example 6.27 Show that a line of $\mathcal{H}(q^2)$ is represented by an equation of the form
$$ax+by+cz+\alpha(a'x+b'y+c'z)=0, \quad \alpha = 1, \text{ or } \alpha \in N\backslash \mathrm{GF}(q),$$
where a, a', b, b', c, c' are elements of $\mathrm{GF}(q)$, uniquely determined by A^{-n}.

Solution. Given n and α, let $A^{-n} = [a_{ij}]$. Since the matrix A is over $\mathrm{GF}(q)$, the a_{ij}'s are necessarily elements of $\mathrm{GF}(q)$. By definition, the point
$$\begin{aligned} v=(x,y,z) \in A^nL(\alpha) &\implies v = w(A^n)^t, \quad \text{for some } w \in L(\alpha),\\ &\implies w = v(A^{-n})^t \in L(\alpha)\\ &\qquad = \begin{bmatrix} x & y & z\end{bmatrix} \begin{bmatrix} a_{11} & a_{12} & a_{13}\\ a_{21} & a_{22} & a_{23}\\ a_{31} & a_{32} & a_{33}\end{bmatrix}^t \in L(\alpha).\end{aligned}$$

Therefore, $(a_{11}x+a_{12}y+a_{13}z)+\alpha(a_{21}x+a_{22}y+a_{23}z)+(a_{31}x+a_{32}y+a_{33}z)=0$. Thus the line $A^nL(\alpha)$ is represented by an equation of the form
$$ax+by+cz+\alpha(a'x+b'y+c'z)=0, \quad \alpha = 1, \text{ or } \alpha \in N\backslash \mathrm{GF}(q),$$

where $a = a_{11} + a_{31}, a' = a_{21}$, etc, are all elements of GF(q), uniquely determined by A^{-n}. □

Note 38 *In particular, corresponding to* $\alpha = 1$, *we have* $q^2 + q + 1$ *lines with equations of type*

$$ax + by + cz = 0, \quad a, b, c \in GF(q).$$

Thus PG$(2, q)$ is a Desarguesian subplane (a Baer subplane) of $\mathcal{H}(q^2)$.

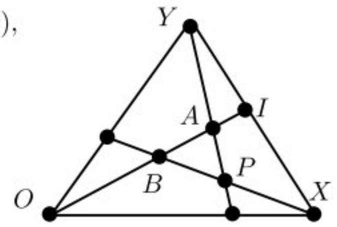
Example 6.28 In $\mathcal{H}(q^2)$, let $O = (0, 0, 1)$, $X = (1, 0, 0)$, $Y = (0, 1, 0)$, $C = (0, b, 1)$, $A = (a, a, 1)$, $B = (b, b, 1)$, $U = (1, 1, 1)$, $I = (1, 1, 0)$, $M = (1, m, 0)$. Find the coordinates of

1. $YA \cap XB$;
2. $CI \cap YA$;
3. $YA \cap OM$.

Solution.

1. The line $A^n L(\alpha)$ has an equation of type

$$ax + by + cz + \alpha(a'x + b'y + c'z) = 0, \quad \alpha = 1, \text{ or } \alpha \in N\backslash\text{GF}(q),$$



where the coefficients are all elements of GF(q), uniquely determined by A^{-n}. In particular, the line OU has equation $x - y = 0$. Thus,

$$OU = \{(a, a, 1) \mid a \in N\} \cup \{(1, 1, 0)\}.$$

Now, YA has equation

$$a_1 x + (-a_1 a)z + \alpha(a'_1 x + (-a'_1 a)z) = 0,$$

for some $a_1, a'_1 \in$ GF(q), and $\alpha = 1$, or $\alpha \in N\backslash$GF(q). The equation of XB is

$$b_1 y + (-b_1 b)z + \beta(b'_1 y + (-b'_1 b)z) = 0,$$

for some $b_1, b'_1 \in$ GF(q), and $\beta = 1$, or $\beta \in N\backslash$GF(q). Therefore, $YA \cap XB = (a, b, 1)$.

2. Let the equation of CI be

$$a_1 x + b_1 y + c_1 z + \alpha(a'_1 x + b'_1 y + c'_1 z) = 0, \quad \alpha = 1, \text{ or } \alpha \in N\backslash\text{GF}(q).$$

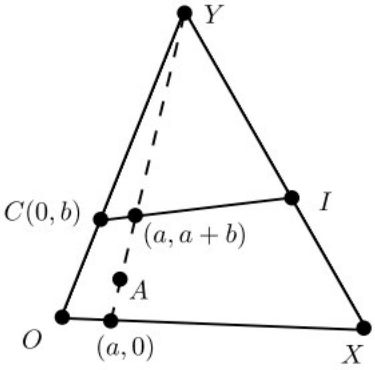
Since $(1,1,0) \in CI$, we have

$$a_1 + b_1 + \alpha(a_1' + b_1') = 0.$$

If $\alpha \in N \backslash \mathrm{GF}(q)$, then

$$a_1 + b_1 = 0 = a_1' + b_1',$$

since $a_1, a_1', b_1, b_1' \in \mathrm{GF}(q)$.
Thus, for $\alpha = 1$, or $\alpha \in N \backslash \mathrm{GF}(q)$, CI has equation of type



$$a_1 x - a_1 y + c_1 z + \alpha(a_1' x - a_1' y + c_1' z) = 0,$$

where

$$-a_1 b_1 + c_1 + \alpha(-a_1' b_1 + c_1') = 0. \tag{1}$$

Now the point $(a, a+b, 1)$ lies on YA and on CI, since

$$\begin{aligned} &a_1 a - a_1(a+b) + c_1 + \alpha(a_1' a - a_1'(a+b) + c_1') \\ &= a_1 a - a_1 a - a_1 b + c_1 + \alpha(a_1' a - a_1' a - a_1' b + c_1'), \quad \text{since } a_1, a_1', \in \mathrm{GF}(q) \\ &= -a_1 b + c_1 + \alpha(-a_1' b + c_1') \\ &= 0, \quad \text{by Equation (1).} \end{aligned}$$

Thus $CI \cap YA = (a, a+b, 1)$.

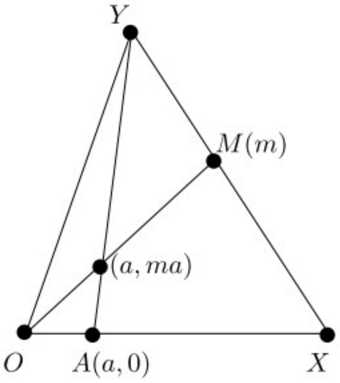
3. Similarly, the equation of OM is

$$a_1 x + b_1 y + \alpha(a_1' x + b_1' y) = 0,$$

where $a, a', a_1', b_1 \in \mathrm{GF}(q), \alpha = 1$, or $\alpha \in N \backslash \mathrm{GF}(q)$, and

$$a_1 + b_1 m + \alpha(a_1' + b_1' m) = 0. \tag{2}$$

The point $(a, ma, 1)$ lies on YA and on OM, since



$$\begin{aligned} a_1 a + b_1 ma + \alpha(a_1' a + b_1' ma) &= \{a_1 + b_1 m + \alpha(a_1' + b_1' m)\} a \\ &= 0a, \quad \text{by Equation (2)} \\ &= 0. \end{aligned}$$

□

Note 39 *Let the point* $v = (x, y, z)$ *of* $\mathcal{H}(q^2)$ *be incident with the line* $A^n L(\alpha)$. *Then* $v = w(A^n)^t$ *for some* $w \in L(\alpha)$. *Therefore,* $vA^t = w(A^n)^t A^t = w(A^{n+1})^t$ *for some* $w \in L(\alpha)$, *and so the point* vA^t *is incident with the line* $A^{n+1}L(\alpha)$. *Thus the map* $\sigma\colon v \mapsto vA^t$ *is a collineation of* $\mathcal{H}(q^2)$, *mapping the line* $A^n L(\alpha)$ *to the line* $A^{n+1}L(\alpha)$, *which is distinct from* $A^n L(\alpha)$. *Suppose that* $\mathcal{H}(q^2)$ *is a translation plane with respect to the line* $A^n L(\alpha)$, *for some* n *and* α. *Then, by Example 6.18,* $\sigma(A^n L(\alpha))$ *is also a translation line of* $\mathcal{H}(q^2)$. *In fact the* q^2+q+1 *distinct lines* $\sigma^i(A^n L(\alpha)), i = 1, 2, \dots, q^2+q+1$, *are all translation lines. These* q^2+q+1 *distinct lines cannot all pass through the same point, since there are exactly* q^2+1 *lines through each point of* $\mathcal{H}(q^2)$. *Therefore, at least three of these* q^2+q+1 *translation lines are non-concurrent. By Exercise 6.6 it follows that every line of* $\mathcal{H}(q^2)$ *is a translation line, making the plane a Moufang plane. It has been remarked before that a finite Moufang plane is a field plane.*

Thus, if $\mathcal{H}(q^2)$ *were a translation plane, it would be isomorphic to* $PG(2, q^2)$.

Theorem 6.29 $\mathcal{H}(q^2)$ *is neither a translation plane, nor a dual translation plane.*

Proof. Example 6.28 part (1) shows that N is a coordinatising set for $\mathcal{H}(q^2)$, as defined in Chapter 5. Let the addition defined (as in Chapter 5) on N be $\oplus$, and the multiplication be $\odot$.

Suppose that $\mathcal{H}(q^2)$ is a translation plane. Then, as observed before, the coordinatising ring $(N, \oplus, \odot)$ is a field of order q^2. By Example 6.28, parts (2) and (3),

$$\begin{aligned}
a + b &= a \oplus b, && \text{for all } a,\ b\ \in N.\\
&= b \oplus a, && \text{since } (N, \oplus, \odot) \text{ is a field.}\\
&= b + a\\
m \circ a &= a \odot m, && \text{for all } a,\ m\ \in N\\
&= m \odot a, && \text{since } (N, \oplus, \odot) \text{ is a field.}\\
&= a \circ m\\
(a + b) \circ m &= (a \oplus b) \odot m\\
&= (a \odot m) \oplus (b \odot m), && \text{since } (N, \oplus, \odot) \text{ is a field.}\\
&= a \circ m + b \circ m.
\end{aligned}$$

The remaining axioms for a field are easily seen to hold in $(N, +, \circ)$. This is a contradiction, since $(N, +, \circ)$, by construction, is not a field. Hence, $\mathcal{H}(q^2)$ is not a translation plane.

It is similarly proved that $\mathcal{H}(q^2)$ is not a dual translation plane. □

The Hall planes

Given a quasifield γ, the plane it coordinatises is a translation plane. The *Hall* quasifields (which we will soon define) are examples of quasifields which are not skew fields; the planes they coordinatise are non-Desarguesian translation planes.

Definition 6.30 *Let γ be a quasifield. The* **kernel** *$K(\gamma)$ of γ is the set of all elements k of γ such that, for all $a, b \in \gamma$,*

$$k(ab) = (ka)b \qquad \text{and} \qquad k(a+b) = ka + kb.$$

Theorem 6.31 *Let γ be a quasifield. The kernel $K(\gamma)$ of γ is a skew field, and γ is a (left) vector space over $K(\gamma)$.*

Note 40 *By left vector space V over a skew field K we mean*

- *If $v \in V, k \in K$, then $kv \in V$.*
- *All the vector space axioms hold, but with scalar multiplication always on the left.*

A right vector is similarly defined.

Proof. For any $a, b \in \gamma$, and any $k, l \in K(\gamma)$, we have

$$\begin{aligned}(kl)(a+b) &= k\{l(a+b)\}\\ &= k\{la+lb\}\\ &= k(la)+k(lb)\\ &= (kl)a+(kl)b.\end{aligned}$$

Thus, $K(\gamma)$ is closed under multiplication.

Similarly, the other axioms of a skew field can be proved to hold in $K(\gamma)$.

Using the addition of γ as vector addition, it follows that γ is a (left) vector space over its kernel. □

This leads to the following important theorem:

Theorem 6.32 *Let $(\gamma, +, .)$ be a quasifield of finite order. Then,*

1. *$q = p^r$ for some prime p, some integer r,*
2. *$(\gamma, +)$ is isomorphic to $(GF(q), +)$.*

Proof.

1. Since γ is finite, its kernel $K(\gamma)$ is a finite skew field. By Wedderburn's Theorem, $K(\gamma)$ is a finite field, and therefore its order is p^h, for some prime p, and positive integer h. Let the dimension of γ, as a vector space over its kernel, be n. Then γ has order $q = p^{hn}$.
2. Both $\mathrm{GF}(q)$ and γ are vector spaces of dimension n over $\mathrm{GF}(p^h)$. Therefore, $(\gamma, +)$ is isomorphic to $(\mathrm{GF}(q), +)$. □

Exercise 6.9

1. Let π be a translation plane of prime order p. Prove that π is isomorphic to $\mathrm{PG}(2,p)$.
2. Give a complete proof of Theorem 6.31.

In view of Theorems 6.31 and 6.32, it is not surprising that every construction of a quasifield γ starts with a Galois field F, and a subfield K of F, retains the addition of F, retains the multiplication of K, and alters the multiplication in $F\backslash K$.

Definition 6.33 1. *A* **finite Hall quasifield** *is a quasifield $\mathcal{H}(q^2,f)$ constructed as follows.*

Let $K = GF(q)$, and let $f(x) = x^2 - rx - s$ be an irreducible quadratic over K. Let λ be a zero of f in $F = GF(q^2)$. Let $\mathcal{H}(q^2,f)=\{a+b\lambda \mid a,b \in K\}$. The addition $\oplus$ in $\mathcal{H}(q^2,f)$ is defined by

$$(a+b\lambda)\oplus(c+d\lambda) = (a+c)+(b+d)\lambda.$$

The multiplication $\odot$ in $\mathcal{H}(q^2,f)$ is defined by

$$\begin{aligned}(a+b\lambda)\odot c &= ac+(bc)\lambda.\\ (a+b\lambda)\odot(c+d\lambda) &= (ac-bd^{-1}f(c))+(ad-bc+br)\lambda, \qquad \textit{for } d\neq 0.\end{aligned}$$

2. *A* **finite Hall plane** *is a plane coordinatised by a Hall quasifield.*

The proof that $\mathcal{H}(q^2,f)$ is indeed a quasifield can be found in M. Hall's book 'The theory of groups'.

Exercise 6.10 Concerning the Hall quasifield $\mathcal{H}(q^2,f)$, as defined above,

1. Verify that every element α of $\mathcal{H}(q^2,f)\ \backslash K$ satisfies $f(\alpha)=0$.
2. Verify that every element of K commutes with every element of $\mathcal{H}(q^2,f)$.
3. Show that $\mathcal{H}(9,f)$, where $f = x^2+1$, is associative, making it a nearfield.
4. Show that $\mathcal{H}(9,f)$, where $f = x^2-x-1$, is not associative.
5. Show that $\mathcal{H}(q^2,f)$ is distributive if and only if $q=2$.
6. Write out the multiplication table for the Hall quasifield $\mathcal{H}(16,f)$, for an appropriate polynomial f (irreducible over $\mathrm{GF}(4)$).

It is interesting to note that the properties, enunciated in questions 1 and 2 above, characterise Hall quasifields. In *Projective Planes* (Trans Amer Math Soc 54 (1943), 229–277), M. Hall used the following definition, which is stated here as a theorem.

Theorem 6.34 *Let* $(H, +, .)$ *be a quasifield, with the field* $K = GF(q)$ *contained in both its centre and its kernel such that* H *is two-dimensional over* K. *If there exists an irreducible quadratic* f *over* K *with* $f(a) = 0$ *for all* $a \in H \backslash K$, *then* H *is a Hall quasifield.*

Remark. Recall the *Bruck–Bose construction* (see Exercise 4.5(10b)), where projective planes are constructed from spreads of projective spaces. It can be shown that every translation plane gives rise to a spread, and from every spread, the Bruck–Bose construction gives rise to a translation plane.

The problem of discovering all quasifields, or of all spreads, is not yet solved. Non-isomorphic quasifields can yield the ‘same’ plane. Criteria, weaker than isomorphism, are needed to decide if two quasifields yield the same plane. One such ‘weak’ criterion is that of isotopism. (See *Hughes and Piper: Projective Planes.*) Unfortunately, while isotopic quasifields give rise to the same plane, there exist translation planes which can be coordinatised by non-isotopic quasifields. For example, $\mathcal{H}(9, f)$, with $f = x^2 + 1$ is a nearfield, while $\mathcal{H}(9, g)$, with $g = x^2 - x - 1$ is not a nearfield. As a consequence, $\mathcal{H}(9, f)$ and $\mathcal{H}(9, g)$ are not isotopic. They both, however, give rise to the unique non-Desarguesian translation plane of order 9.

In fact, it has been proved that there are exactly four projective planes of order 9, namely: PG$(2, 9)$, the Hall translation plane of order 9, the Hall dual translation plane of order 9, and the Hughes plane of order 9.

5.1 The Motivation for a Shape Arithmetic

5.1.1 Does Negative Shape Exist?

Our previous chapter ended up posing a simple question: “Is it possible to do addition and subtraction (or multiplication and division) with geometric shapes as we do in ordinary arithmetic with numbers?” In other words, for a geometric shape, does its inverse – that is, *negative shape* – exist? If this were possible, then we would obtain a remarkable insight into analyzing and synthesizing shapes, just as we have in the case of numbers. Unfortunately, the precise answer to this question is “No,” because the *algebraic structures* of various systems with geometric shapes are, in general, *weaker* than those of systems with numbers. For example, consider some of the most familiar algebraic systems with numbers, such as $(\mathbb{Z}, +)$, $(\mathbb{Q}, +)$, and $(\mathbb{R}, +)$, where $\mathbb{Z}$, $\mathbb{Q}$, and $\mathbb{R}$ denote the sets of integers, rational numbers, and real numbers, respectively, and the composition operation “$+$” denotes the ordinary addition operation. All of these systems are groups. If we exclude the number 0 from all these sets and consider ordinary multiplication “$\cdot$” as the composition operation, the corresponding systems, $(\mathbb{Z} - \{0\}, \cdot)$, $(\mathbb{Q} - \{0\}, \cdot)$, and $(\mathbb{R} - \{0\}, \cdot)$, again turn out to be groups.

On the other hand, take some of the common systems with geometric shapes, such as $(\mathcal{G}, \cup)$, $(\mathcal{G}, \cap)$, $(\mathcal{G}, \oplus)$, or $(\mathcal{G}, \ominus)$, where $\mathcal{G}$ denotes the set of all geometric shapes (more formally, the set of all subsets of real Euclidean space R^d), and $\cup$, $\cap$, $\oplus$, and $\ominus$ denote, respectively, set union, set intersection, and the Minkowski (vector) addition and decomposition of two sets of points. All of these systems are *monoids* – but not groups. We may recall that a group has a *stronger* structure than a monoid, since a restriction imposed on the elements of a monoid – namely, the existence of an inverse for each element – results in a group.

The following question then naturally arises: “Is it possible to extend our notion of geometric shapes so that with a convenient composition operation we can form an algebraic group-like structure?”

This is indeed a very fundamental question. In this chapter, we shall attempt a much modest task by restricting our domain of shapes to the polygons in E^2 and the polyhedra in E^3, where E denotes Euclidean space, and approaching the problem in a more intuitive way, rather than becoming strictly mathematical.

Arithmetics of Geometric Shape

5.1 The Motivation for a Shape Arithmetic

5.1.1 Does Negative Shape Exist?

Our previous chapter ended up posing a simple question: "Is it possible to do addition and subtraction (or multiplication and division) with geometric shapes as we do in ordinary arithmetic with numbers?" In other words, for a geometric shape, does its inverse – that is, *negative shape* – exist? If this were possible, then we would obtain a remarkable insight into analyzing and synthesizing shapes, just as we have in the case of numbers. Unfortunately, the precise answer to this question is "No," because the *algebraic structures* of various systems with geometric shapes are, in general, *weaker* than those of systems with numbers. For example, consider some of the most familiar algebraic systems with numbers, such as $(\mathbb{Z}, +)$, $(\mathbb{Q}, +)$, and $(\mathbb{R}, +)$, where $\mathbb{Z}$, $\mathbb{Q}$, and $\mathbb{R}$ denote the sets of integers, rational numbers, and real numbers, respectively, and the composition operation "$+$" denotes the ordinary addition operation. All of these systems are groups. If we exclude the number 0 from all these sets and consider ordinary multiplication "$\cdot$" as the composition operation, the corresponding systems, $(\mathbb{Z} - \{0\}, \cdot)$, $(\mathbb{Q} - \{0\}, \cdot)$, and $(\mathbb{R} - \{0\}, \cdot)$, again turn out to be groups.

On the other hand, take some of the common systems with geometric shapes, such as $(\mathcal{G}, \cup)$, $(\mathcal{G}, \cap)$, $(\mathcal{G}, \oplus)$, or $(\mathcal{G}, \ominus)$, where $\mathcal{G}$ denotes the set of all geometric shapes (more formally, the set of all subsets of real Euclidean space R^d), and $\cup$, $\cap$, $\oplus$, and $\ominus$ denote, respectively, set union, set intersection, and the Minkowski (vector) addition and decomposition of two sets of points. All of these systems are *monoids* – but not groups. We may recall that a group has a *stronger* structure than a monoid, since a restriction imposed on the elements of a monoid – namely, the existence of an inverse for each element – results in a group.

The following question then naturally arises: "Is it possible to extend our notion of geometric shapes so that with a convenient composition operation we can form an algebraic group-like structure?"

This is indeed a very fundamental question. In this chapter, we shall attempt a much modest task by restricting our domain of shapes to the polygons in E^2 and the polyhedra in E^3, where E denotes Euclidean space, and approaching the problem in a more intuitive way, rather than becoming strictly mathematical.

Mathematics of Shape Description Pijush K. Ghosh and Koichiro Deguchi
© 2008 John Wiley & Sons (Asia) Pte Ltd

To devise a possible approach, we can draw an analogy with the lessons of number systems, as described in the previous chapters. We can start with the system $(\mathbb{N}, +)$, which is a monoid, where $\mathbb{N}$ denotes the set of natural numbers; that is, $\mathbb{N} = \{0, 1, 2, \cdots\}$. Let us take a small subset of $\mathbb{N}$, say $A = \{0, 1, 2\}$, and a composition operation $+$ redefined by the following table:

+	0	1	2
0	0	1	2
1	1	2	0
2	2	0	1

It is evident that the system $(A, +)$ is a group, since each of the elements of A has a unique inverse. You must have realized that we are essentially using *modulo* 3 arithmetic. It is well known that the relation "$a = b$ (*modulo* m)" is an *equivalence relation* that partitions $\mathbb{N}$ into m nonoverlapping subclasses, called *equivalence classes*.The equivalence classes may allow us to form a group structure, as was done in the above example. Since $(A, +)$ is a group, it is possible to solve an equation such as

$$x + 2 = 1$$

using this small system.

Now, instead of taking a small subset of $\mathbb{N}$, such as A, if we consider the whole of $\mathbb{N}$ and try to solve an equation of the above form, we are led to the concept of negative integers, $-1, -2, \cdots$. The set of natural numbers $\mathbb{N}$ augmented by the set of negative integers forms the set of integers $\mathbb{Z}$, and the system $(\mathbb{Z}, +)$ is now obtained as a group where both additions and subtractions become possible.

5.1.2 What Form Must Negative Shapes Take?

Now, let us confirm the theories on the extension of the geometric shape concept that we have constructed so far in this book.

We already have the next fundamental theory that tells us about this extension:

> *Extension of Algebraic Systems:* If an algebraic system $(A, \circ)$ where $\circ$ is a binary operation on the element in a set A has a *unit (identity) element e* which satisfies
>
> $$a \circ e = e \circ a = a$$
>
> for any element $a \in A$, and has next three properties that,
>
> 1. $a \circ b = b \circ a$, (*Commutativity*)
> 2. $(a \circ b) \circ c = a \circ (b \circ c)$, (*Associativity*)
> 3. If $a \circ b = a \circ c$, then $b = c$, (*Injectivity*)
>
> for any elements $a, b, c \in A$, then A can be extended to $A' \supseteq A$ so that all elements $a' \in A'$ have their own respective inverses in A'; that is, $\exists b' \in A'$, for $\forall a' \in A$ and $a' \circ b' = e$.
> Bourbaki, *Algebra I* [11]; see also Section 3.2

Let us recall our system of $(\mathcal{G}, \oplus)$. A single point, say $\{o\}$ (the origin), is a unit element of this system, because, for any geometric shape S, $S \oplus \{o\} = \{o\} \oplus S = S$. (It should be noted that the origin $\{o\}$ is not a unique unit element for the operation of $\oplus$. Actually, every single point $\{p\}$ can be a unit element. This is another substantial weak point in our theory.)

Now, we denote the set of all the convex polygons by $\mathcal{C}$; that is, $\mathcal{C} \subset \mathcal{G}$. Then, all of the above properties 1, 2, and 3 hold in the system $(\mathcal{C}, \oplus)$, as was shown in the previous chapter. This means that the set of all convex polygonal shapes $\mathcal{C}$ can be extended to include the inverses of the shapes. For example, for a rectangular shape R, the above fundamental theory says that we could consider its inverse shape R^{-1} so that $R \oplus R^{-1} = \{o\}$ (or a single point). Also, a circular shape C could have its inverse shape C^{-1}.

So, the first problem here is: What, in reality, are the inverse shapes R^{-1} and C^{-1}? The next question is: "How is the inverse operation actually defined to generate R^{-1} and C^{-1} from R and C, respectively?" Especially, how does the inverse operation of $\oplus$ relate to $\ominus$? And the third problem is: "If we have a proper extension of the set of the convex polygons $\mathcal{C}$, which includes their negative shapes, can it be further extended for all the geometric shapes in $\mathcal{G}$?"

Just as we said at the beginning of this section, the general answer to the third question is "No." Therefore, the question must be rewritten as follows: "To what extent can the set of the convex polygons $\mathcal{C}$ can be defined such that each of the element shapes has its own inverse?"

We present solutions to some of these problems in this chapter, where negative shapes in terms of Minkowski addition are defined as being closely related to Minkowski decomposition. We will only treat convex objects in this chapter: the results will be extended to nonconvex objects in the next chapter.

5.2 Morphology and the Theory of Numbers

5.2.1 Morphology for High-Level Vision

The two operations of Minkowski addition $\oplus$ (also called dilation) and Minkowski decomposition $\ominus$ (also known as erosion), introduced in the previous chapter, form the kernel of all other morphological operations.

To this day, morphological operations are mostly used for low-level image processing; that is, for early processing of binary or gray-scale discrete images [90]. Their applications in representing or understanding two- or three-dimensional geometric objects for the purpose of high-level object recognition are very limited. This is certainly an enigmatic situation, considering the fact that these operations are essentially functions of the form $f : \mathcal{G}(E^d) \rightarrow \mathcal{G}(E^d)$, where $\mathcal{G}(E^d)$ denotes the power set of real d-dimensional Euclidean space E^d; their definitions do not discriminate between whether the underlying sets are discrete images or continuous geometric objects. Moreover, a number of researchers have pointed out the relevance of these operations in high-level vision applications such as geometric modeling, spatial planning, description and understanding of biological forms, crystallography and textured object modeling, and so on [27, 28, 29, 60, 84]. The close resemblance between the representation of a generalized cylinder and the Minkowski addition operation has also been observed.

One factor that may account for this situation has to do with the computational problems associated with Minkowski operations on continuous objects. Note that any binary image can be modeled as a set consisting of a finite number of discrete points. Therefore, in computing the Minkowski sum $A \oplus B$ of two binary images A and B, we can directly use the set operations of Minkowski addition:

$$A \oplus B = B \oplus A = \bigcup_{b \in B} A_b = \bigcup_{a \in A} B_a.$$

Similarly, Minkowski decomposition $A \ominus B$ of a binary image A can be computed by means of

$$A \ominus B = \bigcap_{-b \in \check{B}} A_{-b}.$$

On the other hand, a continuous "well-formed" object (such as a polygon, circle, ellipse, etc. in two dimensions, or a polyhedron, sphere, ellipsoid, etc. in three dimensions) cannot be specified as a collection of a finite number of points. In general, such an object, say A, is specified by its oriented boundary, say ∂A. This necessitates computation of the boundary $\partial(A \oplus B)$ or $\partial(A \ominus B)$ of the products from the boundaries ∂A and ∂B of the operands. But it can immediately be seen that $\partial(A \oplus B) \neq \partial A \oplus \partial B$ and also $\partial(A \ominus B) \neq \partial A \ominus \partial B$.

In general, $\partial(A \oplus B) = f(\partial A, \partial B)$, and also $\partial(A \ominus B) = g(\partial A, \partial B)$, where "$f$" and "$g$" denote some complicated functions whose computations turn out to be quite nontrivial.

5.2.2 The Resemblance between Morphology and the Theory of Numbers

We can observe a remarkable similarity between some number-theoretic results and morphological theorems, particularly in the domain of convex objects. Let us consider the number system $(\mathbb{N}, \cdot, /)$, where $\mathbb{N}$ denotes the set of natural numbers $\{0, 1, 2, \ldots\}$ and "$\cdot$" and "$/$" denote the multiplication and division operations, respectively. Since, within $\mathbb{N}$, the division operation is not an exact inverse, but only a "restricted" inverse of the multiplication operation, we can define the division of a number m by another number n as $\lfloor m/n \rfloor$; the floor function notation $\lfloor x \rfloor$ means the greatest integer less than or equal to x. This number system can be compared with the geometric system $(\mathcal{K}, \oplus, \ominus)$, where $\mathcal{K}$ denotes the set of all compact convex subsets of E^d. We refer to Table 5.1, where $A, B, C \in \mathcal{K}$ and $m, n, p \in \mathbb{N}$.

From the table, it appears as though $A \oplus B$ in the convex domain is similar to $m \cdot n$, whereas $A \ominus B$ is similar to $\lfloor m/n \rfloor$. In this chapter, we do not attempt to seek why such a resemblance exists. Instead, we adopt the computational guideline that can be derived from this resemblance.

Table 5.1 The resemblance between the morphological system and the integer number system

	System $(\mathcal{K}, \oplus, \ominus)$	System $(\mathbb{N}, \cdot, /)$
1.	$A \oplus B = B \oplus A$	$m \cdot n = n \cdot m$
2.	$A \oplus (B \oplus C) = (A \oplus B) \oplus C$	$m \cdot (n \cdot p) = (m \cdot n) \cdot p$
3.	$A \supseteq B$ implies $C \ominus A \subseteq C \ominus B$	$m > n$ implies $\lfloor p/m \rfloor \leq \lfloor p/n \rfloor$
4.	$A \subseteq B \ominus C$ iff $B \supseteq A \oplus C$	$m \leq \lfloor n/p \rfloor$ iff $n \geq m \cdot p$
5.	$A \oplus B = ((A \oplus B) \ominus B) \oplus B$	$m \cdot n = \lfloor (m \cdot n)/n \rfloor \cdot n$
6.	$A \ominus B = ((A \ominus B) \oplus B) \ominus B$	$\lfloor m/n \rfloor = \lfloor (\lfloor m/n \rfloor \cdot n)/n \rfloor$
7.	$(A \ominus B) \ominus C = A \ominus (B \oplus C)$	$\lfloor \lfloor m/n \rfloor / p \rfloor = \lfloor (m/(n \cdot p) \rfloor$
8.	$A \oplus (B \ominus C) \subseteq (A \oplus B) \ominus C$	$m \cdot \lfloor n/p \rfloor \leq \lfloor (m \cdot n)/p \rfloor$
9.	$(A \ominus B) \oplus C \subseteq (A \oplus C) \ominus B$	$\lfloor m/n \rfloor \cdot p \leq \lfloor (m \cdot p)/n \rfloor$
10.	$(A \ominus B) \oplus B \subseteq A$	$\lfloor m/n \rfloor \cdot n \leq m$
11.	$(A \ominus B) \oplus B$ $= (((A \ominus B) \oplus B) \ominus B) \oplus B$	$\lfloor m/n \rfloor \cdot n$ $= \lfloor (\lfloor m/n \rfloor \cdot n)/n \rfloor \cdot n$
12.	If $A \oplus B = A \oplus C$, then $B = C$	If $m \cdot n = m \cdot p$, then $n = p$

The value of m/n is, in general, a real number that consists of the "integer part" $\lfloor m/n \rfloor$ and the "fractional part" $m/n - \lfloor m/n \rfloor$. In the integer number domain, at the time of division we discard that fractional part and take only the integer part. We find that the morphological operations can also be treated in a similar way. The idea is to devise an operation that is the "exact" inverse of the Minkowski addition operation, such that the application of this operation on two convex objects will produce a generalized geometric object (like producing a rational number by the division of two integers) that has a physically "realizable part" (analogous to the integer part) and a "nonrealizable part" (analogous to the fractional part). The Minkowski decomposition $A \ominus B$ can then be thought of as the realizable part of the object after the nonrealizable part is discarded.

The nonrealizable part of a generalized object will be referred to as the *negative* part. (We will avoid using terms such as "nonrealizable" or "fractional" part, since they have some widely accepted literal meanings.) The realizable part – that is, any ordinary geometric object – can be called *positive*.

In our subsequent discussions, we will show how such a computational strategy can be devised.

5.3 Boundary Representation by Support Functions for Morphological Operations

5.3.1 The Support Function Representation

Our starting point in tackling this problem is a basic result given by Shephard [93], which is concerned with the boundary addition of d-dimensional convex polytopes. Informally, a convex polytope in E^d is the d-dimensional analogue of a convex polygon in E^2 or a convex polyhedron in E^3. Mathematically, a polytope is the convex hull of a finite set of points in E^d. Shephard's result is stated in terms of the faces of polytopes. In this subsection, we briefly discuss the formal notion of the faces of a d-dimensional polytope, and then we state the main result in the next subsection.

A face of a convex polytope A in E^d is defined in terms of the *supporting function* and the *supporting hyperplane* of the polytope. The representation of a convex body by means of its support function is a classical approach [8,34] that was introduced by Minkowski in 1903, and has been widely used by mathematicians since that time.

Let $A \in E^d$ be a convex body (i.e., a nonempty compact convex set) in real Euclidean d-dimensional space. The supporting function $H(A, v)$ of A for all $v \in E^d$ (provided that $v \neq 0$ – that is, v – is an arbitrary vector different from the origin O) is defined by

$$H(A, v) = \sup\{ \langle a, v \rangle \mid a \in A\}, \tag{5.1}$$

where $\langle a, v \rangle$ denotes the scalar (or inner) product of the vectors a and v, and "sup" denotes the "supremum' or "least upper bound."

Since $H(A, \lambda v) = \lambda H(A, v)$ for any real number $\lambda > 0$, the support function $H(A, v)$ is completely determined by its value on the unit sphere $\|v\| = 1$. Thus, if u denotes a unit vector – that is, $u \in S^{d-1}$, where S^{d-1} is the unit sphere in E^d with its center at the origin – it is most convenient to use the function $H(A, u)$ as the support function of A. $H(A, u)$ is a *complete representation* of the convex body A, since the values of $H(A, u)$ for all $u \in S^{d-1}$ completely specify A in the following way:

$$A = \{x \in E^d \mid \; < x, u > \; \leq H(A, u) \text{ for all } u \in S^{d-1}\}, \tag{5.2}$$

which, in words, means that A is the intersection of all the half-spaces $< x, u > \leq H(A, u)$.

Although a large part of the theory of convex bodies in mathematics uses $H(A, u)$ as the standard representation of a convex body A, in the fields of computer vision, graphics, and image processing, the support function representation is less frequently used. One primary reason is that the function $H(A, u)$ is, in general, a continuous function of u, whose closed-form specification may not be readily available. It may also appear that the $H(A, u)$-representation is less intuitive than the boundary representation or half-space representation of convex bodies.

5.3.2 The Support Function is a Signed Distance

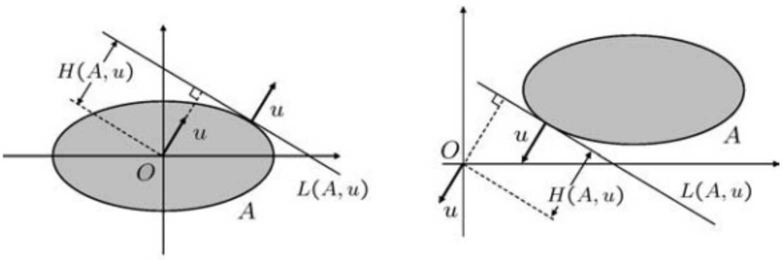
If, for some $u \neq 0$, we have $H(A, u) < \infty$ (this condition ensures that A is bounded), then the hyperplane

$$L(A, u) = \left\{ p \in E^d \mid \langle p, u \rangle = H(A, u) \right\} \tag{5.3}$$

is called the *supporting hyperplane* of A with *outer/outerward normal* u. In E^2, the supporting hyperplane becomes the supporting line of a convex polygon A with outer normal u, while in E^3 it is the supporting plane of a convex polyhedron A.

It is easy to see in Figure 5.1 that the support function $H(A, u)$ is precisely the "signed distance" from the origin O to the supporting hyperplane $L(A, u)$. This distance is to be considered positive if A and the origin lie on the same side of the supporting hyperplane, negative if A and the origin are separated by the supporting hyperplane, and zero if the origin lies in the supporting hyperplane. It is, therefore, convenient for all practical purposes to assume that the origin lies in the interior of A, so that the function $H(A, u)$ is positive for every u.

To provide examples, we consider three simple two-dimensional convex figures – a unit circle having its center at the origin, a triangle, and an ellipse – and show their corresponding $H(A, u)$'s in Figure 5.2. Note that for the unit circle whose center is at O, $H(A, u) = 1$ for all u.



(a) $H(A, u) > 0$ (b) $H(A, u) < 0$

Figure 5.1 The support function $H(A, u)$ is the signed distance from the origin O to the hyperplane $L(A, u)$. It is (a) positive ($H(A, u) > 0$)if A and the origin lie on the same side of the supporting hyperplane, and (b) negative ($H(A, u) < 0$) if A and the origin are separated by the supporting hyperplane

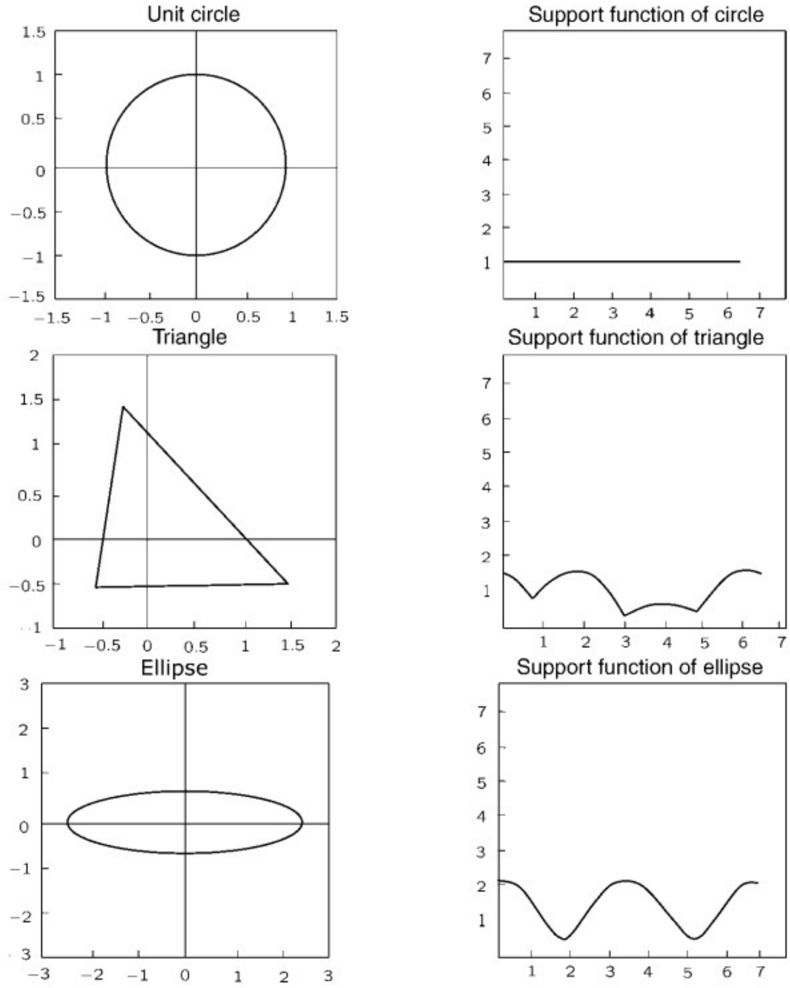


Figure 5.2 The support function representations of some typical convex figures; since in E^2 a unit vector $u = (\cos\theta, \sin\theta)$, it is specified in the graph by the angle θ (in radians) along the x-axis and the corresponding value of $H(A, u)$ along the y-axis

In fact, for some simple convex bodies, we can obtain closed-form representations of the support functions as follows:

1. For a singleton point set $\{a\}$ in E^d, $H(a, v) =< a, v >$.
2. For a ball B_α having radius α and center O, $H(B_\alpha, v) =< \alpha \frac{v}{\|v\|}, v >= \alpha\|v\|$.
3. For a line segment L_{ab} joining points a and b,

$$H(L_{ab}, v) = \max(< a, v >, < b, v >).$$

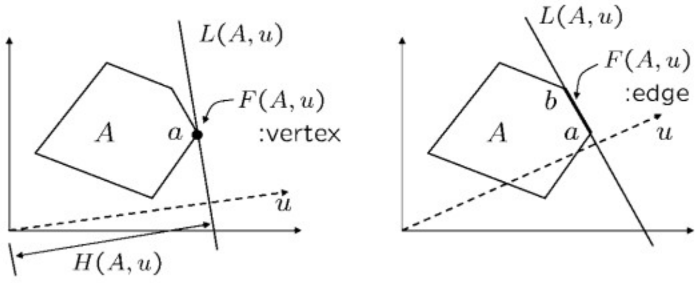
5.3.3 From Support Function Representation to Boundary Representation and Vice Versa

Assume that the support function $H(A, u)$ of a convex body A is given for all $u \in S^{d-1}$. How do we determine the boundary points of A? We answer this question by following the approach given in [8]. The boundary points of A, where the outer normal is either u or parallel to u, are precisely the set of points

$$F(A, u) = L(A, u) \cap A. \tag{5.4}$$

$F(A, u)$ is termed the face of A having outer normal u. Obviously, the dimension of $F(A, u)$ is at most $d - 1$.

Figure 5.3 shows examples of faces in E^2 and E^3 with their supporting functions and supporting hyperplanes.



L(A, u)

(b) $F(A, u)$ for 3-dimensional polyhedron A

Figure 5.3 The faces $F(A, u)$ of (a) a two-dimensional polygon and (b) a three-dimensional polyhedron

Now let u_k be some fixed direction, and let $F(A, u_k)$ be the face of A that has the outer normal u_k. Our task is to determine $F(A, u_k)$. Since $F(A, u_k)$ is a subset of the supporting hyperplane $L(A, u_k)$, for any point $x \in F(A, u_k)$ it must satisfy (because of (5.3))

$$< x, u_k > \; = \; H(A, u_k). \tag{5.5}$$

Moreover, $F(A, u_k)$ is also a subset of the convex body A. So a point x of $F(A, u_k)$ must also satisfy, for all u, all of the following inequalities (see (5.2)):

$$< x, u > \; \leq \; H(A, u). \tag{5.6}$$

Now, if w is a unit vector in an arbitrary direction and $u = u_k + \lambda w$, where $\lambda > 0$, then using (5.5) and (5.6) we can write

$$< x, w > \; \leq \; \frac{H(A, u_k + \lambda w) - H(A, u_k)}{\lambda}. \tag{5.7}$$

Therefore, letting $\lambda \to 0$,

$$< x, w > \; \leq \; H'_w(A, u_k), \tag{5.8}$$

where $H'_w(A, u_k)$ is the directional derivative of $H(A, u)$ at $u = u_k$, in the direction of the unit vector w.

If we consider all of the w's (i.e., unit vectors in all directions), then the inequalities of (5.8) represent the intersection of the corresponding half-spaces, and that intersection is precisely the face $F(A, u_k)$.

Thus we arrive at the following proposition.

Proposition 5.1. *If $H(A, u)$ is the support function of a convex body A, then the face $F(A, u_k)$ of A having the outer normal u_k has the support function $H'_u(A, u_k)$.*

5.3.4 Necessary and Sufficient Conditions for a Function to be a Support Function

The support function $H(A, v)$ is a scalar function of the vector v and hence, in the present case, a mapping from E^d to R. A natural question is: "Which functions from E^d to R could be characterized as support functions?" This question is particularly important to us since, from the next section onward, we will be concerned as to whether or not a function $H(A, v) * H(B, v)$ resulting from some operation $*$ on the given support functions $H(A, v)$ and $H(B, v)$ is a valid support function. Consider, for example, the situation shown in Figure 5.4, where no object could have all of the support function values $H(A, u_1) * H(B, u_1)$, $H(A, u_2) * H(B, u_2)$, $H(A, u_3) * H(B, u_3)$, $H(A, u_4) * H(B, u_4)$, since the supporting line corresponding to the value $H(A, u_3) * H(B, u_3)$ is a redundant line.

For characterization of the support function, we can state the following result.

Proposition 5.2. *(a) Every real-valued function $F(v)$ defined for all $v \in E^d$ and satisfying the properties*

(i) $F(o) = 0$,
(ii) $F(\lambda v) = \lambda F(v)$, *for* $\lambda > 0$, *and*

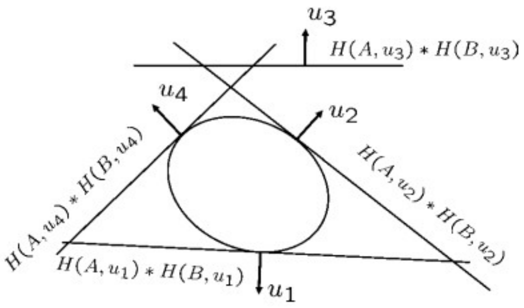

Figure 5.4 An example where the resulting function $H(A, v) * H(B, v)$ cannot be a valid support function; the supporting line corresponding to the value $H(A, u_3) * H(B, u_3)$ is a redundant line

(iii) $F(v + w) \leq F(v) + F(w)$*, is a support function of a convex body.*
(b) If $F(v)$ *is a support function, then the convex body that it represents must be the intersection of all the half-spaces* $< x, v > \leq F(v)$*.*

Part (a) is a classical result, the proof of which can be found in [8]. Part (b) follows easily from (5.2). For a review on the topic of consistency checking of the support function, see also [48]. Condition (iii) in the proposition – that is, $F(v + w) = F(v) + F(w)$ – appears to be the most nonintuitive compared to the other two conditions. However, its connection with the question of redundant half-spaces can be easily demonstrated. You are recommended to visualize this condition for yourself.

5.4 Geometric Operations by Means of Support Functions

We assume that the support functions $H(A, u)$ and $H(B, u)$ of two convex bodies A and B are given. We will now show that some simple algebraic operations on the support functions result in fairly complicated geometric operations involving the bodies A and B.

5.4.1 MAX and MIN Operations (Convex Hull and Intersection)

5.4.1.1 The MAX Operation

The MAX operation is defined as

$$\max\{H(Au),\ H(B, u)\},$$

for every $u \in S^{d-1}$, where "$\max\{\alpha, \beta\}$" specifies the maximum of the two real numbers α and β.

It is not difficult to prove that the MAX operation results in the *convex hull* operation of the union of A and B. Toward that end, we need the following proposition.

Proposition 5.3. *If* $H(A, u)$ *and* $H(B, u)$ *are the support functions of two convex bodies* A *and* B*, then the inequality*

$$H(A, u) \leq H(B, u), \qquad \text{for all } u,$$

holds if and only if $A \subseteq B$.

The proof of the proposition follows immediately from (5.1) and (5.2) (see also [8]).

We can now state and prove the main result concerning the MAX operation.

Proposition 5.4. *(a) The function* $\max\{H(A, u), H(B, u)\}$ *is a support function.*

(b) $\max\{H(A, u), H(B, u)\} = H(C, u)$*, where* $C = conv(A \cup B)$*. (Here,* $conv(X)$ *denotes the* convex hull *of the set* X*.)*

Proof: (a) See Proposition 5.2. Conditions (i) and (ii) obviously hold for $\max\{H(A, u), H(B, u)\}$, since they hold for both $H(A, u)$ and $H(B, u)$. Only condition (iii) – that is, the subadditivity condition – needs to be proved.

Let us write $F(u) = \max\{H(A, u), H(B, u)\}$, and assume that u_1, u_2 are two arbitrary unit vectors. Then,

$$\begin{aligned} F(u_1) + F(u_2) &= \max\{H(A, u_1), H(B, u_1)\} + \max\{H(A, u_2), H(B, u_2)\} \\ &\geq H(A, u_1) + H(A, u_2) \\ &\geq H(A, u_1 + u_2), \end{aligned}$$

since $H(A, u)$ is a support function.

Similarly, $F(u_1) + F(u_2) \geq H(B, u_1 + u_2)$.

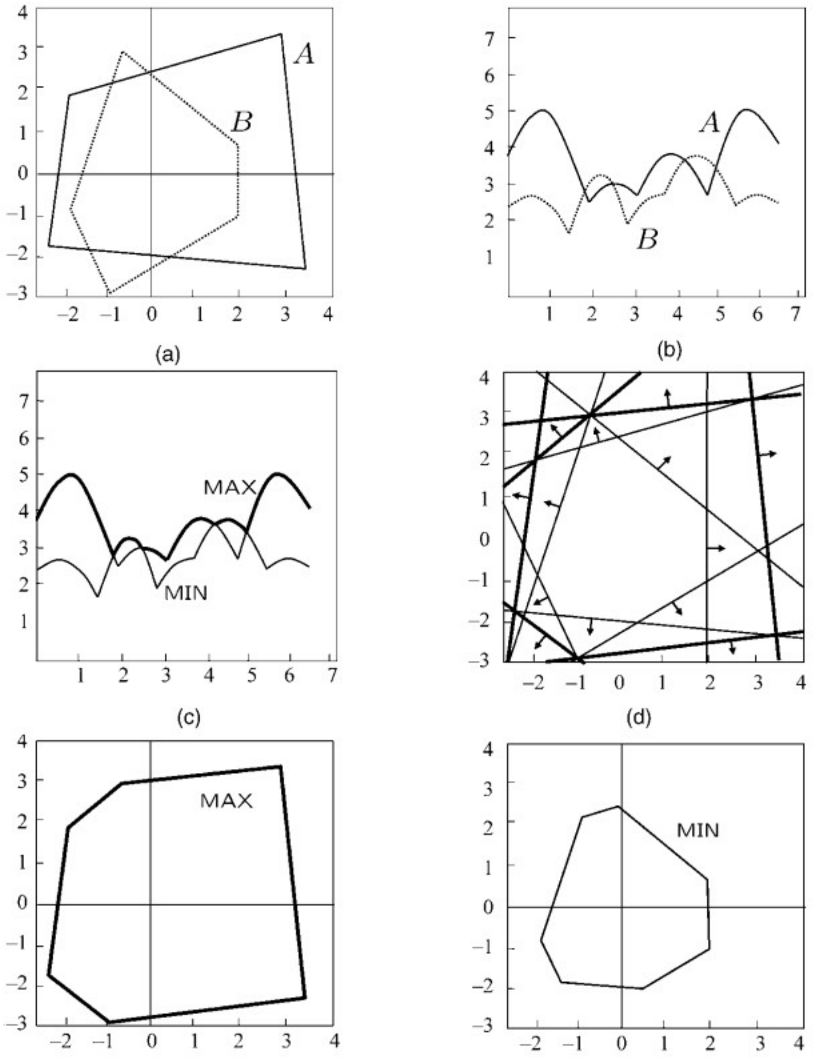
Furthermore, since $F(u_1 + u_2) = \max\{H(A, u_1 + u_2), H(B, u_1 + u_2)\}$, $F(u_1 + u_2)$ is either equal to $H(A, u_1 + u_2)$ or equal to $H(B, u_1 + u_2)$.

Therefore, $F(u_1) + F(u_2) \geq F(u_1 + u_2)$, and hence $\max\{H(A, u), H(B, u)\}$ is a support function of some convex body – say, C.

(b) Let $\max\{H(A, u), H(B, u)\} = H(C, u)$, where C is some convex body. Since $H(C, u) \geq H(A, u)$ and also $H(C, u) \geq H(B, u)$ for all u, according to Proposition 5.3, $C \supseteq A \cup B$.

Let us assume that the convex hull $\text{conv}(A \cup B)$ is not C, but that $\text{conv}(A \cup B) = C'$, and that C' is strictly smaller than C; that is, $C' \subset C$. Therefore, according to Proposition 5.3, $H(C', u) \leq H(C, u)$, for all u. Let us, for some u, say that u_1, $H(C', u)$ is strictly smaller than $H(C, u)$; that is, $H(C', u_1) < \max\{H(A, u_1), H(B, u_1)\}$. But that is not possible, which means that $C = C'$. □

We show two convex polygons A and B (in the xy-space) in Figure 5.5(a) and their support function representations (i.e., A and B in the θ_ρ-space) in Figure 5.5(b). The MAX operation of the support functions and the resulting polygon, which is equal to $\text{conv}(A \cup B)$ in the θ_ρ-space, are shown in Figure 5.5(c) (heavy curves). The supporting lines corresponding to each respective curve are shown in Figure 5.5(d), as heavy lines, and then the resulting MAX convex polygon of A and B is given in Figure 5.5(e).



(a) (b)

(c) (d)

(e) (f)

Figure 5.5 A demonstration of the MAX and MIN operations: (a) the input convex polygons A and B (in the xy-space); (b) their support function representations (the θ_ρ-space); (c)$\max\{H(A, u), H(B, u)\}$ (heavy curves) and $\min\{H(A, u), H(B, u)\}$ (light curves) (the θ_ρ-space); (d) the supporting lines corresponding to $\max\{H(A, u), H(B, u)\}$ (heavy lines), and $\min\{H(A, u), H(B, u)\}$ (light lines); (e) the resulting MAX convex polygon (in the xy-space) represented by $\max\{H(A, u), H(B, u)\}$; and (f) the MIN convex polygon (in the xy-space) represented by $\min\{H(A, u), H(B, u)\}$

5.4.1.2 The MIN Operation

The MIN operation is similarly defined as

$$\min\{H(A, u), H(B, u)\},$$

for every $u \in S^{d-1}$, where "$\min(\alpha, \beta)$" denotes the minimum of the two real numbers α and β.

It is not difficult to show that the MIN operation performs the intersection operation $A \cap B$. But unlike the previous case, $\min\{H(A, u), H(B, u)\}$ is not a support function. As a result, some of the supporting hyperplanes defined by $\min\{H(A, u), H(B, u)\}$ may be redundant. But the common intersection of all the half-spaces (some of which may be redundant, corresponding to the redundant hyperplanes) defined by the function $\min\{H(A, u), H(B, u)\}$ will result in $A \cap B$.

To give an example, we consider the same two polygons as presented in Figure 5.5(a), and show the function $\min\{H(A, u), H(B, u)\}$ in Figure 5.5(c) (light curves). The corresponding supporting lines are depicted in Figure 5.5(d) (light lines). Note that some of the supporting lines are redundant. However, the common intersection of the half-spaces defined by all the supporting lines is $A \cap B$, which is shown in Figure 5.5(f).

5.4.2 Morphological Operations in Boundary Representation

The following result concerning Minkowski addition of convex polytopes can now be derived by using the boundary representation formalized in the previous subsection.

Theorem 5.5. *If A and B are two convex polytopes in E^d, then, for every $u \in E^d$,*

$$H(A \oplus B, u) = H(A, u) + H(B, u) \tag{5.9}$$

and

$$F(A \oplus B, u) = F(A, u) \oplus F(B, u). \tag{5.10}$$

Equation (5.9) comes directly from the definition of Minkowski addition $\oplus$; $A \oplus B = \{a + b \mid a \in A, b \in B\}$. Then, substituting (5.9) into (5.3) and (5.4), we have (5.10). A detailed proof is given either by Grünbaum [34] or Kelly and Weiss [50], but it is not difficult, and we leave it to the readers.

Let us denote the boundary of S by ∂S. Then, because ∂S consists of all the faces of $F(S, u)$,

$$\partial S = \bigcup_{u \in S^{d-1}} F(S, u).$$

This implies that, from (5.10),

$$\partial(A \oplus B) = \bigcup_{u \in S^{d-1}} \left(F(A, u) \oplus F(B, u)\right). \tag{5.11}$$

You may wonder why the $\oplus$ operation appears both on the left- and right-hand sides of (5.11). We shall, however, argue that the computation of the right-hand side finally reduces to two simple operations on real numbers: sorting of real numbers, and addition of real numbers. We will show this first for polygons – that is, in E^2 – and then for polyhedra; that is, E^3.

5.5 Morphological Operations on Convex Polygons

5.5.1 Computation by Means of Support Function Vectors

The boundary of a convex polygon A in E^d can be precisely defined by means of the supporting function of the polygon. From Theorem 5.5, we can immediately infer the following. For the addition of convex polygons, it is not necessary to compute the supporting function $H(A \oplus B, u)$ for every $u \in S^1$ (S^1 in E^2 is simply a unit circle). Since a convex polygon is completely specified by its oriented edges, it is sufficient to consider only those u's whose directions are the same as the outer normal directions of the edges of the summand polygons.

Let us, therefore, consider the class of convex polygons whose edges have the same outer normal vectors. In other words, any two polygons belong to this class have pairwise parallel and similarly directed edges. Note that every convex polygon in E^2 can be included in this class by means of introducing edges of zero length. Let $\mathcal{C}(U)$ denote this class, where U is the ordered set of outer normal vectors of the edges; that is, $U = \{u_1, \cdots, u_n\}$. In other words, if any convex polygon $A \in \mathcal{C}(U)$, then

$$A = \left\{ p \in E^2 \mid \langle p, u_i \rangle \leq \eta_i \; (i = 1, \cdots, n) \right\} \tag{5.12}$$

for some $\eta_i \in R \; (i = 1, \cdots, n)$, where R denotes the set of real numbers. Note that η_i is simply the value of the supporting function of A in the direction of the outer normal u_i.

As we know, each η_i along with u_i specifies a closed half-space (in two dimensions, a "half-space" is generally called a "half-plane"), and the intersections of all these half-spaces for $i = 1, \cdots, n$, in turn, specify all of the edges of A. Therefore, once U is given, A is specified completely by the vector $(\eta_1, \cdots, \eta_n)$. We call this the *supporting function vector* of A, and denote it by $h(A)$.

From Theorem 5.5, we can now easily derive the following result concerning convex polygons.

Proposition 5.6. *If two convex polygons $A, B \in \mathcal{C}(U)$ are represented by the supporting function vectors $(\eta_1^A, \cdots, \eta_n^A)$ and $(\eta_1^B, \cdots, \eta_n^B)$, respectively, then their Minkowski sum $A \oplus B$ is specified completely by the vector $(\eta_1^A + \eta_1^B, \cdots, \eta_n^A + \eta_n^B)$.*

Proposition 5.6 implies that Minkowski addition of two convex polygons can be seen as the vector addition $h(A) + h(B)$ of two points $h(A)$ and $h(B)$ in an n-dimensional space.

Let us clarify the idea described so far by means of an example (Figure 5.6). As is evident from the example, Minkowski addition of two convex polygons is quite straightforward by means of the supporting function vector $h(A) + h(B)$.

From this observation, we can now define the "exact" inverse of Minkowski addition. In computing $A \ominus B$, we shall first compute the vector $h(A) + (-h(B))$. This vector, like the vector $h(A) + h(B)$, again specifies n half-spaces having outer normals u_i's, but some of the half-spaces may become redundant in this case. It then turns out that the Minkowski decomposition $A \ominus B$ discards those redundant half-spaces and considers the rest. Let us state this result as the following proposition.

Proposition 5.7. *If two convex polygons $A, B \in \mathcal{C}(U)$ are represented by the supporting function vectors $(\eta_1^A, \cdots, \eta_n^A)$ and $(\eta_1^B, \cdots, \eta_n^B)$, respectively, then their Minkowski decomposition*

(b) Realization of Minkowski sum

Figure 5.6 Minkowski addition by means of supporting function vectors: (a) convex polygons A and B whose $u = (u_1, u_2, u_3, u_4)$; (b) the realization of the Minkowski sum from its supporting vector specification in terms of intersection of half-spaces, and then conversion of the sum polygon in terms of vertices and edges

$A \ominus B$ can be obtained by discarding the redundant half-spaces specified by the vector $(\eta_1^A - \eta_1^B, \cdots, \eta_n^A - \eta_n^B)$.

The novelty of our approach lies in our treatment of *not discarding* those redundant half-spaces, but retaining them as essentials.

We will show the principle of computation of the Minkowski decomposition by using the supporting function vectors in Figure 5.7. In computing the decomposition $A \ominus B$ as $h(A) + (-h(B)) = (\eta_1^A - \eta_1^B, \cdots, \eta_n^A - \eta_n^B)$ (in Figure 5.7(a)), note that one of the half-planes – namely, the half-plane corresponding to the outer normal u_1 – is redundant. Figure 5.7 Minkowski decomposition by means of supporting function vectors: (a) the support function vector $h(A) + (-h(B))$ in terms of half-spaces, and then conversion of the half-spaces in terms of vertices and edges (which produces a self-crossing polygon); (b) the removal of redundant half-spaces – A and B are given in Figure 5.6

custom is to abandon this redundant half-plane altogether in further considerations. This effectively means an appropriate reduction of the corresponding value of the supporting function in the supporting function vector $h(A) + (-h(B))$. In our example, the corresponding supporting function value $\eta_1^A - \eta_1^B = 5$ has been reduced to 3 (see Figure 5.7(b)). This clearly explains why, in general, $(A \ominus B) \oplus B \subseteq A$.

5.5.2 *Computation by Means of Edges: The Emergence of the Boundary Addition Operation* $\uplus$

Representing a convex polygon A by means of its supporting function vector $h(A)$ is not a very common practice. A more popular representation is the *edge length* representation, where the boundary ∂A is represented by means of a starting vertex v_s^A and the length ι_i^A of the edge corresponding to every u_i; that is, $\partial A = \left\{ \{v_s^A\}, \{\iota_1^A, \cdots, \iota_n^A\} \right\}$. From the $h(A)$-representation, it is easy to arrive at the edge length representation by finding the intersection points of adjacent half-spaces (see the right-hand plots in Figures 5.6(b) or 5.7(a)).

If the other summand B is also represented in a similar way; that is, $\partial B = \left\{ \{v_s^B\}, \{\iota_1^B, \cdots, \iota_n^B\} \right\}$, then by a straightforward computation we get

$$h(A) + h(B) = \left\{ \{v_s^A + v_s^B\}, \{\iota_1^A + \iota_1^B, \cdots, \iota_n^A + \iota_n^B\} \right\}. \tag{5.13}$$

Equation (5.13) states that the boundary $\partial(A \oplus B)$ of the Minkowski sum of two convex polygons can easily be computed when the boundaries ∂A and ∂B are represented in their edge length forms. The computation essentially involves *addition of the lengths of the corresponding edges of the summands.* This operation may be termed the boundary addition operation and denoted by the symbol "$\uplus$." Equation (5.13) can, therefore, be rewritten as

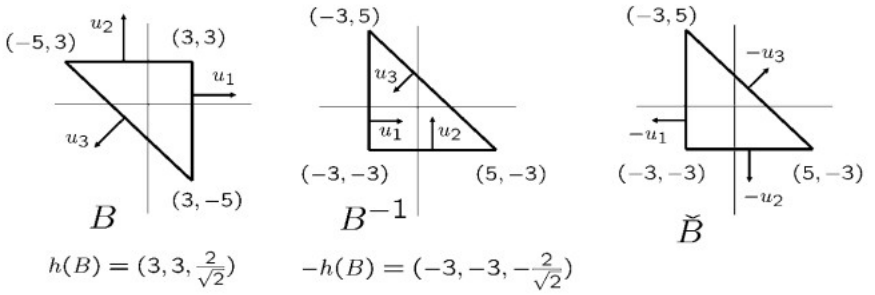
$$\begin{aligned} \partial(A \oplus B) &= \partial A \uplus \partial B \\ &= \left\{ \{v_s^A + v_s^B\},\ \{\iota_1^A + \iota_1^B, \cdots, \iota_n^A + \iota_n^B\} \right\}. \end{aligned} \tag{5.14}$$

For computing Minkowski decomposition, we convert the support function vector $-h(B)$ into the equivalent edge length representation, which turns out to be

$$-h(B) = \left\{ \{-v_s^B\},\ \{-\iota_1^B, \cdots, -\iota_n^B\} \right\}.$$

The polygon represented by $-h(B)$, if drawn pictorially, looks like a hole or a *negative region*, without any positive region surrounding the hole (Figure 5.8(b)). This is because, for any ordinary convex polygon (Figure 5.8(a)), all the outer normals u_i's "diverge outward," whereas the normals u_i's of $-h(B)$ appear to "converge inward"; but the *directions* of the normals remain exactly the same in both cases. We can distinguish these two cases by introducing the concept of the "sense" of the outer normals. The outer normals of ordinary convex objects, which diverge outward, can be thought of as having a "positive" sense; whereas the normals of $-h(B)$ have a "negative" sense. We can consider the polygon represented by $-h(B)$ as the additive inverse of the polygon B, and we can denote it by the symbol B^{-1}.

As far as the geometric shape is concerned, B^{-1} appears exactly like the symmetrical set $\check{B}$. But note the differences among the objects B, $\check{B}$, and B^{-1}. The sense of every outer normal of both B and $\check{B}$ is the same – that is, positive – while the directions of the outer normals at the corresponding faces of the two objects are exactly opposite. Because of the positive sense of the outer normals, we consider both B and $\check{B}$ as positive objects. On the contrary, the directions of the outer normals at the corresponding faces of B and B^{-1} are exactly the same, but the senses are opposite. Because of the negative sense of the outer normals, B^{-1} can be considered as a negative object.



(a) Ordinary B polygon

(b) Additive inverse B^{-1} polygon

(c) $\breve{B}$: Symmetrical set of B

Figure 5.8 (a) The ordinary B polygon; (b) a geometric interpretation of the inverse shape B^{-1}; and (c) for comparison, the symmetrical set of B, $\breve{B}$

Using the notation of boundary addition, we can write

$$h(A) + (-h(B)) \equiv \partial A \uplus \partial B^{-1} = \left\{ \{v_s^A - v_s^B\}, \{\iota_1^A - \iota_1^B, \cdots, \iota_n^A - \iota_n^B\} \right\}. \tag{5.15}$$

Since $h(A) + (-h(B))$ may contain redundant half-spaces, the polygon represented by $\partial A \uplus \partial B^{-1}$ will be, in general, a self- crossing polygon (see the right-hand plot in Figure 5.7(a)). With regard to the senses of the outer normals, a self-crossing polygon may appear to have both a positive part and a negative part (the negative part is shown shaded in Figure 5.7(a)). Since we obtain $A \ominus B$ from $h(A) + (-h(B))$ by discarding the redundant half-spaces, equivalently $\partial(A \ominus B)$ is obtained from $\partial A \uplus \partial B^{-1}$ by discarding the negative part of the polygon $\partial A \uplus \partial B^{-1}$, and considering only its positive part. This can be expressed symbolically as

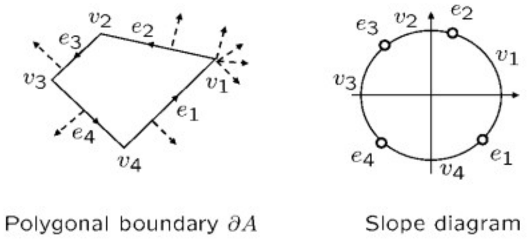
$$\partial(A \ominus B) = \mathrm{Pos}(\partial A \uplus \partial B^{-1}), \tag{5.16}$$

where $\mathrm{Pos}(X)$ denotes a unary operation, which extracts the positive portion of a self-crossing object X.

Note: In the case that we are only interested in the "shapes" of the objects, and not their positions in the plane, then the starting vertices v_s^A, v_s^B, and so on (which appeared in (5.14) and (5.15)) can be ignored.

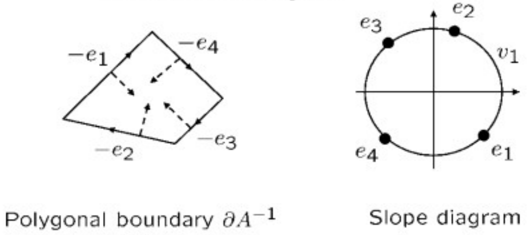
5.5.3 Computation by Means of Slope Diagrams: The Unification of Minkowski Addition and Decomposition

The *slope diagram* representation of a polygon is essentially the edge length representation in a pictorial form. Since all the outer normals u_i's of a convex polygon lie on a unit circle S^1, in slope diagram representation we consider a unit circle as the basis. The representation scheme is as follows (see Figure 5.9):



Polygonal boundary ∂A Slope diagram

(a) A typical convex polygon A and its slope diagram



Polygonal boundary ∂A^{-1} Slope diagram

(b) The inverse polygon A^{-1} and its slope diagram

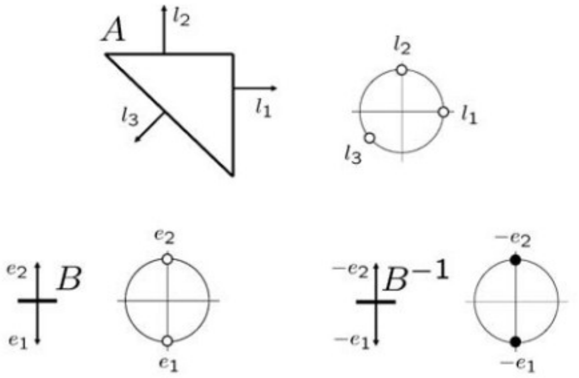
Figure 5.9 (a) A typical convex polygon A and its slope diagram; (b) the inverse polygon A^{-1} and its slope diagram

1. The outer normal direction at each edge of the polygon is represented by the corresponding point on a unit circle, which is called an *edge point*. (By "corresponding point," we mean that point on the unit circle where the outer normal direction is the same as the outer normal direction of the edge.)
2. At each vertex of the polygon, it is possible to draw innumerably many outer normals filling an angle (supplementary to the interior angle at the vertex). This set of outer normal directions at the vertex is represented by the corresponding arc on the unit circle, which is called a *vertex arc*.
3. Apart from the direction of an outer normal, the sense of the outer normal must also be indicated. If the sense of an outer normal is negative, it will be shown by heavy black points or arcs, while an outer normal that has a positive sense will be drawn using light lines.
4. The length of each edge is associated with its corresponding edge point, like a label.

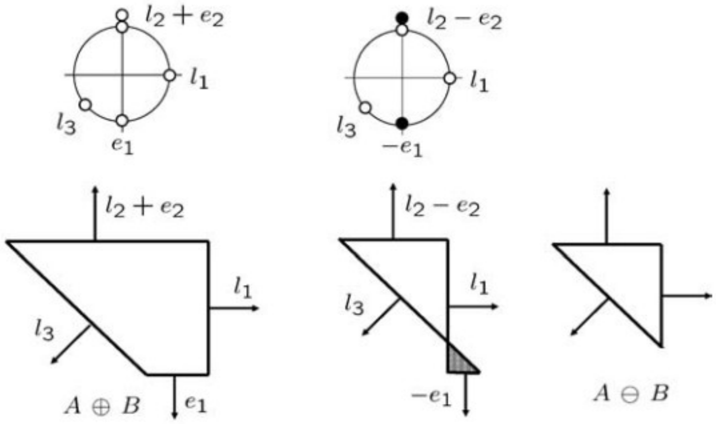
5.5.4 The Computation of Boundary Addition

The computation of $\partial A \uplus \partial B$ or $\partial A \uplus \partial B^{-1}$ (see (5.14) or (5.15); we will ignore v_s^A, v_s^B, etc. at present) by means of slope diagrams becomes quite straightforward:

1. *Merging of slope diagrams.* Merge the slope diagrams of the two operands (given in Figure 5.10(a)) into a single one.



(a) Operands A, B and its additive inverse, and the corresponding slope diagrams



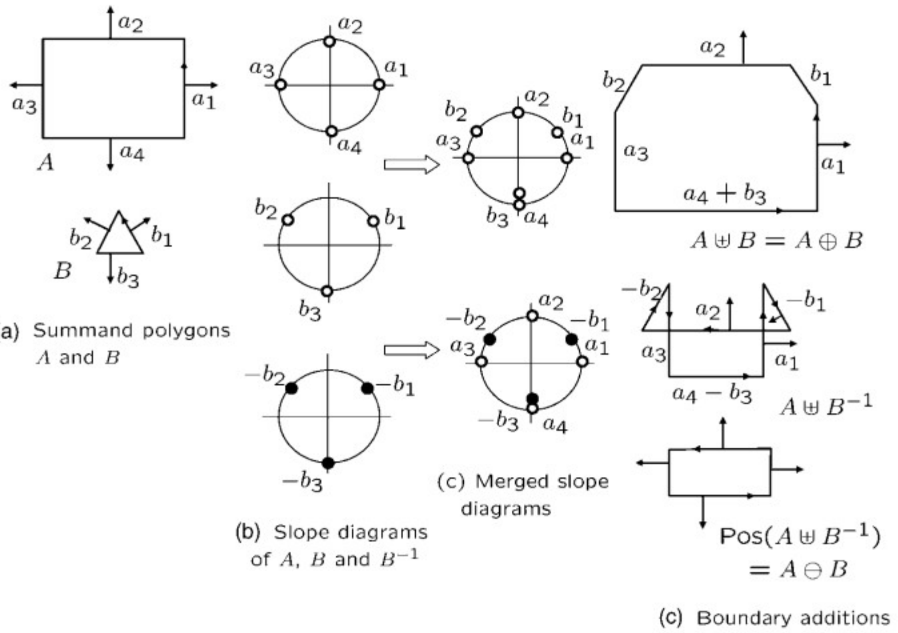
(b) Merged slope diagram of A and B and realization of $\partial A \uplus \partial B$

(c) Merged slope diagram of A, B^{-1} and $\partial A \uplus \partial B^{-1}$, and Minkowski decomposition $A \ominus B$

Figure 5.10 Minkowski addition and decomposition by means of slope diagrams – in this case, $\partial A \uplus \partial B = \partial(A \oplus B)$, but $\partial(A \ominus B) = \mathrm{Pos}(\partial A \uplus \partial B^{-1})$: (a) the operands A, B, and the additive inverse B^{-1}, and the corresponding slope diagrams; (b) the merged slope diagram of A and B and the realization of $\partial A \uplus \partial B$; (c) the merged slope diagram of A, B^{-1}, and $\partial A \uplus \partial B^{-1}$, and Minkowski decomposition $A \ominus B$

2. *Realization of the boundary sum.* From the merged slope diagram, realize the polygon that it represents. The term "realization" means "concatenation" of the edges (that is, joining the end-point of one edge to the start-point of the next edge) in the sequence in which they appear in the merged slope diagram (Figures 5.10(b) or (c)).

Another example of Minkowski addition and decomposition by means of slope diagrams is given in Figure 5.11. The realization/concatenation process may need some further clarification.



(a) Summand polygons A and B

(b) Slope diagrams of A, B and B^{-1}

(c) Merged slope diagrams

(c) Boundary additions

Figure 5.11 Another example of Minkowski addition and decomposition by means of slope diagrams: (a) summand polygons A and B; (b) the slope diagrams of A, B, and B^{-1}; (c) the merged slope diagrams; (d) the boundary additions

First, see (5.14), concerning Minkowski addition. In the merged slope diagram, two distinct cases may arise: (1) If two edge points of the summands occur at the same position of the unit circle, this means that both of the edges have the same outer normal direction. Therefore, concatenation of these two edges effectively means the addition of the lengths $\iota_i^A + \iota_i^B$ of the edges. (2) If one edge point of a summand lies on a vertex arc of the other summand, this means that the edge of the second summand has zero length at that outer normal direction. The addition of zero length simply involves consideration of the edge of the first summand, and that is precisely what we achieve by concatenation. Next, see (5.15), concerning Minkowski decomposition. Here, everything remains as before, except that some of the edge points (resulting from the B^{-1} polygon) in the merged slope diagram are black; that is, have negative sense. If the sense is negative, we have to subtract the corresponding length of the edge of B from that of A. Clearly, the subtraction of one directed edge from another simply involves reversing the direction of the former and then concatenating with the latter.

This slope diagrammatic approach clearly illustrates the following:

- Just as in real number arithmetic, instead of treating the division m/n as a separate operation, we can consider it as multiplication with the multiplicative inverse $\frac{1}{n}$, in a similar way, the Minkowski decomposition $\partial(A \ominus B)$ operation can also be viewed as addition with the *additive inverse* ∂B^{-1}.

- Just as in the system $(\mathbb{N}, \cdot, /)$, we do not obtain *closure* under the division operation. Therefore, we need to extend the number domain from $\mathbb{N}$ to the set of all positive rational numbers $\mathbb{Q}^+$ for the purpose of closure; and, similarly, to obtain closure under Minkowski decomposition it is necessary to extend the domain $\mathcal{K}$ of the ordinary convex objects – it is done here by introducing the concept of negative shape.
- Both Minkowski addition and decomposition can be reduced to a single operation $\uplus$: Minkowski addition involves boundary addition $\uplus$ of two positive (ordinary) objects, while Minkowski decomposition involves boundary addition of one positive and one negative object. Boundary addition, as we have shown, is essentially just addition of real numbers (representing the lengths of the edges of the operand polygons; those lengths may be positive or negative).
- Just as $\lfloor m/n \rfloor$ is obtained by discarding the fractional part of m/n, similarly $\partial(A \ominus B)$ is obtained by discarding the negative part of $\partial A \uplus \partial B^{-1}$.

5.6 In the Domain of Convex Polyhedra

One of the basic theses of this chapter is that Minkowski operations on three- or higher-dimensional boundary-represented objects in E^d eventually reduce to Minkowski operations on polygons in E^2, which, in turn, boil down to addition of real numbers. At present, we shall consider the case of polyhedral objects, though our approach is general enough to extend beyond three dimensions. The approach is to find relations for convex polyhedra that will be similar to (5.14) and (5.15), and then to resort to the slope diagrammatic technique, as we have done for convex polygons.

5.6.1 Computation by Means of Faces

The boundary of a convex polyhedron can be represented by means of vertices, edges, and facets. Our approach demands that these concepts are defined more precisely.

If, for some $u \neq 0$, we have $H(A, u) < \infty$ (this condition ensures that A is bounded), then the hyperplane

$$L(A, u) = \{\, p \in E^d \mid (p, u) = H(A, u)\}$$

is called the supporting hyperplane of A with *outer normal* u. In E^2, the supporting hyperplane becomes the supporting line of a convex polygon A with outer normal u, while in E^3 it is the supporting plane of a convex polyhedron A.

A face of A with outer normal u, denoted by $F(A, u)$, is then defined as

$$F(A, u) = L(A, u) \cap A.$$

Thus $F(A, u)$ is precisely that set of boundary points of A where the outer normal is either u or parallel to u. Now, considering all the directions of the E^d space as the directions of the outer normal u, the collection of the corresponding faces will describe the entire boundary of A. That is, the entire boundary of A can be described as $\partial A = \bigcup_{u \in S^{d-1}} F(A, u)$.

This notion of $F(A, u)$ is related to our conventional concept of the boundary of an object in terms of vertices, edges, faces, and so on in the following way. If A is a convex d-dimensional object, then $L(A, u)$ is a $(d-1)$-dimensional hyperplane. Therefore, $F(A, u)$ may have dimensions $0, 1, \cdots, (d-1)$. Normally, a face $F(A, u)$ of dimension r ($r = 0, 1, \cdots, (d-1)$) is called a *r-face* of A. A maximal proper face of A – that is, a $(d-1)$-dimensional face – is called a *facet* of A. Clearly, if A is a two-dimensional convex polygon, then $F(A, u)$ is either a 0-face (*vertex*) or an 1-face (*edge*). Since an edge of a polygon is a maximal proper face, it can also be called a facet of the polygon. When A is a three-dimensional convex polyhedron, in addition to being either a vertex or an edge, $F(A, u)$ may also be a 2-face (*facet*). (Note that, for three-dimensional objects, instead of "facet," the term planar "face" is more frequently used.)

From Theorem 5.5, it is not difficult to derive the following result [34, 50].

Theorem 5.8. *Let A and B be two convex polytopes in* E^d. *Then, for every* $u \in S^{d-1}$,

$$F(A \oplus B, u) = F(A, u) \oplus F(B, u). \tag{5.17}$$

Therefore, in terms of faces of the summands, the boundary $\partial(A \oplus B)$ can be expressed as

$$\begin{aligned} \partial(A \oplus B) &= \bigcup_{u \in S^{d-1}} F(A \oplus B, u) \\ &= \bigcup_{u \in S^{d-1}} \left(F(A, u) \oplus F(B, u)\right). \end{aligned} \tag{5.18}$$

Equation (5.18) will be our basis for computing Minkowski operations on convex polyhedra. We shall first argue that it is not necessary to compute $(F(A, u) \oplus F(B, u))$ for every $u \in S^2$ in the three-dimensional space. Just as a convex polygon is completely specified by its oriented edges, similarly a convex polyhedron is completely specified by its oriented facets (planar faces). Therefore, it is sufficient if we compute only the facets of $A \oplus B$, but not every $F(A \oplus B, u)$'s. As is evident from (5.18), the facets of $A \oplus B$ can be obtained in the following way:

1. *Minkowski addition of two facets.* Adding a facet of A to a facet of B; that is, $facet_A \oplus facet_B$.
2. *Minkowski addition of a facet and an edge.* Adding a facet of one of the two summands to an edge of the other; that is, $facet_A \oplus edge_B$ or $edge_A \oplus facet_B$.
3. *Minkowski addition of a facet and a vertex.* Adding a facet of one of the two summands to a vertex of the other; that is, $facet_A \oplus vertex_B$ or $vertex_A \oplus facet_B$.
4. *Minkowski addition of two nonparallel edges.* Adding nonparallel edges of A and B; that is, $edge_A \oplus edge_B$.

Here, the facets, edges, and vertices added in this way lie in supporting planes, with parallel outer normals.

Now, Minkowski addition of two facets that lie in supporting planes having parallel outer normals is equivalent to Minkowski addition of those facets lying in the same plane. That, in turn, is simply Minkowski addition of two convex polygons in E^2. The same is true for Minkowski addition of a facet and an edge, or the addition of two edges.

We depict a typical such addition in Figure 5.12. (In a similar way, we can continue further and show that Minkowski addition of two convex polytopes in E^d reduces to Minkowski addition operations in $E^{d-1}, \ldots,$ and eventually reduces to the Minkowski addition of convex polygons in E^2. This means that it finally reduces to addition of real numbers.)

In computing the Minkowski decomposition $A \ominus B$, exactly as in the polygonal case, the first step is to compute the boundary addition $\partial A \uplus \partial B^{-1}$, and then to determine its positive

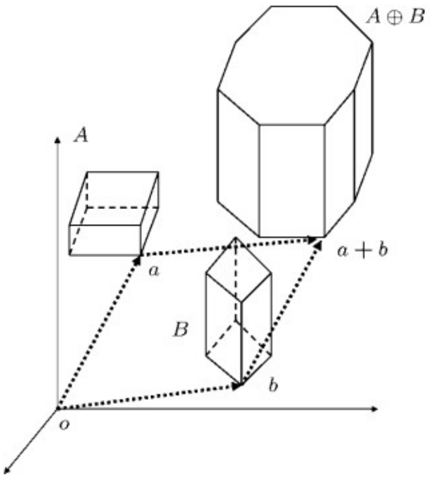


Figure 5.12 The computation of $\bigcup_{u\in S^{d-1}} (F(A,u) \oplus F(B,u))$ for two convex polyhedra A and B in E^3

portion $\mathrm{Pos}(\partial A \uplus \partial B^{-1})$. In terms of the faces of the operand polyhedra, the first step is to compute $\bigcup_{u\in S^{d-1}}(F(A,u) \oplus F(B^{-1},u))$. Therefore, according to our previous discussion, it will reduce to $\mathit{facet}_A \oplus \mathit{facet}_{B^{-1}}$, $\mathit{facet}_A \oplus \mathit{edge}_{B^{-1}}$ or $\mathit{edge}_A \oplus \mathit{facet}_{B^{-1}}$, $\mathit{facet}_A \oplus \mathit{vertex}_{B^{-1}}$ or $\mathit{vertex}_A \oplus \mathit{facet}_{B^{-1}}$, and $\mathit{edge}_A \oplus \mathit{edge}_{B^{-1}}$ (where they lie in supporting planes with parallel outer normals). As we have argued previously, each of these additions can first be reduced to the boundary addition of a positive and a negative convex polygon in E^2, which, in turn, reduces to subtraction of real numbers.

We present an example of a negative polyhedron, B^{-1}, in Figure 5.13(a). In Figure 5.13(b), we show the Minkowski decomposition of two convex polyhedra by means of boundary addition $\uplus$ and, thereafter, the Pos operation.

5.6.2 The Slope Diagram Representation of a Convex Polyhedron

The essential goal of the slope diagram representation of an object is to capture the behavior of the outer normals of the object in an explicit way. The behavior of the directions of the outer normals at various faces (that is, at the facets, edges, and vertices) of a convex polyhedron can be described as follows:

1. At each interior point of a facet of a polyhedron, there can be drawn only one outer normal.
2. At each point of an edge (different from a vertex), it is possible to draw an infinite number of normals filling a plane angle, which will be supplementary to the corresponding interior angle. (In some of the literature, this interior angle is called the *dihedral angle* corresponding to the edge. The exact definition is as follows: the dihedral angle corresponding to an edge is the angle between the planes of its two adjacent facets.)
3. At each vertex, it is possible to draw infinitely many outer normals that fill a solid angle (interpolating between the incident facet normals).

For the slope diagram of a polyhedron, we have to start with a unit sphere S^2.

(a) *Facet representation.* As in the polygonal case, each facet can be represented by the corresponding point on the unit sphere, which is referred to as a *facet point*.

(b) *Edge representation.* Each edge of the polyhedron, we claim, can be represented by the arc of the great circle joining the two facet points corresponding to the two adjacent facets of the edge. We call such an arc an *edge arc* of the polyhedron.

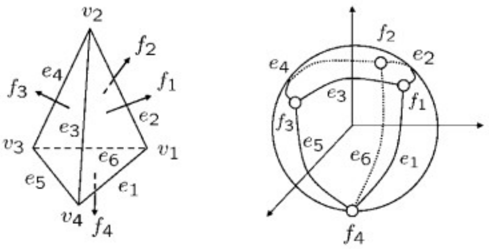
Note: The intersection of the surface of a sphere by a plane is called a great circle if the plane passes through the center of the sphere. Clearly, only one great circle can be drawn through two given points on the surface of the sphere, except when the points are the extremities of a diameter of the sphere. By the "arc of a great circle," we generally mean the shorter of the two arcs joining the two points.

(c) *Vertex representation.* According to the scheme, it easy to see that the directions of the outer normals at any vertex v of the polyhedron will be represented by a region on the unit sphere. This region is bounded by the edge arcs corresponding to the edges incident at v, and the vertices of this region are the facet points corresponding to the facets of the polyhedron incident at v. We call this a *vertex region*.

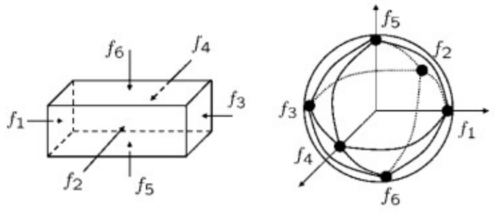
(d) To denote the sense of an outer normal and the length of an edge, we use the same conventions as adopted for polygons.

In Figure 5.14, we show the slope diagram representations of two convex polyhedra. The heavy lines and solid black dots in the diagrams indicate the negative sense of the outer normals.

Note: In Mount and Silverman [75] and Guibas and Seidel [36], we find notions that are similar in some ways to the idea of the slope diagram of a convex polyhedron. However, these authors did not take into account the notion of "sense" of a outer normal, which is crucial in our approach.



(a) Positive convex polyhedron



(b) Negative convex polyhedron

Figure 5.14 Two convex polyhedra and their slope diagram representations (not to scale): (a) a positive convex polyhedron; (b) a negative convex polyhedron

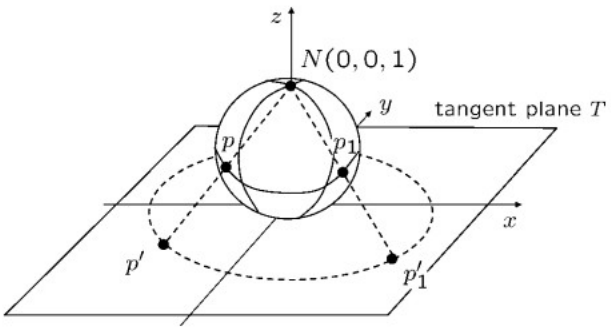


Figure 5.15 Transforming a three-dimensional slope diagram by stereographic projection on two dimensions

Since the slope diagram of a polyhedron is a three-dimensional figure, it may not be a very convenient representation to deal with for the purpose of intuitive understanding and visualization. Therefore, we transform this representation into an equivalent two-dimensional form by means of the *stereographic projection.* As shown in Figure 5.15, the stereographic projection is a projection of a sphere from one of the points N onto the plane T tangent to the sphere at the diametrically opposite point N'. The point N is called the *projection center.*

The transformation equations for the stereographic projection are given in many standard texts, such as [88]. Consider a unit sphere whose center o is at the origin, and the projection center N for which is located on the $o - z$ axis (see Figure 5.15). In this case, the point N has the coordinates (0, 0, 1) and the projection plane T is the plane $z = -1$. Let the point $p(x, y, z)$ of the sphere be projected stereographically into the point $p'(x', y', -1)$ of the plane T. Then the coordinates of the point p, corresponding to the point p', are equal to

$$x = \frac{4x'}{x'^2 + y'^2 + 4},$$

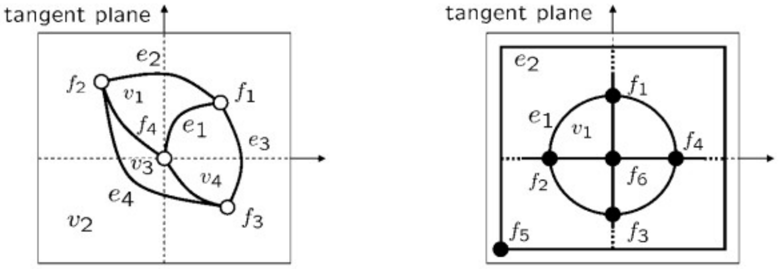
$$y = \frac{4y'}{x'^2 + y'^2 + 4},$$

$$z = \frac{x'^2 + y'^2 - 4}{x'^2 + y'^2 + 4}.$$

The inverse mapping – that is, the coordinates of the point p', corresponding to the point p – is equal to

$$x' = \frac{2x}{1 - z}, \quad y' = \frac{2y}{1 - z}, \quad z' = -1.$$

From the above equations, we find that if p is the projection center itself – that is, $p = (0, 0, 1)$ – then we have difficulty in computing x' and y'. This difficulty is circumvented by extending the plane T by an "ideal" point, which is called the *point at infinity*.



(a) Projected slope diagram of a positive tetrahedron

(the regions denote vertices, the arcs denote edges, and the vertex points denote facets).

(b) Projected slope diagram of a negative parallele-piped

(black dots denote facets ; the faset point f_5 is projected on the point at infinity).

Figure 5.16 Stereographic projections of the slope diagrams of the convex polyhedra depicted in Figure 5.14 (not to scale): (a) the projected slope diagram of a positive tetrahedron (the regions denote vertices, the arcs denote edges, and the vertex points denote facets); (b) the projected slope diagram of a negative parallelepiped (black dots denote facets – the facet point f_5 is projected on the point at infinity)

In the stereographic projection of a slope diagram, any facet point at (x_1, y_1, z_1) will be projected onto the point (x_1', y_1') of the T-plane; the point (x_1', y_1') can be determined using the above equations. Any edge arc will be projected either as a straight line or a circular arc. An edge arc joining two facet points (x_1, y_1, z_1) and (x_2, y_2, z_2) will be projected on the plane T as $(x_1y_2 - x_2y_1)(x'^2 + y'^2) + 4(y_1z_2 - y_2z_1)x' + 4(z_1x_2 - z_2x_1)y' - 4(x_1y_2 - x_2y_1) = 0$. This is the equation of a circular arc – unless $x_1y_2 = x_2y_1$, when it degenerates into a straight-line segment.

In Figure 5.16, we present the stereographic projections of the slope diagrams shown in Figure 5.14.

5.6.3 Computation by Means of Slope Diagrams

Assume that two convex polyhedra, A and B, are given in the form of their slope diagram representations. Exactly as in the polygonal case, the boundary addition computation involves two steps: (a) merging of slope diagrams of the operands, and (b) realization of the boundary sum from the merged slope diagram.

If we *merge* these two slope diagrams (that is, overlay both of the slope diagrams on the same unit sphere S^2), we can immediately identify the corresponding $F(A, u)'$s and $F(B, u)'$s (or $F(B^{-1}, u)'$s in the case of decomposition) that have the same outer normal direction u, because they will occupy the same positions on the sphere. This means that *wherever there are intersections between two slope diagrams, the corresponding faces of the operands need to be added (or subtracted).*

To *realize* the boundary sum $\partial A \uplus \partial B$ or $\partial A \uplus \partial B^{-1}$ from the merged slope diagram, we have to identify only the facet points of the boundary sum. Any facet point will be created in one of the following ways: (a) the intersection of a facet point of one operand with that of the

other, which means *addition of two facets*; (b) the intersection of a facet point of one operand with an edge arc of the other, which means *addition of a facet and an edge*; (c) the intersection of a facet point of one operand with a vertex region of the other, which means, *addition of a facet and a vertex*; or (d) the intersection of an edge arc of one operand with a nonparallel edge arc of the other, which means *addition of two nonparallel edges*.

In the case of Minkowski decomposition, if $\partial A \uplus \partial B^{-1}$ turns out to be a self-crossing polyhedron (as shown in Figure 5.13(b)), we have to discard the negative portion and consider only the positive portion.

In Figure 5.17, we demonstrate computation by means of slope diagrams through an example of addition of a rectangular plane (A) that is parallel to the xz-plane to another rectangular plane (B) parallel to the yz-plane. The resulting sum shape $A \oplus B$ will be a rectangular parallelepiped.

Here, α is the angle between the directions (ϑ, φ) and (ϑ', φ'). Denoting the corresponding unit vectors by $\boldsymbol{\omega}$ and $\boldsymbol{\omega}'$, we have $\cos\alpha = \boldsymbol{\omega} \cdot \boldsymbol{\omega}'$.

In Cartesian coordinates (x, y, z), with $r = (x^2+y^2+z^2)^{1/2}$, the spherical harmonics are (for $m \geq 0$)

$$Y_\ell^m(x, y, z) = \sqrt{\frac{2\ell+1}{4\pi}\frac{(\ell-m)!}{(\ell+m)!}} \left(\frac{x+\mathrm{i}y}{\sqrt{x^2+y^2}}\right)^m P_\ell^m\left(\frac{z}{r}\right). \tag{1.112}$$

For example,

$$Y_0^0 = \frac{1}{\sqrt{4\pi}}, \quad Y_1^0 = \sqrt{\frac{3}{4\pi}}\,\frac{z}{r}, \quad Y_1^{\pm 1} = \mp\sqrt{\frac{3}{8\pi}}\,\frac{x \pm \mathrm{i}y}{r}. \tag{1.113}$$

1.7. Particle on a Sphere

1.7.1. Classical particle on a sphere

Here, we consider a quantum mechanical system that is only able to perform a rotational motion. Imagine a particle with mass[4] m whose motion is restricted to the surface of a sphere. There are no other forces. This particle has two degrees of freedom, its position on the sphere is given by two angular coordinates, the longitude and the latitude, described by the angles ϑ and φ. A classical particle subject to these constraints will move along the geodesics of the sphere (great circles) with constant (angular) velocity. Its kinetic energy is given by

$$E = \frac{1}{2}\mathrm{m}v^2 = \frac{1}{2}\mathrm{m}(r\omega)^2 = \frac{1}{2}I\omega^2, \tag{1.114}$$

where we have introduced the angular speed $\omega = v/r$ and the moment of inertia

$$I = \mathrm{m}r^2. \tag{1.115}$$

The angular momentum of a particle moving with velocity v on a sphere of radius r is $L = \mathrm{m}vr$, or $v = L/\mathrm{m}r$. Insert this into the expression for the energy to obtain

$$E = \frac{L^2}{2\mathrm{m}r^2} = \frac{L^2}{2I}. \tag{1.116}$$

CD 1.2.1, CD 1.5.4, and CD 1.6.3 are all visualizations of the classical motion at a fixed distance from the coordinate origin.

---

[4] It is general custom to denote the mass of the particle and the eigenvalue of L_3 by the same letter. Usually there is little danger of confusion. To be on the safe side, we denote the mass by the roman letter m and use the italic letter m for the eigenvalue of L_3.

1.7.2. The rigid rotator

The particle on a sphere is a mathematical model for the rigid rotator. Consider two point-like particles of mass m_1 and m_2 that are connected by a weightless, rigid rod of length r. Denote by $\mathbf{x} = \mathbf{x}_2 - \mathbf{x}_1$ the vector pointing from m_1 to m_2. The position of the center of mass is given by

$$\mathbf{X} = \frac{\mathrm{m}_1\mathbf{x}_1 + \mathrm{m}_2\mathbf{x}_2}{\mathrm{m}_1 + \mathrm{m}_2} \tag{1.117}$$

The distances of the particles from the center of mass are therefore

$$r_1 = |\mathbf{x}_1 - \mathbf{X}| = \frac{\mathrm{m}_2\, r}{\mathrm{m}_1 + \mathrm{m}_2}, \quad r_2 = |\mathbf{x}_2 - \mathbf{X}| = \frac{\mathrm{m}_1\, r}{\mathrm{m}_1 + \mathrm{m}_2}. \tag{1.118}$$

If we are only interested in the internal motion of the two-particle system, we can choose a coordinate system that has its origin at the center of mass. In this coordinate system, the moment of inertia of the rotator is thus

$$I = \mathrm{m}_1 r_1^2 + \mathrm{m}_2 r_2^2 = \frac{\mathrm{m}_1\mathrm{m}_2}{\mathrm{m}_1 + \mathrm{m}_2}\, r^2. \tag{1.119}$$

This is precisely the moment of inertia of a particle with mass

$$\mu = \frac{\mathrm{m}_1\mathrm{m}_2}{\mathrm{m}_1 + \mathrm{m}_2} \tag{1.120}$$

at a distance r from the origin. Thus, we can replace the two-particle system with an effective one-particle system. This particle has the so-called *reduced mass* μ and the fixed distance r from the origin, that is, it is a particle on a sphere with radius r.

This is a good model for a diatomic molecule. It consists of two atoms that can oscillate along the line connecting their centers and rotate around the center of mass. The vibrational motion is much faster than the rotational motion. So, the vibrations belong to much higher energies. Quantum mechanically, oscillation states have a quantized energy. As long as the diatomic molecule is in its vibrational ground state, it is a rigid rotator.

1.7.3. Transition to quantum mechanics

In order to define the quantum mechanical Hamiltonian for a particle that is constrained to the surface of a sphere, we start with the classical expression (1.116) for the energy. From this, the Hamiltonian operator of the rigid rotator is obtained by replacing L^2 with the quantum mechanical angular-momentum operator. Note that r, the radius of the sphere, is treated as a fixed parameter. Using the expression (1.91) for the angular momentum in spherical coordinates, we arrive at

$$\hat{H} = \frac{1}{2\mathrm{m}\, r^2}\, \hat{L}^2 = \frac{1}{2I}\, \hat{L}^2. \tag{1.121}$$

The operator $\hat{L}^2$ has a discrete spectrum of eigenvalues, therefore the same is true for the energy of the rotator.

Eigenvalues of the rigid rotator:

A particle with mass m on a sphere with radius r can only have the energies

$$E_\ell = \frac{\hbar^2}{2\mathrm{m}r^2}\,\ell(\ell+1), \quad \ell = 0, 1, 2, 3, \ldots. \tag{1.122}$$

Each eigenvalue E_ℓ has the multiplicity $2\ell+1$, that is, there are $2\ell+1$ orthogonal wave functions all belonging to the eigenvalue E_ℓ:

$$\psi_{\ell,m}(\vartheta,\varphi) = \frac{1}{r}\,Y_\ell^m(\vartheta,\varphi), \quad m = -\ell, -\ell+1, \ldots, \ell. \tag{1.123}$$

It follows from (1.109) that

$$\int_{S_r^2} \bigl|\psi_{\ell,m}(\vartheta,\varphi)\bigr|^2\, r^2\, \sin\vartheta\, d\vartheta\, d\varphi = 1. \tag{1.124}$$

The factor $1/r$ in (1.123) thus guarantees that the eigenfunctions are normalized on the sphere with radius r. We conclude that the eigenfunctions form an orthonormal basis in the Hilbert space $L^2(S_r^2)$ of square integrable functions on the sphere of radius r.

We want to stress that $\hat{L}^2$ is part of any single-particle Hamiltonian, because it appears in the angular part of the kinetic energy in spherical coordinates (see (1.150) below). For a particle constrained to the surface of a sphere, the operator $\hat{L}^2$ plays the same role as the operator $-\hbar^2\Delta$ for a particle in $\mathbb{R}^3$: It is proportional to the kinetic energy and it generates the free time evolution. (In fact, $\hat{L}^2/\hbar^2$ is the so-called Laplace-Beltrami operator of the sphere.) The action of the free time evolution $\exp(-\mathrm{i}\hat{L}^2 t/2I)$ on a sphere will be discussed next.

1.7.4. Dynamics of the rigid rotator

The time evolution of an eigenfunction of the rigid rotator Hamiltonian is rather trivial. If $\psi_{\ell,m}(\vartheta,\varphi)$ is an eigenfunction belonging to the eigenvalue E_ℓ, then the function

$$\psi_{\ell,m}(t,\vartheta,\varphi) = \exp(-\mathrm{i}E_\ell\, t)\,\psi_{\ell,m}(\vartheta,\varphi) \tag{1.125}$$

is a solution of the time-dependent Schrödinger equation. The ground state of the rigid rotator has energy $E_0 = 0$, and hence the corresponding wave function does not depend on time at all.

The fact that the Schrödinger equation is linear means that we can consider linear combinations of eigenfunctions. For example, for the initial function $\psi_0(\vartheta,\varphi) = \sum_{\ell,m} c_{\ell,m}\,\psi_{\ell,m}(\vartheta,\varphi)$, the time evolution is

$$\psi(t,\vartheta,\varphi) = \sum_{\ell,m} c_{\ell,m}\,\exp(-\mathrm{i}E_\ell\,t)\,\psi_{\ell,m}(\vartheta,\varphi) \tag{1.126}$$

and this clearly gives us the solution for any initial function that is square integrable on the sphere, because the set of functions $\psi_{\ell,m}$ forms an orthonormal basis in $L^2(S^2_r)$.

Given any initial function ψ_0, the expansion coefficient $c_{\ell,m}$ can be found by an integration,

$$c_{\ell,m} = \int_{S^2_r} \overline{\psi_{\ell,m}(\vartheta,\varphi)}\,\psi_0(\vartheta,\varphi)\,r^2\,d\Omega \tag{1.127}$$

(with $d\Omega = \sin\vartheta\,d\vartheta\,d\varphi$). It is remarkable that all nonzero energies $E_\ell = \ell(\ell+1)/2I$ are integer multiples of $E_1 = 1/I$, hence all time-dependent factors $\exp(-\mathrm{i}E_\ell\,t)$ have the same basic time period. Hence, any state of the rigid rotator is periodic in time.

For the unit sphere ($r = 1$), we summarize our results in the following box.

Time evolution of the rigid rotator:

For a particle with mass m = 1 on the unit sphere S^2 the time evolution of any square-integrable initial function $\psi_0(\vartheta,\varphi)$ is given by the formula

$$\psi(t,\vartheta,\varphi) = \sum_{\ell,m} c_{\ell,m}\,\exp(-\mathrm{i}E_\ell\,t)\,Y_\ell^m(\vartheta,\varphi) \tag{1.128}$$

with

$$c_{\ell,m} = \int_{S^2} \overline{Y_\ell^m(\vartheta,\varphi)}\,\psi_0(\vartheta,\varphi)\,d\Omega. \tag{1.129}$$

The time evolution of the wave function is periodic in time,

$$\psi(t+T,\vartheta,\varphi) = \psi(t,\vartheta,\varphi) \quad \text{with period} \quad T = 2\pi. \tag{1.130}$$

CD 1.9–CD 1.12 is a collection of several movies showing various time-dependent states of the rigid rotator. CD 1.13 visualizes the time evolution of initially well-localized (Gaussian) states. In CD 1.14, the initial state has roughly the shape of the letter Ψ. This illustrates that we can indeed compute the time evolution of any square-integrable initial function on the sphere.

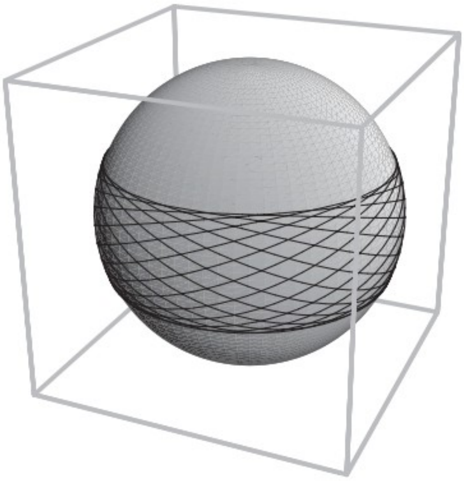

FIGURE 1.9. Possible trajectories of classical particles on a sphere. For all trajectories, the angular-momentum vector has $|\mathbf{L}| = \sqrt{\ell(\ell+1)}$, with $\ell = 6$ and $L_3 = 6$.

1.8. Quantization on a Sphere

1.8.1. Comparison of classical and quantum probability densities

Figure 1.9 shows a set of classical trajectories of particles for which the angular momenta have a fixed absolute value $|\mathbf{L}| = L$ and a fixed value of the third component L_3. The admissible positions of classical particles with these angular momenta form the classically allowed region on the sphere. This region is determined by the polar angle of the classical angular-momentum vector. We denote the polar angle of $\mathbf{L}$ by θ in order to distinguish it from the polar angle ϑ of the particle's position vector, see Figure 1.10.

Assuming $L_3 = m$, we find that the polar angle of $\mathbf{L}$ is

$$\theta = \arccos\left(\frac{m}{L}\right) \tag{1.131}$$

and hence the classically allowed region for the position of the particle is between the polar angles

$$\vartheta_{\min} = \pi/2 - \theta, \qquad \vartheta_{\max} = \pi/2 + \theta. \tag{1.132}$$

All the classical trajectories are grand circles of the sphere. The particles move on these circles with a constant angular velocity. When a particle circles around the sphere, the polar angle ϑ performs a periodic motion

Force between Nucleons

3.1 INTRODUCTION

Considering the mass of a nucleus proportional to the number of nucleons in it and the radius equal to $r_0A^{1/3}$, it is easy to calculate the density for the nuclear matter of a spherical nucleus to be of the order of 10^{17} kg/m^3. In addition, the density of the densest metal, mercury, is of the order of 10^{10} kg/m^3. The very large difference, of the order of 10^7, between the density of nuclear matter and the ordinary matter indicates two facts: (1) the ordinary matter contains large volumes of empty spaces, (2) the force responsible for the binding nucleons inside a nucleus is very much stronger than and may be very different from the forces responsible for the binding of ordinary matter.

3.2 INADEQUACY OF CLASSICAL FORCES

On the first point, it may be mentioned that the ordinary matter is made of molecules and atoms. There is large vacuum in an atom around the nucleus in which electrons revolve and the intra-atomic spaces in a molecule are also empty. With regard to the second point, the forces that bind atoms and molecules in ordinary matter are largely electrical forces and to a much lesser extent gravitational and magnetic forces. It may be remembered that the range, the distance up to which the effect of the force can be felt, of all the three forces (also called classic forces) extends up to very large distances essentially up to infinity. Scattering and other experiments have indicated that the range of the force responsible for the binding of nucleons in nucleus is very small of the order of 2×10^{-15} m or 2 F. Very short-range nuclear force is a major point of difference between the classical and nuclear forces. Another difference is the manner in which atomic electrons are bound in an atom and the binding of nucleons in a nucleus. In an atom, the central positively charged nucleus produces an electric field spreading up to a large distance and electrons, relatively far away from the centre of force, are held in stationary orbits. Electrons are held at relatively weaker part of the central electric field, which is apparent from the fact that the binding energies of outer (valence) electrons are only of the order of few electron volts. The inner electrons in an atom are also not very strongly bound, their binding energies being of the order of few keV. By contrast, in a nucleus there is no source that may produce a central field; nucleons exert force on each other to bind themselves strongly, B/A of the order of 8 MeV. Such a large binding force between two nucleons cannot be provided by classical forces, as the gravitational attraction between two nucleons (a proton and a neutron) at a separation of 2 F may give a potential energy which is at least 10^{36} orders of magnitude smaller than the binding energy of nucleons. There is no question of electrostatic force of attraction between nucleons as neutron has no electric charge and protons will repel each other. A force of magnetic nature may come into play between two nucleons because of their magnetic dipole moments. However, this force will have opposite nature when the two nucleons have parallel and anti-parallel spins. Also, critical analysis of the data on the separation energies of the last nucleon from various nuclei has indicated that the nuclear force between nucleons is attractive for both the anti-parallel and parallel spin orientations. In view of this, classical forces are totally inadequate to provide the strong binding to nucleons in a nucleus.

One way to understand nuclear structure is to start with the force between two nucleons, find a potential for the nucleon–nucleon interaction, develop a structure for the nucleon consistent with the potential, and extend it to construct the nuclear structure. The first step in this approach is to find the properties of nucleon–nucleon force.

Exercise p-3.1: Calculate the gravitational potential energy between two protons at 2 F apart.

Exercise p-3.2: Calculate the electrical potential energy between two protons held 2 F apart.

3.3 TWO-BODY NUCLEON–NUCLEON FORCE

If it is assumed that nucleons exert force on each other in pairs, then the following nucleon pairs are possible: (n–n), (p–p), and (n–p). As both neutron and the proton have intrinsic spins S_n and S_p $(=\frac{1}{2}\hbar)$, there are two possibilities for the spin orientations of the two nucleons of the pair. The first possibility is that the spins are parallel making the total angular momentum (j) of the pair 1 $\hbar$ with three possible values of $m_j = 1, 0, -1$. The parallel spin state is, therefore, called the *triplet state* and is denoted by superscript 3. The second possibility is that the spins of the nucleons in the pair are anti-parallel, making the j of the pair zero, and only single possible value for $m_j = 0$. The system with anti-parallel spins is called *singlet state* and is denoted by superscript 1. In view of this, there are six possible states of a two-nucleon system: ^{1}(n–n), ^{1}(p–p), ^{1}(n–p), ^{3}(n–n), ^{3}(p–p), ^{3}(n–p). States ^{3}(n–n) and ^{3}(p–p) are disallowed by Pauli exclusion principle, which states that no two identical fermions can have identical quantum numbers. It may, however, be noted that ^{3}(n–p) state is allowed. (Can you tell which quantum number is different for neutron and proton?) As such only four pairs, three singlet, and one triplet states are left for consideration. The forces corresponding to these states may be denoted by $F_{1(n-n)}$, $F_{1(p-p)}$, $F_{1(n-p)}$, and $F_{3(n-p)}$. A word of caution about $F_{1(p-p)}$ is that it is the specific nuclear force between two protons and does not contain the Coulomb repulsive force, which is in addition to the nuclear force but of very small magnitude as compared with it.

Information about the nucleon–nucleon (n–n) force may be obtained from (1) the systematic of the separation energies of last nucleon in light nuclei, (2) level scheme of mirror nuclei, (3) study of the properties of deuteron, (4) nucleon–nucleon scattering data, and the (5) constant density of nuclear matter.

3.3.1 Separation Energy of the Last Nucleon in Light Nuclei

Energy required to take out the outermost neutron (or proton) from the nucleus is called the separation energy of last neutron (or proton) and is denoted by S_n (or S_p).

$$S_n(Z, N) = [M(Z, N-1) + M_n - M(Z, N)]c^2 \quad \text{and} \quad S_p(Z, N) = [M(Z-1, N) + M_p - M(Z, N)]c^2$$

Here, M represents the mass of the nucleus having neutrons and protons as specified in the bracket, M_n and M_p, respectively, the neutron and the proton masses. The multiplication with c^2 is done to convert mass into energy. The c^2 term can be dropped if masses are given in the unit of energy (MeV) and the nuclear mass may be replaced by the corresponding atomic mass without much error as electron mass ultimately cancels out. Replacement of nuclear masses by atomic masses only brings in some negligible error due to the difference in the electron binding energies in the two atoms. Alternatively, S_n and S_p can also be given in terms of the binding energies of the two nuclei.

$$S_n(Z, N) = B(Z, N) - B(Z, N-1) \text{ and}$$
$$S_p(Z, N) = B(Z, N) - B(Z, N-1)$$

To confine a particle within a given space, the de Broglie wavelength of the particle must be of the order of the size of the space. This condition puts a limit on the minimum energy of the particle for confinement in the limited space. For example, to confine a nucleon inside a nucleus of size of the order of 10^{-14} m, the minimum kinetic energy T of the nucleon must be of the order of 20 MeV. This implies that inside the nucleus a nucleon is in a potential well of depth V larger than 20 MeV as shown in figure 3.1. The separation energy $S = (V - T)$. The depth of the potential V must not be less than ≈30 MeV, considering the average binding energy of nucleon to be around 8 MeV.

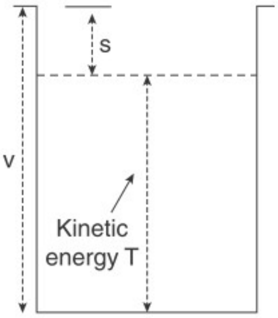

Figure 3.1 *Nuclear potential well and the nucleon separation energy*

An analogous quantity in atomic case is the binding energy of the last valance electron. The binding energy of valance electron in an atom shows cyclic variation. This is attributed to the electronic shell closure. Once a given shell is completely filled, the binding of the next electron becomes very weak. Similar cyclic variation is exhibited by S_n and S_p. This and some other systematic trends observed in stable nuclei, such as the extra stability associated with nuclei having the number of neutrons or/and protons equal to the magic numbers 2, 8, 20, 28, 50, 82, 126, and so on, indicates that nucleons inside the nucleus move in some sort of shell structure. Shell structure in atomic case is the outcome of confining particle in a central field. In case of the nucleus, there is no central field as such. To explain the apparent shell structure, it is assumed that all the nucleons inside a nucleus produce a mean central field in which each nucleon moves independently. This is the basis of the independent or single-particle model of the nucleus. The motion of nucleons in single particle approach may be grouped into states of different angular moment l. The experimental data on S_n and S_p states the following:

1. Only nucleons in the same l state (have no relative angular momentum relative to each other with even parity) exert force on each other. Interaction between nucleons in states of different orbital angular momentum is insignificant.
2. In the case of lightest nuclei, ${}^2_1$H, ${}^3_1$H, and ${}^4_2$He, the S_n increases from 2.2 to 5.4 to ≈20 MeV. Similarly, for ${}^6_3$Li, ${}^7_3$Li, and ${}^8_4$Be, S_n increases from 5.4 to 7.2 to ≈18.1 MeV. Similar trends are also observed for S_p. For example, for ${}^2_1$H, ${}^3_2$He, and ${}^4_2$He, S_p increases from 2.2 to 5.2 to 20 MeV. Systematic observations of the above-mentioned type shows that in light

nuclei neutron is less bound in case N is odd, neutron binding increases if the number of neutrons become even and it becomes maximum when the both number of neutron and proton are even. Similarly, S_p is less for odd Z, nucleus is larger in even–odd nucleus and attains maximum value for even–even nuclei. The tight binding of the last neutron or proton when the number of neutrons or protons in the nucleus is even provided the concept of some additional energy associated with the pair of the same kind. This is called the pairing energy and is denoted by δ_n or δ_p, respectively, for the neutron and the protons. Neutron and proton pairing energies are defined as

$$\delta_n = \frac{1}{2}[S_n^{(\text{even-}N)} - S_n^{(\text{odd-}N)}] \quad \text{and} \quad \delta_p = \frac{1}{2}[S_p^{(\text{even-}P)} - S_p^{(\text{odd-}P)}]$$

The magnitudes of S_n and S_p in odd-N and even-Z, and in even-N and odd-Z light nuclei are almost equal. In addition, the magnitudes of δ_n and δ_p are also nearly equal in light nuclei. In the case of heavy nuclei, similar trend in S_n and S_p values have been observed, particularly for nuclei near magic numbers, but they are less pronounced.

These close similarities in separation energies and pairing energies for neutrons and protons suggest that fundamentally the force between any pair of nucleons is independent of the charge.

Solved example S-3.1

Calculate the minimum kinetic energy of a proton that is confined in a nucleus of $^{27}{}_{13}\text{Al}$. Consider the value of r_0 as 1.2 F.

Solution. The radius of the aluminium nucleus

$$r = r_0(27)^{\frac{1}{3}} = 3.6 \times 10^{-15} \text{ m}.$$

Considering the de Broglie wavelength λ of the proton to be equal

$$\lambda = 2r = 2 \times 3.6 \times 10^{-15} \text{ m}.$$

Let M_p denote the mass of the proton and E be its kinetic energy. The momentum p of the proton is related to its energy E by the expression $p = \sqrt{2M_pE}$. The de Broglie wavelength λ of a proton of energy E is $\lambda = \frac{h}{p} = \frac{h}{\sqrt{2M_pE}}$. If the proton is confined in a nucleus of radius 3.6 F, then λ should either be smaller or at the most equal to $r = 3.6$ F. Therefore,

$$\left(2\times3.6\times10^{-15}\right)^2 = \frac{h^2}{2M_pE} \quad \text{or} \quad E = \frac{h^2}{2M_p}\frac{1}{\left(2\times3.6\times10^{-15}\right)^2}$$

Substituting the value of $M_pM_p = 1.67 \times 10^{-27}$ kg and $h = 6.62\times10^{-34}$ Js, we get

$$E = \frac{\left(6.62\times10^{-34}\right)^2}{2\times1.67\times10^{-27}}\frac{1}{51.84\times10^{-30}} = 0.25 \times 10^{-11} \text{ J}$$

$$= \frac{0.25\times10^{-11}}{1.6\times10^{-16}} \text{MeV} = 15.78 \text{ MeV}$$

It may be noted that the minimum energy required for confining a particle in given distance *d* is inversely proportional to the square of the distance. Therefore, if the nucleon is confined within a distance *r* (=3.6 F), the minimum energy will be around 64 MeV. Also, the average kinetic energy of nucleons inside a nucleus of average size is considered as 20 or 25 MeV.

Ans: The minimum kinetic energy of proton should be 15.78 MeV.

Solved example S-3.2

The mass defect ($M_{(Z,A)} - A$) for ${}^{16}_{8}O$, ${}^{15}_{8}O$, ${}^{1}_{0}N$, and, ${}^{1}_{1}P$ in μ u are, respectively, −5085, +3070, +8665, and, +7825.

Calculate the binding energies of ^{16}O and ^{15}O nuclei and the separation energies of last neutron from ^{16}O nucleus.

Solution. Mass defects in the problem are given in units of micro-unified mass unit. The masses of the respective nuclides in the unit of u are

$$M_{16O} = 16 - 0.005085 = 15.994915 \text{ u}; M_{15O} = 15 + 0.003070 = 15.003070 \text{ u}$$

$$M_N = 1 + 0.008665 = 1.008665 \text{ u}; M_P = 1 + 0.007825 = 1.007825 \text{ u}.$$

(i) Binding energy of ^{16}O, $B_{16O} = 8\,(M_N + M_P) - M_{16O} = 8(1.008665 + 1.007825) - 15.994915 = 16.13192 - 15.994915 = 0.137005 \text{ u} = 0.137005 \times 931.48 = 127.62$ MeV.

Binding energy per nucleon in $^{16}O = 127.62/16 = 7.97$ MeV

(ii) Binding energy of ^{15}O, $B^{15}{}_O = (7 \times M_N + 8 \times M_P) - M^{15}{}_O$

$$= (7.060655 + 8.0626) - 15.003070 = 0.120185 \text{ u} = 111.95 \text{ MeV}$$

Binding energy per nucleon in $^{15}O = 111.95/15 = 7.43$ MeV

(iii) Separation energy of last neutron from ^{16}O, $S_n = (M^{15}{}_O + M_N) - M^{16}{}_O$

$$= (15.003070 + 1.008665) - 15.994915 = 0.01682 \text{ u} = 15.67 \text{ MeV}$$

The binding energy of the last neutron may also be calculated from the difference of the binding energies of ^{16}O and ^{15}O nuclei

$$= 127.62 - 111.95 = 15.67 \text{ MeV}.$$

It may be observed from the calculations that the average binding energy per nucleon in ^{16}O is larger than for ^{15}O nucleus. Further the separation energy of the last neutron from the nucleus ^{16}O is much larger (15.67 MeV) than the average binding energy per nucleon (7.97 MeV). This is because ^{16}O is a doubly magic nucleus and is very strongly bound.

Exercise p-3.3: A target nucleus ${}^{A}_{Z}X$ is bombarded by energetic deuterons to produce the following (*d*, *p*) reaction:

$${}^{A}_{Z}X + {}^{2}_{1}D \rightarrow {}^{(A+1)}_{\;\;\;Z}X + {}^{1}_{1}H + Q_{(d,p)}$$

Show that the separation energy S_n of the last neutron from ${}^{(A+1)}_{Z}X$ is given by

$S_n = Q_{(d,p)} +$ Binding energy of deuteron.

Exercise p-3.4: The mass excess $(M - A)$ for the four stable isotopes ${}^{110}_{48}\mathrm{Cd}$, ${}^{111}_{48}\mathrm{Cd}$, ${}^{112}_{48}\mathrm{Cd}$, ${}^{113}_{48}\mathrm{Cd}$ and for neutron and proton are, respectively, −95,072, −95,811, −97,237, −95,591, +8665, and +7825 μu. Calculate the increase in the total nuclear binding energy when one neutron is added each to ^{110}Cd, ^{111}Cd, and ^{112}Cd nuclei.

3.3.2 Energy Levels of Mirror Nuclei

In several pairs of mirror nuclei, such as ${}^{7}_{3}\mathrm{Li}$, ${}^{7}_{4}\mathrm{Be}$; ${}^{11}_{5}\mathrm{B}$, ${}^{11}_{6}\mathrm{C}$; and ${}^{13}_{6}\mathrm{C}$, ${}^{13}_{7}\mathrm{N}$, the higher charge isobar decays into the lower charge isobar by emitting β^+ and neutrino. As the atomic mass number A for the two members of a mirror pair is same, they have same radius and same volumes. In the higher charge isobar, the charge Ze and in the lower charge isobar $(Z - 1)e$ charge is distributed in the same volume.

The schemes of low-lying level for the mirror pairs ${}^{7}_{3}\mathrm{Li}$, ${}^{7}_{4}\mathrm{Be}$ and ${}^{13}_{6}\mathrm{C}$, ${}^{13}_{7}\mathrm{N}$ are shown in figure 3.2a,b. It may be clearly seen in these diagrams that: (1) the angular moment and parity of the levels in the members of a pair are same. (2) The sequence of levels for the two members of a pair is identical, but (3) each level of the higher charge isobar of the pair is shifted in energy by the amount ΔU with respect to the corresponding level of lower charge isobar. The two members of each isobar-pair have two differences; first, their electric charge differs by one unit and second the higher charge isobar has one more proton and one less neutron compared with the lower charge isobar. Except these differences, the two members of a pair have all other properties such as radius, volume,

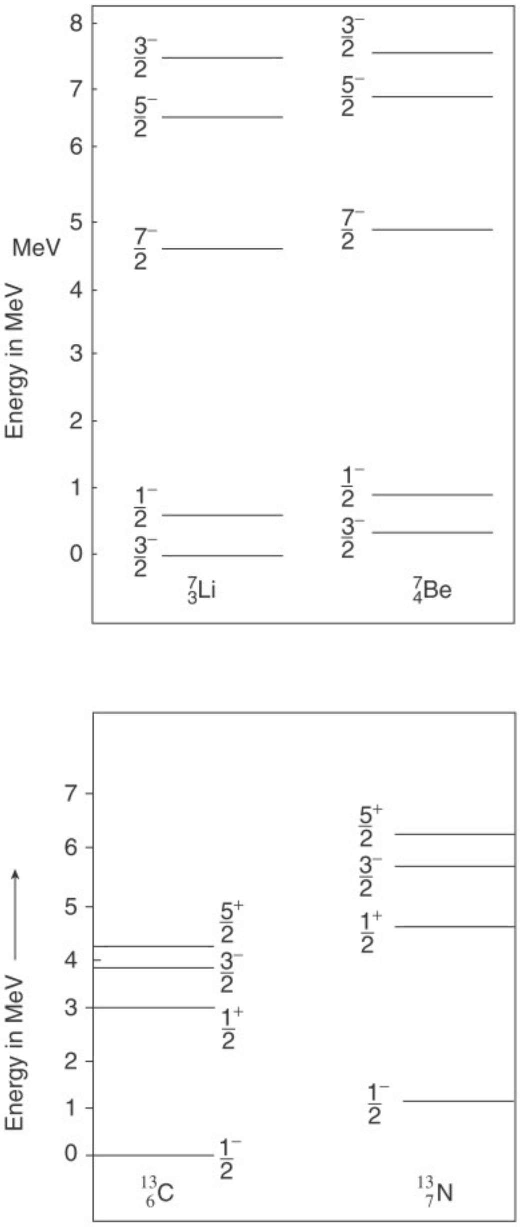

Figure 3.2 *Energy levels of (a)* ${}^{7}_{3}Li$ *and* ${}^{7}_{4}Be$ *and (b)* ${}^{13}_{6}C$ *and* ${}^{13}_{7}N$ *mirror pairs*

and total number of nucleons same. It is obvious that above-mentioned differences are responsible for the energy difference ΔU. ΔU will contain contributions from three effects:

1. Difference in the electrostatic energies of the two members of the pair ΔU_{Cou}
2. Neutron–proton mass difference ΔU_{mass}
3. Difference in the (nuclear) binding energies of the two members of the pair ΔU_{nuc}

Now, the electrostatic Coulomb energy U_{Cou} of a charge q, which is uniformly distributed in the volume of a sphere of radius r, is given by

$$U_{\text{Cou}} = \frac{3}{5}\left(\frac{q^2}{4\pi\varepsilon_0 r}\right)$$

Therefore,

$$\Delta U_{\text{Cou}} = \frac{3}{5}\left(\frac{e^2}{4\pi\varepsilon_0 r}\right)\left\{Z^2 - (Z-1)^2\right\} = \frac{3}{5}\left(\frac{e^2}{4\pi\varepsilon_0 r}\right)\{2Z-1\}$$

However, $r = r_0 A^{1/3}$, $r_0 = 1.5 \times 10^{-15}$ m, and $(2Z - 1) = A$, which gives

$$\Delta U_{\text{Cou}} = \frac{3}{5}\left(\frac{e^2}{4\pi\varepsilon_0 r_0}\right)\left\{A^{2/3}\right\}$$

The value of ΔU_{Cou} for any pair can be easily calculated from the above-mentioned equation.

Apart from the difference in the electrostatic Coulomb energy, the mass difference between a neutron and a proton in the parent and daughter nucleus also contributes to the total energy difference between the two isobars. The $\Delta U_{\text{mass}} = (M_{\text{n}} - M_{\text{p}})c^2 = 1.29$ MeV. The nuclear-binding energies of the two members of a pair may be different if the nuclear-binding force for a neutron is different from the binding force for a proton. The term ΔU_{nuc} will arise from that difference.

Putting all these terms together, we get

$$\Delta U = \Delta U_{\text{Cou}} + \Delta U_{\text{mass}} + \Delta U_{\text{nuc}} = \frac{3}{5}\,(e^2/4\pi\varepsilon_0 r_0)\,\{A^{2/3}\} - 1.29 + \Delta U_{\text{nuc}} \tag{3.1}$$

Experimentally, the magnitude of ΔU can be obtained from the decay products. The higher charge isobar of the pair decays into other members by β^+ (positron) emission. Neutrino is also emitted along with the positron. When the positron is emitted with maximum energy $E\beta_{\text{max}}$ the neutrino has zero kinetic energy. Since neutrino has zero rest mass the sum of $E\beta_{\text{max}}$ and the rest mass energy ($m_e c^2$) of the positron must be equal to ΔU.

$$\Delta U = E\beta_{\text{max}} + m_e c^2 \tag{3.2}$$

where m_{e} is the rest mass of the positron (or the electron).

A comparison of ΔU value calculated using Eq. (3.1) with the experimental values obtained from Eq. (3.2) or from other reaction data for each mirror pair, gave ΔU_{nuc} to be zero.

The fact that the shift in the energy of corresponding levels of mirror nuclei can be fully explained by the sum of the electrostatic Coulomb energy difference and the difference in the masses of neutron and proton clearly shows that the replacement of a neutron by a proton (or vice versa) does not change the nuclear binding energy. This simply means that nuclear forces do not differentiate between neutron and proton. In nuclear physics, the equivalence of the neutron–neutron force and the proton–proton force ($F_{1(n-n)} = F_{1(p-p)}$) is called charge symmetry and the more general equivalence of neutron–neutron, proton–proton, and the neutron–proton force [$F_{1(n-n)} = F_{1(p-p)} = F_{1(n-p)}$] is referred to as charge independence.

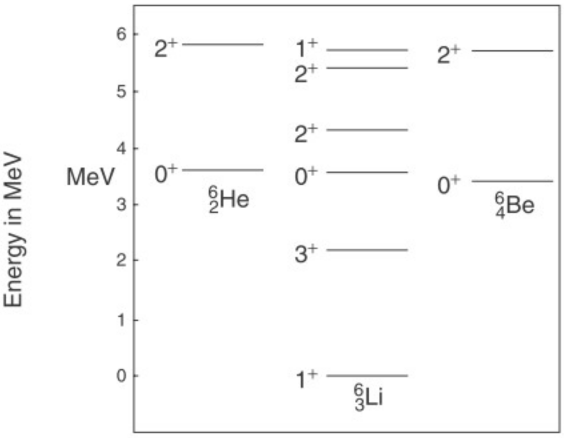

Figure 3.3 *Energy levels of ${}^6_2$He, ${}^6_4$Be, and ${}^6_3$Li*

Next, let us consider mirror nuclei that differ by two unit of charge, such as ${}^6_2$He and ${}^6_4$Be. In these nuclei, the total number of nucleons is same and hence their radii are equal. As may be seen in figure 3.3, the levels of the two nuclei are almost identical except a little energy shift. It is, however, important to note that in this pair, ${}^6_2$He has two (p–n) bonds and one (n–n) bond while in case of ${}^6_4$Be there are two (p–n) bonds and one (p–p) bond. Clearly, if there is any difference in the nuclear binding energies of the two nuclei, it must be due to the difference in the binding energies of (n–n) and (p–p) bonds. Calculations have shown that the slight energy difference in corresponding levels of the mirror pair can be fully accounted for by the differences in the Coulomb electrostatic energy and the energy corresponding to the difference in the masses of neutron and proton. Once again this shows that the nuclear force between two neutrons is equal to the force between two protons, proving the charge symmetry of nuclear force.

It is interesting to look at the energy levels of the nucleus ${}^6_3$Li (figure 3.3), which also have six nucleons and same radius as the other two nuclei. Some levels in figure 3.3 correspond to the levels in ^{6}He and ^{6}Be as expected; however, there are some additional levels as well. These additional levels in ^{6}Li appear because in the case of ^{6}He and ^{6}Be nuclei, some (p–p) or (n–n) states are restricted and are not populated due to the Pauli exclusion principle. In addition, additional (p–n) states in which exclusion principle does not apply are populated in ^{6}Li creating additional levels.

> *In short, the similarity of the low-lying levels of mirror nuclei and the fact that the energy shift between the corresponding levels is fully accounted by the electrostatic energy difference and the difference in the neutron proton masses states that fundamentally nucleon−nucleon force is charge independent.*

3.3.3 Difference in the Binding Energies of ${}^3_1$H and ${}^3_2$He

The mirror nucleus ${}^3_1$H has one proton and two neutrons and, therefore, the possible nucleon–nucleon interaction states are ^{3}(n−p) + ^{1}(n−p) + ^{1}(n−n), ^{3}(n−n) state is forbidden by Pauli exclusion principle. In ${}^3_2$He, the possible states are ^{3}(n−p) + ^{1}(n−p) + ^{1}(p−p); ^{3}(p−p) state is excluded because of exclusion principle. Any difference in the binding energies of the pair will come from the Coulomb energy difference and the binding energy difference of ^{1}(n–n) and ^{1}(p–p) states. The difference in the binding energies ≈0.76 MeV could be fully accounted by the difference of the Coulomb energies of the two nuclei. This again indicates that *nuclear force is charge symmetric*, $F^1(\text{n–n}) = F^1(\text{p–p})$.

Exercise p-3.5: Determine the Coulomb energy difference between the mirror isobars $^{13}_{7}$N and $^{13}_{6}$C and hence the maximum energy of positrons emitted by ^{13}N. Consider $r_0 = 1.4$ F.

3.3.4 Study of Deuteron Properties

Deuteron, $^2_1$H, is the smallest stable nucleus and has one neutron and one proton. The nucleons in deuteron revolve round the centre of mass and their relative separation vary with time. The square root of the mean of the squares of the distance between the centre of mass and the proton is called the r.m.s. electromagnetic radius and is denoted by r_d. Experimental values of some properties of deuteron are: (1) binding energy $B_d = 2.22$ MeV. (2) $r_d = 2.1$ F. (3) spin or the angular momentum $J = 1\hbar$. (4) Parity = even or positive. (5) Magnetic dipole moment $\mu_d = 0.857393$ nm. (6) Electric quadrupole moment $Q_d = +0.00282$ barn.

As the spin of deuteron is 1, the neutron and proton spins are parallel and, therefore, deuteron is an example of triplet neutron–proton state represented as a ^{3}(n–p) state. The deuteron has been analysed under quantum mechanical approach, in which a potential well is assumed to represent the system. In principle potential well of any shape may be used, but the simplest one is a square or rectangular well with two parameters, the depth V and the width b. High-energy scattering experiments have already suggested that there is a hard core of infinite height at a distance c from the centre of a nucleus such that nucleons cannot come closer than the distance c. This is also required for nuclear stability; otherwise nucleons will all collapse into each other under the strong attractive nuclear force between them. The radius of the core c has been estimated to be of the order of 0.4 F. A pictorial representation of the square-well approach is shown in figure 3.4. The appropriate well parameters should reproduce the observed properties of the deuteron, particularly, the binding energy, and the r.m.s. radius. The analysis shows that no unique values for the

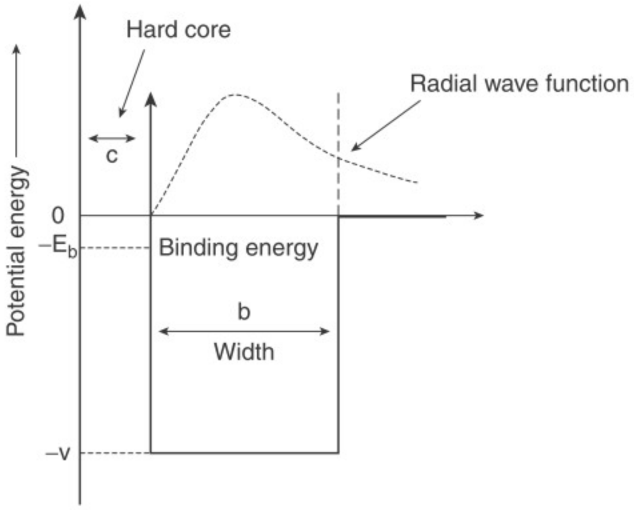

Figure 3.4 *Pictorial representation of square-well approach to deuteron and the shape of the radial wave function*

depth V and the width b could be obtained, rather several combinations of V and b could reproduce the observed binding energy. For example, a square-well potential of depth $V \approx 35$ MeV and width $b \approx 2$ F or $V = 73$ MeV and $b = 1.33$ F can give the correct binding energy of the deuteron. Detailed quantum mechanical analysis of deuteron has given the following information about the two body nucleon–nucleon forces.

1. Triplet (n–p) force $F_{3(n-p)}$ is just strong enough to bind deuteron, while the singlet force $F_{1(n-p)}$ is not enough strong to provide a bound singlet state. It means $F_{3(n-p)} > F_{1(n-p)}$.
2. In deuteron, the two nucleons remain outside the range of the nuclear force for a considerable period of time, resulting in small binding energy of deuteron. This is possible only in quantum mechanical systems where particles may undergo tunnelling, which is not possible in classical systems.
3. To reproduce the quadrupole moment of deuteron, an admixture of S and D states is necessary. The $F_{3(n-p)}$, thus, mixes states.
4. Further, the prolate shape of the deuteron suggests that the force between the neutron and the proton in deuteron is attractive when they are one above the other, and less attractive or even repulsive when they are side by side as shown in figure 3.5.

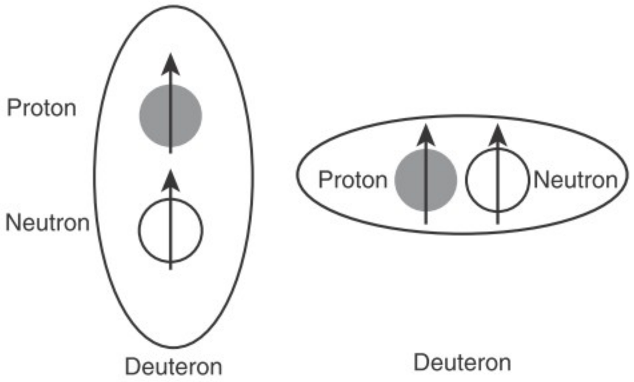

Figure 3.5 *The force between neutron and proton is attractive when they are one above the other and less attractive or even repulsive when they are side by side. That is why the shape of deuteron is prolate. Tensor force depends on the angle between the spins and the line joining the centres of nucleons*

This shows that the force also depends on the angles between the spin directions and the line joining the centres of nucleons. Such force is called a tensor force. The tensor dependence in radial nucleon–nucleon potential is generally represented by the term

$$S_{12} = (1/r^2)\,[3(\sigma_1 r)\,(\sigma_2 r) - (\sigma_1 \sigma_2) r^2]$$

Here, σ_1 and σ_2 are the spin vectors for the two nucleons. The term has different values for the cases when σs are parallel and perpendicular to the radius vector r, even for the same value of $\sigma_{\text{total}} = \sigma_1 + \sigma_2$.

Exercise p-3.6: Calculate the value of the tensor term S_{12} for the two configurations shown in figure 3.5 and for the same configurations in case of anti-parallel spins.

3.3.5 Nucleon–Nucleon Scattering

3.3.5.1 Neutron–proton scattering

As there is no bound singlet state of n–p system (system such as deuteron but with spin zero), it is not possible to study the properties of $F_{1(n-p)}$ directly. These un-bound states are, however, formed in scattering of neutrons with protons and their effect can be seen in scattering cross-sections. It may be noted that in scattering both triplet ^{3}(n–p) and singlet ^{1}(n, p) states are simultaneously populated as there is no restriction on any state from Pauli exclusion principle. The triplet state has three sub-states and the singlet state has one. As such the total number of sub-states is four. If it is assumed that each sub-state is populated with same probability, the total scattering cross-section will be equal to the weighted average of the sub-states, which will be given as

$$\sigma^{\text{total}} = \frac{3}{4}\sigma^{\text{triplet}} + \frac{1}{4}\sigma^{\text{singlet}} \tag{3.3}$$

Large number of precise experiments using neutrons from nuclear reactors and from secondary neutron-producing reactions initiated by accelerated charged particles has been conducted to measure the n–p scattering cross-sections. Polyethylene, organic material with carbon and hydrogen, is often used as target. In some experiments at very low energy, hydrogen gas has also been used as target. The measured total (n, p) cross-section between 0.01 eV and 15 MeV is shown in figure 3.6. As may be noticed in this figure, the curve can be divided into three distinct parts: (1) from 0.01 to 10 eV neutron energy, (2) between 10 and 10^4 eV, and (3) from 10^4 eV to 15 MeV. In the large energy range of 10–10^4 eV, the cross-section is nearly constant at a value of about

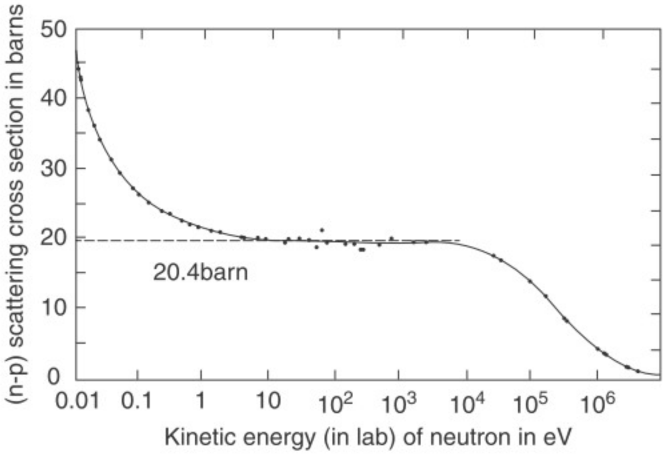

Figure 3.6 *(n, p) cross-section between 0.01 eV and 15 MeV*

20 barn. At lower energies, the scattering cross-section increases rapidly while at higher energies $>10^4$ eV, it decreases slowly. Analysis of the experimental data has been carried out assuming that the protons are fixed at their location and are free. At energies >10 eV, this assumption is true; however, at lower energies where mostly gaseous targets have been used, the protons were neither free nor fixed. At lower energies, the de Broglie wavelength of neutron becomes large and, therefore, the neutron interacts with the hydrogen molecule rather than the proton. The thermal motion of gas molecules also increases the apparent target size. Moreover, the molecular binding energy becomes comparable to the energy of incident neutron. All these effects enhance the measured scattering cross-section at lower energies. On applying corrections for these effects in the measured cross-section values, it turns out that in the lower energy range also the actual scattering cross-section is of the order of 20 barn.

In the quantum mechanical framework, the scattering problem is treated by decomposing the incoming neutron wave into partial waves of different orbital angular momentum l with respect to a fixed target. In elastic scattering, the target potential changes the phases of the incident partial waves without affecting the flux. The net effect of scattering potential is a shift in the phase of the l-th partial wave by an angle d_l. The scattering cross-section for each partial wave then becomes proportional to $\sin^2 d_l$. At low energies below 15 MeV, only $l = 0$ or S-wave contributes to scattering because the higher partial waves lie beyond the range of the nuclear field of the target proton. As such for low energy, the total (n−p) scattering cross-section $s^{s}_{(n,p)} = \{4p \sin^2 d_0/k^2\}$, where $k = \frac{\sqrt{2mE}}{\hbar}$ and m is the reduced mass = $M_n/2$ and E the centre of mass energy of incident neutron. In the zero energy limit $k \rightarrow 0$, the scattering cross-section can be given in terms of the parameters a_t and a_s, which are the scattering lengths for the triplet and singlet scattering events. Scattering lengths is the intercept of the tangent to the radial wave function at the outer boundary of the potential well. Scattering length a_t is positive for the bound ^{3}(n, p) state and a_s is negative for an unbound state like ^{1}(n, p). Precise values for a_t and a_s determined from coherent and incoherent scattering of neutrons by protons give $a_t = 5.38$ F and $a_s = -23.7$ F. The experimental value of scattering length for triplet state is consistent with the deuteron potential well parameters that give correct binding energy and r.m.s. radius of deuteron.

The negative value of the scattering length for singlet potential is consistent with the fact that the singlet state is not bound. If same well width $b = 1.33$ F that gives correct binding energy for deuteron is used with the singlet scattering length = −23.7 F, the singlet potent depth for zero energy approximation comes out to be 54.7 MeV, while the minimum depth of the well to produce a bound system is about 57 MeV. As such it may be stated that the singlet state narrowly misses to become a bound state by only about 3 MeV or so.

In summary, it may be said that a rectangular well with appropriate width and depth parameters can satisfactorily reproduce the binding energy, r.m.s. radius, scattering lengths for triplet and singlet states obtained from measured scattering cross-sections at low energy and for zero-energy approximation. Also, for higher energies, the cross-sections for both triplet and singlet state scatterings can be represented in terms of two additional parameters, the effective range r_{ot} and r_{os}, respectively, for the triplet and the singlet states. With the parameters $a_t = 5.28$ F, $a_s = -23.7$ F, $r_{ot} = 1.7$ F and $r_{os} = 2.4$ F, the measured total scattering data between 10 eV and 15 MeV can be satisfactorily explained. This shows the great success of quantum mechanical treatment of both the deuteron and the scattering process.

3.3.5.2 Proton–proton scattering

Proton–proton scattering has also been extensively studied. The major points of difference between n–p and p–p scattering are: (1) Triplet ^{3}(p–p) state in not possible due to exclusion principle. (2) Coulomb force is always present at all angles and for all partial waves. To overcome the interference due to Coulomb scattering differential scattering cross-section, $\left(\frac{d\sigma}{d\Omega}\right)$ is measured and the experimental value is corrected for the contribution from Coulomb scattering. (3) As the target and the incident particles are same, it becomes difficult to differentiate the incident particle and the scattered target. As a result, it becomes impossible to differentiate between small-angle and large-angle scattering events. (4) According to Dirac's theory, the vacuum is filled with negative energy electrons. In the presence of strong electrostatic field around proton, the wave functions of negative energy electrons get distorted resulting in the polarization of space and at very small distance from the proton the $1/r^2$ dependence of Coulomb field does not hold. However, at larger distances there is not much effect. Proton–proton scattering has been successfully treated quantum mechanically and vacuum polarization and interference between Coulomb and nuclear scattering terms have been clearly observed. Although the p–p scattering phase shift and n–p scattering phase shifts at the same energy cannot be compared but it is possible to calculate back the potential well parameters for p–p scattering. These calculations have shown that the potential well parameters for singlet p–p scattering are nearly equal to the parameters for singlet n–p scattering, once again confirming that nuclear forces are charge independent.

Nucleon scattering at higher energies confirmed the presence of a hard core. Further, the concept of phase shift has been successfully applied at high energies and consistent set of phase shift parameters have been obtained that can explain all the quantities that are observed in nucleon–nucleon scattering.

The study of deuteron and of the nucleon–nucleon scattering has revealed the following:

1. Nuclear forces are charge independent. The same inference was also drawn from the study of separation energies of last nucleon and the level schemes of mirror nuclei.
2. Scattering at high energies show that there is hard or repulsive core at the centre of the nuclear potential.
3. Nuclear force is spin dependent and of tensor nature.

Exercise p-3.7: In n–p scattering cross-section, triplet state contributes three times more than the singlet state. Explain the reason for this larger contribution of the triplet state.

Exercise p-3.8: The experimentally measured (n, p) scattering cross-section is found to increase with the decrease of energy, in the very low energy region. How can this be explained?

Exercise p-3.9: Clearly bring out the differences in (n, p) and (p, p) scattering.

3.3.6 Constant Density of Nuclear Matter: Exchange Forces

The density of the nuclear matter can be readily calculated by dividing the mass of a nucleus by its volume. Mass of a nucleus with A nucleons = $M_n A$, where M_n is the nucleon mass and the volume = $4/3\pi r^3$, where r is the radius. The radius $r = r_0 A^{1/3}$, where the unit radius r_0 (=1.5 F) is constant. The density of nuclear matter, therefore, is $\frac{M_n}{\frac{3}{4}\pi r_0^3}$ (where M_n is the nucleon mass) a constant value for all nuclei. As all nuclei big or small have same density, they may be compared with the big and small drops of a liquid. The similarity between a liquid drop and a nucleus may be looked in another way as well. In case of a liquid drop, each molecule of the liquid is bound with only few molecules around it and not to all the molecules present in the liquid. As a result, the total binding energy of a liquid drop becomes proportional to the number of molecules in the drop. In a similar way, each nucleon inside a nucleus is bound only to few other nucleons around it and not to all other nucleons present in the nucleus. This results in the total binding energy of the nucleus being proportional to A, the number of nucleons in it. [If each nucleon in the nucleus was interacting and was bound to all other $(A - 1)$ nucleons, then the binding energy of the nucleus should have been proportional to the number of all the bonds which are $A\ (A - 1)$. For heavy nuclei, $A\ (A - 1) \approx A^2$ and, therefore, the total binding energy of heavy nuclei would have been proportional to A^2 instead of A].

The property of the nucleon–nucleon force that restricts the interaction of a nucleon to only a few around it is called the saturation property of the nuclear force in analogy to the saturation of the force binding molecules in liquids. The analogy between the nucleus and the liquid drop may be further explored to understand the binding between the nucleons in a nucleus.

Let us consider a drop of liquid hydrogen. In this drop, two atoms of hydrogen are chemically bound through homopolar binding to make an H_2 molecule. A third atom of hydrogen is not attracted now to join with a molecule of H_2. This is called the saturation of chemical binding force. In homopolar binding, this saturation is achieved by assuming that the electrons continuously exchange their position from one atom to the other in the molecule. Mathematically, this exchange of electrons between the atoms of a molecule can be achieved by using exchange operators.

Extending the concept of exchange operator to the case of nucleon, there may be three types of operators: (1) operator that may exchange the space coordinates of two nucleons, (2) operator that may exchange the spin coordinates of two nucleons, and (3) the operator that may exchange both the spin and space coordinates. Apart from these exchange operators, there may also be a non-exchange operator that does not exchange any property. In simple terms, operators of a force are generally multiplicative factors. For example, if an attractive force is operated by the operator -1, the force becomes repulsive. Operators of exchange forces change the nature of the force between nucleon from attractive to repulsive depending on the value of the relative angular momentum between the nucleons.

1. **Majorana force:** The Majorana force exchanges the position coordinates of the two nucleons. It simply means that the Majorana force operator only interchanges the positions of the two interacting nucleons, while their spins and other properties remain same. Majorana force is attractive for the two nucleons if their relative angular momentum l is zero or even repulsive for odd l states. For example, in S ($l = 0$) and D ($l = 2$) states it will give attraction and for the P state ($l = 1$) it will provide repulsion between the two nucleons.
2. **Bartlett force:** The operator of Bartlett force interchanges the spins of the two interacting nucleons, leaving all other parameters including their positions unchanged. For example, if the first nucleon has its spin up and the other spin down, then as a result of Bartlett interaction the spin of the first nucleon will turn down and that of the other up. (*What will be the effect of Bartlett interaction on two parallel spin nucleons?*). For zero or even angular momentum states, Bartlett force is attractive in triplet and repulsive in singlet states. For odd l states, Bartlett force is repulsive for triplet and attractive for singlet states.

3. **Heisenberg force:** This force exchanges both the spin and the space coordinates of the two interacting nucleons. Naturally, the operator produces the same effect that is produced by the successive operations of Majorana and Bartlett force operators. The Heisenberg force is attractive for even-l triplet and odd-l singlet states. It is repulsive for the even-l singlet and odd-l triplet states.
4. **Wigner force:** Wigner force is not a force that provides saturation. This force provides only binding to the two interacting nucleons. Its operator is +1 for states of all l values.

Table 3.1 *Exchange operators for different type of forces*

Type of Force	Even-l Singlet	Odd-l Singlet	Even-l Triplet	Odd-l Triplet
Majorana	+1	−1	+1	−1
Bartlett	−1	−1	+1	+1
Heisenberg	−1	+1	+1	−1
Wigner	+1	+1	+1	+1

The actual force between two nucleons cannot be totally of Wigner type as it will not be able to provide the saturation. Also, it cannot be totally of Heisenberg type because Heisenberg force is attractive for triplet state if nucleons are in the state of $l = 0$ (S-state). The deuteron fulfils these conditions, and should have been the most tightly bound system if nucleon–nucleon force was totally of Heisenberg type. We know that the binding energy of deuteron is only 2.23 MeV. Alpha particle, the nucleus of helium, is the most tightly bound nucleus with binding energy of 28 MeV. Hence, Heisenberg force alone cannot be the nucleon–nucleon force. As the exchange of π meson between two nucleons corresponds to the exchange of their positions, Majorana force must be a significant component of the total nucleon–nucleon force. The two nucleon system can be represented as a mixture of Majorana and Wigner forces.

3.4 MEDIATION OF NUCLEAR FIELD

How does two nucleons stick together to make a nucleus? The answer to the question is obtained by drawing an analogy from the interaction of two charges. In quantum electrodynamics, a well-understood and developed theory of Coulomb field, two charged bodies interact through Coulomb field. Let us, therefore, first review the mechanism of interaction between two charges.

Quantization of electric field generates photon, which communicates the electric field between charged bodies through their exchange. This mechanism of interaction brings in the concept of the speed of the field and the time delay in action at a distance. In case of electric charges, the speed of the field is the speed of light, as photon, the quanta of the field travels with the speed of light. The mechanism also brings in the concept of virtual photons in case of electric field and virtual field particles in general.

Virtual photons are quite different from the real photons. These are called virtual because they exist within the constraints imposed by the uncertainty principle. According to this principle, an uncertainty ΔE in energy can stay for a time duration Δt such that $\Delta E \times \Delta t \sim \hbar$. As such, if a virtual photon of energy E is created, it will live for a time $\Delta t \sim \hbar/E$. A virtual photon travelling with the speed of light c will cover a distance $r = c\Delta t$ in time Δt. Hence, $r = c(\hbar/E)$. A virtual photon of energy E can be created for time duration $\Delta t = \hbar/E$ and can make a trip of distance $r = \hbar c/E$ during the time interval Δt. After this time interval, the photon must disappear to conserve the energy.

This fluctuation in energy is allowed only within the limits of time Δt, allowed by the uncertainty principle. Hence, a virtual photon of energy E is emitted by an electron, it carries a momentum $p = E/c$. The virtual photon is absorbed by the other charged particle changing its momentum by the amount of p. As such the total change of momentum during the process of exchange (emission and absorption) of virtual photon between two charged particles is $2p$. Now, according to the law of mechanics the force F responsible for the change of momentum (for the exchange of virtual photons in this case) is equal to the rate of change of momentum $= 2p/\Delta t$. As such

$$F = 2p/\Delta t = (2E/c)/(\hbar/E) = 2E^2/\hbar c = [2(\hbar c/r)^2)/\hbar c] = (2\hbar c/e^2)\,(e^2/r^2)$$

This is how the electrostatic force between two charges may be derived from the concept of the virtual photon exchange. The electromagnetic force is an infinite range force and this is due to the exchange of mass-less particles, that is photons. However, these photons are not real but virtual. These virtual photons exist only in association with charges and currents and are not to be confused with real photons. However, the 'virtual' photons have real affects and, in that respect, are real. For example, a real photon moving in free space can be represented as in figure 3.7a where the photon dissociates in to a virtual $e^{\pm}$ pair which heals up (or recombines) after a time $\Delta t = \hbar/\text{mc}^2$. Similarly, (see figure 3.7b) an electron passing in free space may be represented as a particle that emits a virtual photon, which dissociates into a virtual $e^{\pm}$ pair that eventually heals and emits a virtual photon, which is reabsorbed. The free e^- is thus surrounded by charges (virtual) in the vacuum and the e^- of e pair is repelled while e^+ of $e^{\pm}$ pair is attracted by the real e^-. This is called vacuum polarization and affects the inverse square law in the immediate vicinity of charges. The effect of vacuum polarization is felt in p–p scattering and in other processes.

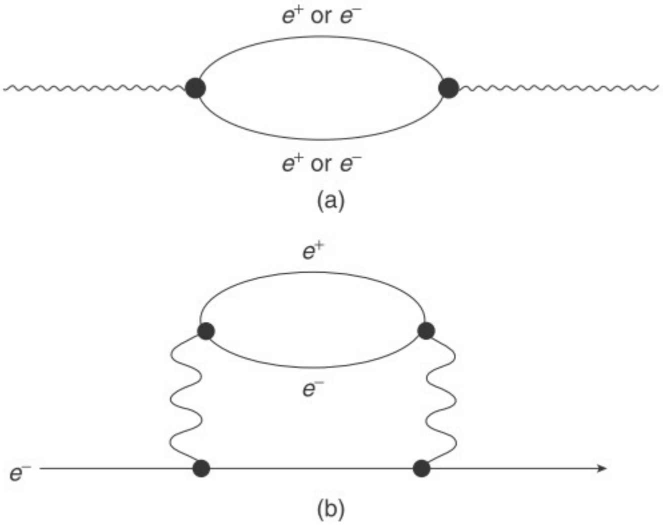

Figure 3.7 *(a) A real photon moving in free space may dissociates into a virtual e^+ and e^- pair. (b) An electron may emit a virtual photon that may create a virtual electron–positron pair which recombine to produce a virtual photon that is absorbed by the electron*

(Virtual photon emitted by a charged particle, an electron in the figure, creates a pair of virtual electron and positron which live for a short time and recombine (heal up) to give back virtual photon which in turn is reabsorbed by the electron)

This analogy to the electrodynamics was used by Yukawa to predict the emission and absorption of a virtual particle for mediation of nuclear force, now known as the p -meson or, pion. The nuclear force that has finite range, obviously, has to be mediated by the exchange of finite mass particle. Its range r = ħc/E = ħ/mc is controlled by the mass of mesons such as pion.

Yukawa considered the following scalar potential equation of electrodynamics

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)U = 0 \tag{3.4}$$

which reduces to$\nabla\ ^2U = 0$, for the static field and on integration gives the static solution $U = q/(4\pi\varepsilon_0 r)$. It may be observed that Eq. (3.4) can be obtained from the equation giving energy of a mass less particle by substituting the quantum mechanical operator $(-\hbar^2\nabla^2)$ for the square of the momentum (p^2) and $(-i\hbar\ \partial/\partial t)$ for the energy.

For a mass-less particle:

$$E^2 = p^2c^2 \text{ or } -p^2 + E^2/c^2 = 0 \tag{3.5}$$

On substituting the values of p and E in terms of the operators in Eq. (3.5), one obtains Eq. (3.4). The equation for the energy of a particle of rest mass m is

$$E^2 = p^2c^2 + m^2c^4 \quad \text{or} \quad -p^2 - m^2c^2 + E^2/c^2 = 0 \tag{3.6}$$

Yukawa argued that if quantum mechanical operators for momentum and energy are substituted in Eq. (3.6), it should give the equation for the scalar potential u for the mass m particle that may be exchanged between nucleons. On substitution of operators, we get

$$(\nabla^2 - m^2c^2/\hbar^2 - 1/c^2\ \partial^2/\partial t^2)\ u = 0.$$

which in case of static field (time independent case) reduces to

$$(\nabla^2 - \frac{m^2c^2}{\hbar^2})\ u = 0 \text{ or } (\nabla^2 - \mu^2)\ u \tag{3.7}$$

where $\mu = mc/\hbar$. A solution of Eq. (3.7) is $u = g\left(\frac{e^{-\mu r}}{r}\right)$ (3.8)

Here, g is a constant, which plays the same role as is played by charge in electrostatic. g depends on the properties of the source, the nucleon in the present case. In electrostatic case, the mechanical potential resulting from the scalar potential U is $V = q^2/4\pi\varepsilon_0 r$. Extending the analogy, the mechanical potential in the case of two nucleons each of strength g is

$$V = g^2\,\frac{e^{-\mu r}}{r} \tag{3.9}$$

3.4.1 Virtual Mesons

Virtual particles (mesons) are continuously exchanged between nucleons giving binding and saturation. These particles of mass m and energy $E = mc^2$ are virtual because they are created out of the uncertainty principle and live for a time $\Delta t = \hbar/mc^2$. In the interval of time Δt, the virtual particle if travelling with the maximum speed, the speed of light may travel a maximum distance $d = \Delta tc = \hbar/mc$. Thus, d gives the maximum range of the field. Substituting the range of nuclear field $d \approx 2\,\text{F}$, the mass m of the virtual particle may be calculated to be around 200 m_e, m_e being the mass of electron. It may be remarked that the range of the virtual particle that communicate the field is inversely proportional to the mass of the virtual particle.

Soon after the prediction by Yukawa, a particle named μ-meson (presently called muon) was discovered in cosmic rays. Initially, it was thought that μ-meson is Yukawa's particle. However, it was soon recognized that μ-meson could not be the right candidate for two reasons. First, it weakly interacts with matter and second, it has a spin $\frac{1}{2}\hbar$, therefore, cannot be absorbed or emitted from a nucleon without changing its spin. As a matter of fact, all field quantas that mediate fields, such as photon, π-meson, gluon, W and Z bosons, and so on are bosons with zero or integer intrinsic spins.

3.4.2 Yukawa Particle: π-meson

Soon the right Yukawa particle, the π-meson (also called pion) with a mass about 280 m_e was found, again in cosmic rays. There are three types of pions π^+, π^0, and π^-. Charged virtual pions are exchanged between proton and neutron, while neutral pions between neutron–neutron and proton–proton. Substituting the mass of π-meson as 300 m_e the range of the force comes out to be about 0.7 F. There is one problem with π-meson as well. It is that the parity of π-meson is negative. If the virtual π-meson is emitted or absorbed by a nucleon in $l = 0$ (S-state), then the parity of the nucleon will change. Therefore, the π-mesons are emitted or absorbed in $l = 1$ state or in other higher odd l states. This leaves the parity of nucleon unchanged but their spins are flipped, that is changes from 1/2 pointing up to 1/2 pointing down. In case of deuterons, the exchange of charged virtual pions between proton and neutron in $l = 1$ state automatically makes the wave function for the system non-spherical. Thus, tensor force term, which makes deuteron shape prolate and gives rise to additional attraction when the nucleons are one over the other as compared to when they are side by side, evolves naturally. It is also possible that not one but two virtual pions are emitted and absorbed simultaneously. The two-pion potential is of shorter range and varies as $e^{-2\mu r}/r$. Other heavy pions may also be exchanged but only when the nucleons are much closer. Figure 3.8 shows the emission and absorption of virtual pions. A very crude sketch of nucleon–nucleon potential showing relative distances where one-, two-, and three-pion exchanges become important is shown in figure 3.9.

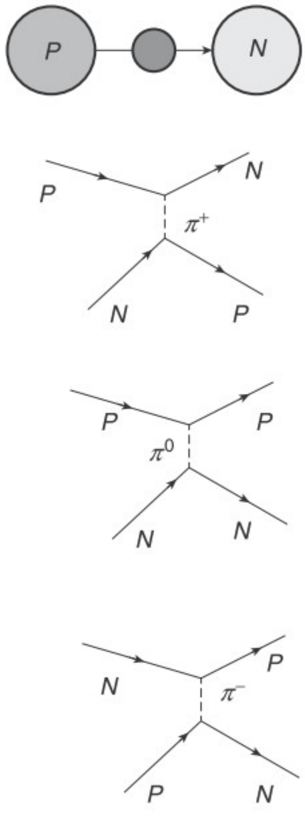

Figure 3.8 *Exchange of virtual pions between nucleons*

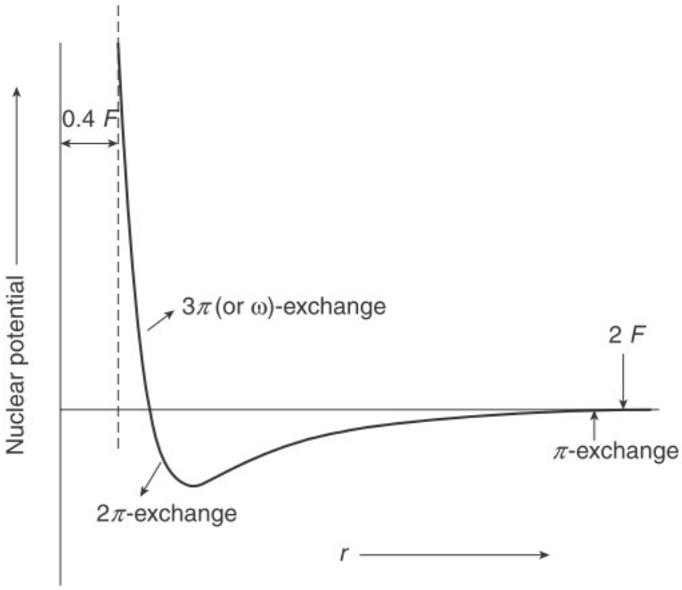

Figure 3.9 *A crude sketch of nucleon–nucleon potential showing distances where one-, two-, and three- pion exchanges become important*

3.5 SPIN–ORBIT DEPENDENCE OF NUCLEAR FORCE

The occurrence of magic numbers suggested that nucleons inside a nucleus move in some sort of shells just like the electrons in an atom. The cyclic behaviour of separation energy for the last neutron and proton further confirm the shell structure. Nuclear shell closures at lower magic numbers Z and/or $N = 2, 8, 20$ could be easily explained on the basis of shell model. However, to achieve the closure of shells at higher neutron or proton numbers 28, 50, 82, and 126 it was necessary to invoke strong coupling between the orbital and the spin motions of each individual nucleon**.** Detailed study of shell model of the nucleus revealed that the nuclear force also depends on the relative directions of the orbital angular momentum l and the spin angular momentum s of the nucleon. The force is attractive if l and s are parallel and repulsive if anti-parallel. This gives rise to what is called the spin orbit coupling term in nuclear potential. As the orbital angular momentum of a nucleon depends on its velocity of motion, the spin-orbit dependent force is also called the velocity-dependent force.

3.6 NUCLEON–NUCLEON POTENTIAL

Before proceeding further let us once again recapitulate the basic information about nucleon–nucleon force obtained from different sources.

1. They are of short range, charge symmetric, and charge independent.
2. Force is spin dependent. Triplet (n, p) force is strong enough to form a bound state but the singlet (n, p) force is just not strong enough to form a bound state. Singlet (n, p), (n, n), and (p, p) forces are of equal or nearly equal magnitude.

3. Nucleon–nucleon force is of tensor nature that means the force between two nucleons not only depends on the spins of the two nucleons but also on the angles which their spins make with the line joining their centres.
4. Nucleon–nucleon force is saturated, which means that a nucleon interacts with only a few nucleons around it. Saturation of force is brought about by exchange of pions between nucleons. Exchange force can explain saturation as it may also become repulsive depending on the property that is exchanged.
5. The nucleon–nucleon force also depends on the relative orientation of their angular momentum and spins. This is called the velocity dependence of the force.
6. High-energy scattering experiments have demonstrated that there is a hard repulsive core (≈0.4 F) such that two nucleons cannot came closer than this distance.
7. Since total electric charge is conserved in nuclear processes and the isotopic spin is related to charge, it is also conserved like the total angular momentum. All properties shown by angular momentum are expected to be shown by the isotopic spin as well.

As has been indicated earlier, a nucleon–nucleon potential now needs to be developed that may incorporate the above-mentioned properties of nucleon–nucleon force. A very crude shape of the potential is shown in figure 3.9 in which the distance where one, two, and three pion transfer becomes important is also shown. The potential may then be used in the Schrödinger equation of the given system to get its important parameters. The simplest potential is the square-well or rectangular-well potential. Other potential forms such as Woods–Saxon (figure 3.10), Yukawa (figure 3.11), Harmonic oscillator (figure 3.12), and many other have been tried each with limited success.

$V(r) = \frac{V_0}{1 + e^{\frac{(r-R)}{a}}}$
$R = r_0 A^{1/3}, r_0 = 1.25\ F$
$V_0 \approx 50$ MeV, $a = 0.5\ F$
Woods-saxon potential

Figure 3.10 *Woods–Saxon potential*

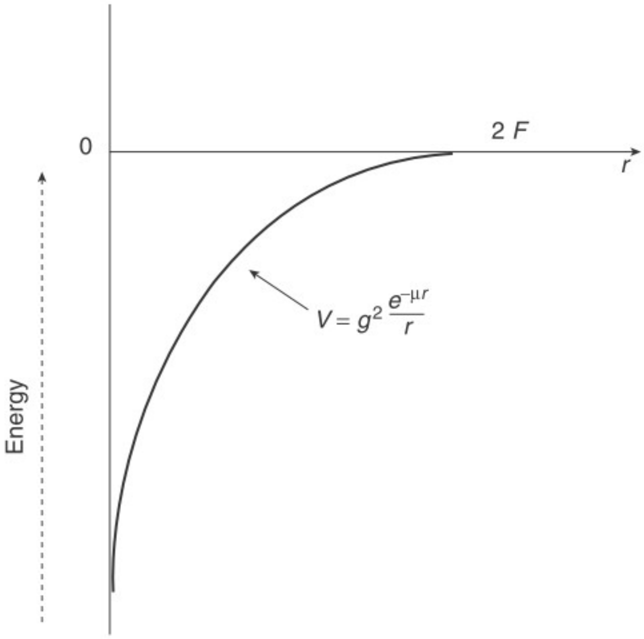

Figure 3.11 *Yukawa potential*

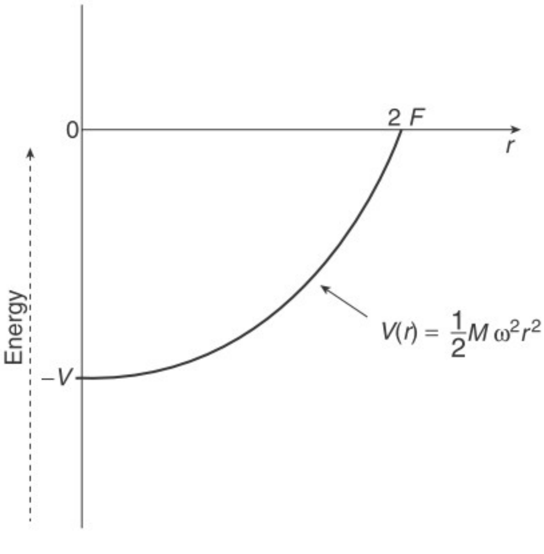

Figure 3.12 *Harmonic oscillator potential*

One form of total potential between two nucleons, in modern parlance called AV8 potential is as follows.

$$V_{12} = V(r) + V_{\sigma}(r)\,(\sigma_1\sigma_2) + V_{\varsigma}(r)\,(\zeta_1\zeta_2) + V_{\mathrm{T}}(r)S_{12} + V_{\mathrm{T}\varsigma}(r)S_{12}(\zeta_1\zeta_2) + V_{\mathrm{T}\sigma}(r)\,(\sigma_1\sigma_2)\,(\zeta_1\zeta_2) + V_{\mathrm{ls}}(r)\,(ls) + V1_{\varsigma}(r)\,(ls)\,(\zeta_1\zeta_2)$$

Here, $V(r)$s are radial potentials which may have square well or Woods–Saxon or any other form for each component of the total potential. Terms I, II, III …VIII of the potential represent, respectively, pure radial, spin–spin, isospin–isospin, tensor, tensor–isospin, tensor spin–spin, spin–orbit, and isospin–orbit interactions. As already indicated, the tensor term S_{12} is generally given as:

$$S_{12} = 1/r^2[3\,(\sigma_1 r)\,(\sigma_2 r) - (\sigma_1\sigma_2)\,r^2]$$

where σ_1 and σ_2 are the spins of the two nucleons and ζ_1 and ζ_2 their isospins. It may be observed that the first term in the expression for S_{12} depends on the angles between the spins and the radius vector while the second term on the relative orientation of the spins of the two nucleons.

3.6.1 Local and Global Nuclear Potentials

Instead of using a two-nucleon potential, attempts have been made to write the potential for the whole nucleus. Optical potential – which contains two terms, the real and the imaginary – has been quite successful in explaining the scattering and nuclear reactions. Nuclear potentials are generally classified as local – which is applicable to a small range of energy and/or the nuclear mass. Global nuclear potentials can be applied for a broader range of energy/nuclear mass. None of the potentials developed so far is applicable to all the stable nuclei. It has also been observed that not only two-body force but three-body forces are also important in case of the nucleus.

3.7 QUARK AND GLUON

It is now well established that all matter in the universe is made of two types of entities: quarks and leptons. Quarks and their anti-particles, anti-quarks, may group together to make particles that may stay free, such as nucleons and π-mesons. Particles formed by the grouping of quarks are called HADROS. Leptons may interact with quarks and with their groupings but they do not group or pair among themselves. Electrons, muons, and their neutrinos are leptons. There are two types (called flavours) of quarks; the up-quark denoted by u has an electric charge of $+2/3e$ and the down-quark denoted by d has an electric charge of $-1/3e$, e being the charge of proton. Their antiparticles denoted by $\bar{\mathrm{u}}$ and $\bar{\mathrm{d}}$ have $-3/2e$ and $+1/3e$ charges. The quark structure of some of the particles is as follows:

Proton = (uud); neutron = (udd); π^+ meson = $(\mathrm{ud}\bar{\mathrm{d}})$; π^- meson = $(\mathrm{u}\bar{\mathrm{u}}\mathrm{d})$

While Yukawa showed that the strong interaction between nucleons is communicated by the exchange of π-mesons, it has now become clear that the interaction between quarks is more fundamental. The strong force between quarks is communicated through the exchange of a particle called gluon and not by the exchange of π-mesons. The force that is communicated by the exchange of π-meson is now treated as a residual force of gluons, such as the van der Waals force in chemical binding is the residual electrostatic force between the positively charged atomic nucleus and the negatively charged electrons. It may, however, be pointed out that the Yukawa theory of meson exchange still remains valid for the nuclear two-body residual interaction, although the more fundamental strong nuclear force is communicated by gluons between quarks.

The quark structure of particles though quite successful; however, there was no apparent reason why three quarks group up to form a nucleon or a quark and an anti-quark join to make a π-meson. There was another problem: two very short lived particles Δ^{++} and Δ^{-} with quark structures (uuu) and (ddd) were identified. This was in violation with Pauli exclusion principle. To overcome this difficulty, Moo Young Han of Duke University, Yoichiro Nambu (University of Chicago), and Oscar Greenberg (University of Maryland) suggested that a new quantum number called 'colour' may be assigned to each quark. The quantum number colour was assumed to have three components, 'red', 'green', and 'blue' denoted, respectively, by subscripts 'r', 'g', and 'b'. As such there can be six types of quarks: u_r, u_g, u_b, d_r, d_g, and d_b along with their six anti-quarks with inverse colours. These colours were assigned with a specific purpose, red, green, and blue colours on mixing produce white colour – neutrality of colour, in a similar way it was demanded that particles that may stay freely must have a combination of quarks such that the total system is colourless or white. As such Δ^{++} with the structure ($u_r u_g u_d$) does not violate Pauli principle as each quark is in a different quantum state because of its colour quantum number. Further, the total structure is colour neutral or achromatic. Pions also may stay freely because they make a colourless combination of quarks. In Yukawa theory, the pions carry charge from one nucleon to the other. In case of the quark, the quanta of strong nuclear field gluon exchange colour between quarks. Colour is regarded as the equivalent of electrical charge in quark–gluon physics and the atomic physics where stability demands electrical charge neutrality, the particle physics demands colour neutrality or chromatic neutrality.

Exercise p-3.10: What are virtual particles? Clearly distinguish between a real and a virtual pion and explain how virtual pions mediate between nucleons.

Exercise p-3.11: Briefly describe how Yukawa developed the concept of the mediation of nuclear interaction between nucleons through the exchange of π-meson.

Exercise p-3.12: Using the range of the nuclear field as 2 F, show that the mass of the virtual particle that mediate interaction between nucleons should be around 168×10^{-27} kg.

Multiple choice questions

Note: In some of the following questions more than one alternative may be true. Tick all the correct alternatives in such cases for the complete answer.

Exercise M-3.1: A system of two half-integer spin particles has repulsive singlet-state for all values of relative angular momentum. The most likely exchange force is

(a) Majorana (b) Bartlett (c) Heisenberg (d) Wigner

Exercise M-3.2: The range of a virtual particle of mass m is of the order of

(a) $\frac{\hbar}{mc^2}$ (b) $\frac{\hbar}{mc}$ (c) $\frac{\hbar c}{m}$ (d) $\frac{mc}{\hbar}$

Exercise M-3.3: The mass excess ($M - A$), defined as the difference between the atomic mass M and the atomic mass number A of the nucleus, for four isobars X, Y, M, and N is, respectively, −5432−3248, +3269, and +5671 μm (micro mass unit). The most and the least bound nuclei are, respectively,

(a) N and X (b) M and Y (c) X and N (d) Y and M

Exercise M-3.4: The maximum Coulomb potential energy (in MeV) between $^{27}_{13}$Al and $^{64}_{29}$Cu nuclei is about ($r_0 = 1.2$ F)

(a) 15 (b) 25 (c) 35 (d) 45

Exercise M-3.5: The life time of a virtual particle of mass m cannot be larger than

(a) $\frac{\hbar}{mc^2}$ (b) $\frac{\hbar}{mc}$ (c) $\frac{\hbar c}{m}$ (d) $\frac{mc}{\hbar}$

Exercise M-3.6: Which type of nuclear force is always attractive?

(a) Majorana (b) Bartlett (c) Heisenberg (d) Wigner

Exercise M-3.7: Arrange the nuclides $^{14}_{7}N$, $^{16}_{8}O$, and $^{17}_{9}F$ in the decreasing order of neutron separation energies.

(a) $^{14}_{7}N$, $^{16}_{8}O$, and $^{17}_{9}F$ (b) $^{17}_{9}F$, $^{14}_{7}N$, and $^{16}_{8}O$

(c) $^{17}_{9}F$, $^{16}_{8}O$, and $^{14}_{7}N$ (d) $^{16}_{8}O$, $^{17}_{9}F$, and $^{14}_{7}N$

Exercise M-3.8: Deuteron is considered to be an admixture of S and D states. Deuteron could not be an admixture of S and P states because such an admixture will not reproduce the

(a) mass of deuteron (b) spin of deuteron

(c) quadrupole moment of deuteron (d) parity of deuteron

Exercise M-3.9: Deuteron could not be an admixture of S and F($\ell = 4$) states because such an admixture will not reproduce the

(a) mass of deuteron (b) spin of deuteron

(c) quadrupole moment of deuteron (d) parity of deuteron

Exercise M-3.10: Strong spin orbit coupling is required to explain

(a) stability of nuclei (b) higher magic numbers

(c) n-p scattering data (d) deuteron quadrupole moment

Quantum Mechanical Analysis of Some Nuclear Systems

Information about the nuclear force that binds nucleons in the nucleus is obtained essentially from four types of studies: (1) the systematic of stable nuclei, (2) properties of the ground state and excited states of stable and long-lived radioactive nuclei, (3) nucleon–nucleon scattering, and (4) nuclear reactions. The other possible approach is to assume a certain nature for the nuclear force and theoretically generate a nucleus with given numbers of neutrons and protons and then to compare the properties of the theoretically generated nucleus with the one actually existing in nature. Refinements in the assumptions made about the nuclear force may then be carried out to reproduce the experimental data. Both these approaches have been followed in nuclear physics. However, from the perspective of developing a theoretical model of the nucleus, light stable nuclei with only a few nucleons are best suited. The lightest nucleus is the nucleus of hydrogen atom that contains a single proton. There is no excited state of hydrogen nucleus and, therefore, not much information about the nature of nuclear force can be obtained from it. Electron scattering experiments have indicated that the positive charge distribution in proton has a radius of about 0.8 F. Deuteron is the next stable nucleus that has one neutron and one proton. Deuteron does not have any excited state as well. However, the measured values of the spin, magnetic dipole moment, electric quadrupole moment, and the electromagnetic radius of deuteron have given valuable information about the nature of the nuclear force.

Successful application of quantum mechanical approach to the hydrogen atom by Bohr and subsequent development of detailed quantum mechanical frame work by Heisenberg, Schrödinger, and others established beyond doubt its power of describing subatomic systems. In this chapter, elementary quantum mechanical treatment of deuteron, nucleon–nucleon scattering, and barrier transmission is developed.

4.1 DEUTERON AND ITS PROPERTIES

Deuteron is the only stable system with two nucleons, a proton, and a neutron that is found in a free state in nature. Study of the deuteron is, therefore, of considerable value in getting information about the nature and properties of nucleon–nucleon force. Both di-neutron (a system with two neutrons) and di-proton are unstable and not found in nature. The presently accepted values of deuteron parameters along with brief notes on the method of their measurement and significance are as follows:

1. Deuteron represented as ${}^{2}_{1}\mathrm{D}$ or ${}^{2}_{1}\mathrm{H}$ is found only in ground state and its excited states are unstable.
2. **Mass:** $3.34358325 \times 10^{-27}$ kg, or 2.01355532 u; or 1875.61282 MeV.
   It is determined by penning trap technique.
3. **Binding energy:** 2.225 MeV.
   It is determined from the energy of gamma rays emitted in the radiative capture reaction ${}^{1}_{0}\mathrm{n} + {}^{1}_{1}\mathrm{p} = {}^{2}_{1}\mathrm{D} + \gamma$ (also written in short as n (p, γ) D). It may be noted that the binding energy per nucleon (B/A) in deuteron is only 1.11 MeV, which is much smaller than the average binding energy per nucleon of ≈8 MeV in the case of heavy nuclei. This indicates that the deuteron is a loosely bound system.
4. **Spin (or angular momentum) $J = 1$.**
   The spin of the deuteron has been determined by counting the number of components in hyperfine multiplet.

   Deuteron contains one neutron and one proton, each with spin ½. A spin value of 1 for deuteron is possible when the spins of the proton and the neutron are parallel and point in the same direction. As the spin $J = 1$ can have three possible values of the magnetic quantum number m_J, the deuteron is a triplet state. The singlet state of a neutron and a proton system, where the spins of the two particles are opposite to each other giving a resultant $J = 0$, does not exist. It means that ^{3}(n, p) state (deuteron) is a bound stable state and the ^{1}(n, p)-singlet state is unbound.
5. **Magnetic dipole moment μ_d:** 0.857393 nm (nuclear magneton).
   It is determined using magnetic resonance method.
   It may be noted that the magnetic dipole moment of deuteron is nearly, *but not exactly equal to* the sum of the magnetic moments of neutron and proton.

   $$\mu_n = -1.913 \text{ nm}; \mu_p = 2.792 \text{ nm. Hence, } \mu_n + \mu_p = 0.879 \text{ nm} \neq \mu_d.$$

   The fact that the magnetic moment of deuteron is nearly equal to the sum of the inherent magnetic moments of neutron and proton suggests that there is almost no contribution to the magnetic moment μ_d by the orbital motion of the proton. That means in deuteron, neutron, and proton are essentially in a state of a relative motion for which the relative orbital angular momentum ℓ is zero. The state of motion for which $\ell = 0$, is called the S-state. In deuteron, the neutron and the proton are in ${}^{3}\mathrm{S}_{1}$-state, the superscript 3 giving the multiplicity of the state and subscript 1 indicating the J value. The ${}^{3}\mathrm{S}_{1}$-state is spherically symmetric.
6. **Electric quadrupole moment Q_d:** 2.86×10^{-3} b (b = barn; 1b = 10^{-24} cm^{2}).
   The electric quadrupole moment of deuteron has been determined from the shift in the energy of lines in the rotational band spectrum. As Q_d is positive, the deuteron has a positive charge distribution of prolate shape.

   Now, there is a contradiction. As mentioned earlier, from the magnitude of the magnetic moment it appears that deuteron is a ${}^{3}\mathrm{S}_{1}$-state. However, S-state is spherically symmetric and, therefore, the quadrupole moment of deuteron should have been zero. As will be discussed later, the deuteron is not a pure S-state. It is an admixture of ${}^{3}\mathrm{S}_{1}$ and ${}^{3}\mathrm{D}_{1}$ states.

If it is assumed that for about 96% time of the motion the neutron and proton remain in $^3S_1$-state but for a very small time, about 4% of the time period, they are in the $^3D_1$-state for which the relative angular momentum $\ell = 2$, but $J = 1$, then the magnitudes of both Q_d and μ_d can be satisfactorily reproduced. When in $^3D_1$-state, the magnetic moment of proton due to orbital motion also contributes to the magnetic moment of the deuteron along with the inherent magnetic moments of neutron and the proton. This explains why $\mu_d \neq \mu_p + \mu_n$. Also, when deuteron changes from $^3S_1$ to $^3D_1$, the spin of the deuteron flips to keep the value of $J = (\ell + s) = 1$. This means that the directions of ℓ and s are parallel but opposite. As such, the magnetic moment due to the orbital motion of proton is negative. This explains why $\mu_d < (\mu_n + \mu_p)$.

7. **Radius of the deuteron:** The root mean square electromagnetic radius, which is defined by the relation $[<r^2>]^{1/2} = [\int r^2\rho(r)d^3r/\rho(r)d^3r]^{1/2}$, where $\rho(r)$ is the charge density at a distance r from the nuclear centre, has been determined from electron scattering and is about 2.1 F for deuteron.
8. **Parity of deuteron:** Parity of deuteron, deduced from deuteron reactions and theoretical consideration, is even.
9. **Statistics:** Deuteron with two nucleons (in $J = 1$ state) follows Bose–Einstein statistics.

4.2 SCHRÖDINGER EQUATIONS FOR A SYSTEM OF TWO SPINLESS PARTICLES IN SPHERICAL POLAR COORDINATES

We consider the general case of a system of two *spinless* particles of mass M_1 and M_2 with total energy W and potential energy U. The two-body problem can be reduced to a one-body problem by using the centre of mass (CM) coordinates. In CM system, one considers the motion of only one particle of reduced mass M, where $M = \frac{M_1 M_2}{M_1 + M_2}$ moving with the velocity V with respect to the centre of mass. Here, V is the relative velocity of M_1 and M_2. The Schrödinger equation for the particle of reduced mass M in Cartesian coordinates is

$$\nabla^2\psi + \left(\frac{2M}{\hbar^2}\right)[W - U]\psi = 0 \tag{4.1}$$

Here, ψ is the space part of the wave function. Next step is to write Eq. (4.1) in spherical polar coordinates. Spherical polar coordinates are better suited for problems related to the nucleus because of the spherical symmetry. The three spherical polar coordinates r, θ, and φ are related to the Cartesian coordinates x, y, and z through the relations $x = r \sin\theta \cos\varphi$; $y = r \sin\theta \sin\varphi$; and $z = r \cos\theta$, as shown in figure 4.1, the polar axis is taken in z-direction.

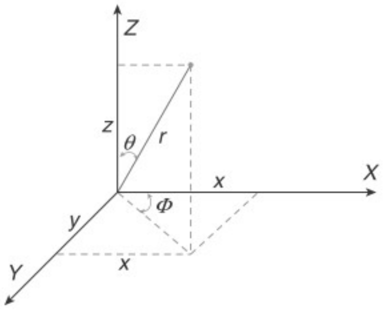

Figure 4.1 *Relation between the spherical polar and Cartesian coordinates*

Schrödinger Eq. (4.1) in spherical polar coordinates is

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial \psi}{\partial r}\right)+\frac{1}{r^2\sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta\frac{\partial \psi}{\partial \theta}\right)+\frac{1}{r^2 sin^2\theta}\frac{\partial^2 \psi}{\partial \varphi^2}+\frac{2M}{\hbar^2}[W-U]\psi=0 \qquad (4.2)$$

We now make another assumption that the potential U is a function of r alone and does not depend on θ and φ, that is $U = U(r)$, then the wave function $\psi(r, \theta, \varphi)$ may be written in two parts: $\chi(r)$, a function of r only and $Y(\theta, \varphi)$ a function of (θ, φ) only. Therefore, substituting $\psi(r, \theta, \varphi) = \chi(r)Y(\theta, \varphi)$, and dividing by ψ, we get

$$\frac{1}{\chi(r)}\frac{d}{dr}\left(r^2\frac{d}{dr}\chi(r)\right)+\frac{2Mr^2}{\hbar^2}[W-U(r)]=-\frac{1}{Y(\theta,\varphi)}\left[\frac{1}{\sin\theta}\frac{\partial}{\partial \boldsymbol{\theta}}\{Y(\theta,\varphi)\}+\frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\varphi^2}\{Y(\theta,\varphi)\}\right] \qquad (4.3)$$

In Eq. (4.3), LHS is a function of r alone and RHS is a function only of θ and φ. As r, θ, and φ are all independent variables, Eq. (4.3) will hold only if the two sides are equal to some constant. Let the constant be $\ell\,(\ell + 1)$. Thus, the radial part of Eq. (4.3) may be written as

$$\frac{1}{\chi(r)}\frac{d}{dr}\left(r^2\frac{d}{dr}\chi(r)\right)+\frac{2Mr^2}{\hbar^2}[W-U(r)]=\ell(\ell+1)$$

or
$$\frac{1}{\chi(r)}\frac{d}{dr}\left(r^2\frac{d}{dr}\chi(r)\right)+\frac{2Mr^2}{\hbar^2}[W-U(r)-\{(\ell(\ell+1)\hbar^2/2Mr^2\}]=0 \qquad (4.4a)$$

And the angular part as

$$-\frac{1}{Y(\theta,\varphi)}\left[\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\{Y(\theta,\varphi)\}+\frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\varphi^2}\{Y(\theta,\varphi)\}\right]=\ell(\ell+1) \qquad (4.4b)$$

The constant of separation $\ell(\ell + 1)$ has been chosen with a purpose. Let us recall that Eq. (4.4) in classical framework represents the motion of a particle of mass M, total energy W, and potential energy $U(r)$ moving with a velocity V in the centre of mass. V is the relative velocity of the particles. The kinetic energy of the particle is $\frac{1}{2}MV^2$. The total energy W is the sum of the kinetic and potential energy. Therefore,

$$W=\left(\frac{1}{2}\right)MV^2+U(r) \qquad (4.5)$$

As $U(r)$ is positive, it is derived from a force of repulsion between the two particles. A rough sketch of the classical motion of the particle of mass M around the centre of mass C is shown in figure 4.2.

Let the distance of closest approach of the particle to the centre of mass be x when the particle is at point P. Now, at point P the velocity V of the particle is normal to x and hence the angular momentum J of the particle is given by

$$J = MVx \quad \text{or} \qquad (4.6)$$

$$V = J/Mx \qquad (4.7)$$

Substituting the value of V in Eq. (4.5), for the total energy of the particle, we get

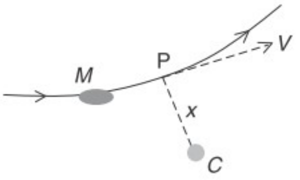

Figure 4.2 *Classical motion of the particle of reduced mass M about the centre of mass C*

$$
\begin{aligned}
W\,(\text{at P}) &= \frac{1}{2}(MJ^2/M^2x^2) + U(r = x) \\
&= (J^2/2Mx^2) + U(r = x) = (J^2/2I) + U(r = x) \qquad (4.8)
\end{aligned}
$$

Here, I represents the moment of inertia of the particle of mass M about an axis passing through the centre of mass. In Eq. (4.8), the kinetic energy of the linear motion of the particle is replaced by the energy of rotational motion with angular momentum J along an axis perpendicular to the polar axis and passing through the centre of mass. As no torque is present in the system, the angular momentum of the system is conserved. It means that the value of J remains same irrespective of the instantaneous position of the particle. Hence, Eq. (4.8) will remain valid for all values of r. In addition, in going from classical to quantum mechanical frame work $J^2 = \ell(\ell + 1)$ and therefore at any instance, the total energy of the particle may be written as

$$W = [\{(\ell(\ell + 1)\,\hbar^2/2Mr^2\} + U(r)] \qquad (4.9)$$

From Eq. (4.9), it may be observed that the sign of both the terms $\{(\ell(\ell + 1)\hbar^2/2Mr^2\}$ and $U(r)$ is the same. A potential with positive sign is derived from a repulsive force and, therefore, the first term in Eq. (5.9) also represents a potential that corresponds to a repulsive force. The first term, which has the dimensions of energy, is called the centrifugal potential because like the classical centrifugal force it has the tendency to pull the particle away from the centre of mass. Larger the value of the angular momentum ℓ more will be the centrifugal force.

Coming back to Eq. (4.4a), for the ground state of the system, which is the lowest energy state, ℓ should be zero. *It may, therefore, be said that for the ground state of a two-body system of spinless particles in a central potential, the orbital angular momentum of the relative motion of the particles is zero and the system is said to be in S state.* States of a system with relative angular momentum $\ell = 0, 1, 2, 3 \ldots$ are, respectively, designated as S, P, D, … states.

Finally, the Schrödinger equation for the ground state of a system of two spinless particles of reduced mass M, total energy W, and in a central potential $U(r)$, which depends only on r is

$$\frac{1}{\chi(r)}\frac{d}{dr}\left(r^2\frac{d}{dr}\chi(r)\right) + \frac{2Mr^2}{\hbar^2}[W - U(r)] = 0 \qquad (4.10)$$

To simplify the calculations, we substitute

$$u(r) = r\chi(r) \qquad (4.11)$$

The function $u(r)$ is called the reduced radial wave function. With this substitution, Eq. (4.10) reduces to

$$\left(\frac{d^2u(r)}{dr^2}\right) + \frac{2Mr^2}{\hbar^2}[W - U(r)]\,u(r) = 0 \qquad (4.12)$$

Equation (4.12) is the *reduced radial equation* for the ground state of a system of two spinless particles of reduced mass M, total energy W, and potential energy $U(r)$, which is a function of r alone. Eq. (4.12) is quite general, the only conditions imposed so far are (i) the particles are spinless and (ii) that $U(r)$ is a spherically symmetric function of r. It may be remarked that in Eq. (4.12), if W is positive it refers to a system of two particles that are free and not bound. A positive value of $U(r)$ means a repulsive force between the two particles. A negative value of

W means a bound system and a negative value of $U(r)$ refers to a force of attraction between the particles.

Next, we consider the angular part of the wave function described by Eq. (4.4b)). If it is further assumed that the function $Y(\theta, \varphi)$ may be written as the multiplication of two independent functions $\Theta(\theta)$ and $\Phi(\varphi)$, which are functions only of θ and φ, respectively, then on substituting $Y(\theta, \varphi) = \Theta(\theta)\, \Phi(\varphi)$ in Eq. (4.4b)), we get

$$\sin^2\theta\left[\frac{1}{\Theta\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right)+\ell(\ell+1)\right]=-\frac{1}{\Phi}\frac{d^2\Phi}{d\phi^2}$$

$$= m^2 \text{ (separation constant)} \tag{4.4c}$$

In Eq. (4.4c), the LHS and the RHS are independent of each other and are, therefore, equal to some constant of separation, for instance, m^2. Eq. (4.4c) gives two equations, one polar and the other azimuthal as

$$\left[\frac{1}{\Phi\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Phi}{d\theta}\right)+\ell\left(\ell+1\right)\right]-\frac{m^2}{\sin^2\theta}=0 \tag{4.4d}$$

And
$$\frac{d^2\Phi}{d\phi^2}+m^2\Phi=0 \tag{4.4e}$$

Equation (4.4d) is the well-known Legendre's equation. Being a second-order differential equation, it has two independent solutions. Except for the values of the separation constant $\ell(\ell+1) = 0, 2, 6 \ldots$ for which ℓ has the values 0, 1, 2, 3, … both the solutions of Legendre's equation becomes infinite for $\cos\theta = \pm 1$ and, therefore, not acceptable. It can be shown that for $\ell = 0$ and for other positive integer values and for $\ell \geq |m|$, one of the solution of Legendre's equation remains finite, single valued, and continuous, that is a well-behaved function.

If $m = 0$, from Eq. (4.4e), $\Phi(\phi)$ becomes constant. Under these conditions, the acceptable Legendre's solutions are called Legendre's polynomials and are represented by $P_\ell(\cos\theta)$. The expressions for the first few Legendre's polynomials are as follows:

$$P_0(\cos\theta) = 1$$

$$P_1(\cos\theta) = \cos\theta;$$

$$P_2(\cos\theta) = \frac{1}{2}(3\cos^2\theta - 1) = \frac{1}{4}(3\cos 2\theta + 1)$$

$$P_3(\cos\theta) = \frac{1}{2}(5\cos^3\theta - 3\cos\theta) = \frac{1}{8}(5\cos 3\theta + 3\cos\theta)$$

The azimuthal Eq. (4.4e) has the solution

$$\Phi_{\mathrm{m}}(\varphi) = e^{\pm m\varphi} \tag{4.4f}$$

As an increase in φ by 2π should bring back to the starting position in space and must give the same value of Φ, the allowed values of m, the magnetic quantum number, may be negative or positive integers.

In the case when the magnetic quantum number m is not zero but $|m| \leq \ell$, solution of Legendre's equation are called associate Legendre's polynomials and are represented by $P^{\mathrm{l}}_{\mathrm{m}}(\cos\theta)$.

$$P^{\ell}{}_{\mathrm{m}}(\cos\theta) = \left[(1-cos^2\theta)^{\frac{|m|}{2}}\right] \frac{d^{|m|}(P_\ell \cos\theta)}{d\cos\theta^{|m|}}$$

The angular part of the space wave function $Y = \Theta(\theta)\Phi(\varphi)$ depends on l, m, θ, and φ and may be written as

$$Y_{\ell\mathrm{m}}(\theta, \varphi) = N_{\ell\mathrm{m}}\, P_\ell^m(\cos\,\theta)\, e^{im\varphi}$$

Here, $N_{\ell\mathrm{m}}$ is the normalization constant. $Y_{\ell\mathrm{m}}(\theta, \varphi)$ are called the spherical harmonics.

4.3 SIMPLE QUANTUM MECHANICAL DESCRIPTION OF DEUTERON

Now, we move to the specific case of the deuteron and rewrite Eq. (4.12). In the case of deuteron, the reduced mass $M = \{(M_\mathrm{n}M_\mathrm{p})/(M_\mathrm{n} + M_\mathrm{p})\}$, where M_n and M_p are, respectively, the masses of neutron and proton. As the masses of neutron and proton are nearly equal, the reduced mass M is nearly equal to half the mass of a neutron or a proton. The deuteron is a bound system and, therefore, $W = -E_\mathrm{b}$, where E_b is the binding energy of the ground state. As in deuteron the nuclear force between neutron and proton is attractive, we represent it by a negative square-well (also called rectangular-well) potential of depth V_0 and width b (figure 4.3).

The phase angle between earth and Mars when the spacecraft reaches Mars is given by Eq. (8.13).

$$\phi_f = \pi - n_{\text{earth}} t_{12} = \pi - 0.017202 \cdot 258.82 = -1.3107\,\text{rad}$$

Since $n_{\text{earth}} > n_{\text{Mars}}$, we choose Eq. (8.16) to find the wait time

$$t_{\text{wait}} = \frac{-2\phi_f - 2\pi N}{n_{\text{Mars}} - n_{\text{earth}}} = \frac{-2(-1.3107) - 2\pi N}{0.0091327 - 0.017202} = 778.65N - 324.85\,\text{days}$$

$N = 0$ yields a negative value, which we cannot accept. Setting $N = 1$, we find

$$\boxed{t_{\text{wait}} = 453.8\,\text{days}}$$

This is the minimum wait time (1.24 years). Obviously, we could set $N = 2, 3, \ldots$ to obtain longer wait times.

For a spacecraft to depart on a mission to Mars by means of a Hohmann (minimum energy) transfer, the phase angle between earth and Mars must be that given by Eq. (8.12). Using the results of Example 8.2, we find it to be

$$\phi_0 = \pi - n_{\text{Mars}} t_{12} = \pi - 0.0091327 \cdot 258.82 = 0.7778\,\text{rad} = 44.57°$$

This opportunity occurs once every synodic period, which we found to be 2.13 years in Example 8.1. In Example 8.2, we found that the time to fly to Mars is 258.8 days, followed by a wait time of 453.8 days, followed by a return trip time of 258.8 days. Hence, the minimum total time for a manned Mars mission, using Hohmann transfers is

$$t_{\text{total}} = 258.8 + 453.8 + 258.8 = 971.4\,\text{days} = 2.66\,\text{years}$$

8.4 SPHERE OF INFLUENCE

The sun, of course, is the dominant celestial body in the solar system. It is over 1000 times more massive than the largest planet, Jupiter, and has a mass of over 300,000 earths. The sun's gravitational pull holds all the planets in its grasp according to Newton's law of gravity (Eq. 1.31). However, near a given planet, the influence of its own gravity exceeds that of the sun. For example, at its surface the earth's gravitational force is over 1600 times greater than the sun's. The inverse-square nature of the law of gravity means that the force of gravity F_g drops off rapidly with distance r from the center of attraction. If F_{g0} is the gravitational force at the surface of a planet with radius r_0, then Fig. 8.5 shows how rapidly the force diminishes with distance. At 10 body radii, the force is 1% of its value at the surface. Eventually, the force of the sun's gravitational field overwhelms that of the planet.

To estimate the radius of a planet's gravitational sphere of influence, consider the three-body system comprising a planet p of mass m_p, the sun s of mass m_s, and a space vehicle v of mass m_v illustrated in Fig. 8.6. The position vectors of the planet and spacecraft relative to an inertial frame centered at the sun are $\mathbf{R}$ and $\mathbf{R}_v$, respectively. The position vector of the space vehicle relative to the planet is $\mathbf{r}$. (Throughout this chapter we will use uppercase letters to represent position, velocity, and acceleration measured relative to the sun and lowercase letters when they are measured relative to a planet.) The gravitational force exerted on the vehicle by the planet is denoted $\mathbf{F}_p^{(v)}$, and that exerted by the

sun is $\mathbf{F}_s^{(v)}$. Likewise, the forces on the planet are $\mathbf{F}_s^{(p)}$ and $\mathbf{F}_v^{(p)}$, whereas on the sun we have $\mathbf{F}_v^{(s)}$ and $\mathbf{F}_p^{(s)}$. According to Newton's law of gravitation (Eq. 2.10), these forces are

$$\mathbf{F}_p^{(v)} = -\frac{Gm_v m_p}{r^3}\mathbf{r} \tag{8.18a}$$

$$\mathbf{F}_s^{(v)} = -\frac{Gm_v m_s}{{R_v}^3}\mathbf{R}_v \tag{8.18b}$$

$$\mathbf{F}_s^{(p)} = -\frac{Gm_p m_s}{R^3}\mathbf{R} \tag{8.18c}$$

Observe that

$$\mathbf{R}_v = \mathbf{R} + \mathbf{r} \tag{8.19}$$

From Fig. 8.6 and the law of cosines we see that the magnitude of $\mathbf{R}_v$ is

$$R_v = \left(R^2 + r^2 - 2Rr\cos\theta\right)^{1/2} = R\left[1 - 2(r/R)\cos\theta + (r/R)^2\right]^{1/2} \tag{8.20}$$

We expect that within the planet's sphere of influence, $r/R \ll 1$. In that case, the terms involving r/R in Eq. (8.20) can be neglected, so that, approximately,

$$R_v = R \tag{8.21}$$

The equation of motion of the spacecraft relative to the sun-centered inertial frame is

$$m_v \ddot{\mathbf{R}}_v = \mathbf{F}_s^{(v)} + \mathbf{F}_p^{(v)}$$

Solving for $\ddot{\mathbf{R}}_v$ and substituting the gravitational forces given by Eqs. (8.18a) and (8.18b), we get

$$\ddot{\mathbf{R}}_v = \frac{1}{m_v}\left(-\frac{Gm_v m_s}{{R_v}^3}\mathbf{R}_v\right) + \frac{1}{m_v}\left(-\frac{Gm_v m_p}{r^3}\mathbf{r}\right) = -\frac{Gm_s}{{R_v}^3}\mathbf{R}_v - \frac{Gm_p}{r^3}\mathbf{r} \tag{8.22}$$

Let us write this as

$$\ddot{\mathbf{R}}_v = \mathbf{A}_s + \mathbf{P}_p \tag{8.23}$$

where

$$\mathbf{A}_s = -\frac{Gm_s}{{R_v}^3}\mathbf{R}_v \qquad \mathbf{P}_p = -\frac{Gm_p}{r^3}\mathbf{r} \tag{8.24}$$

$\mathbf{A}_s$ is the primary gravitational acceleration of the vehicle due to the sun, and $\mathbf{P}_p$ is the secondary or perturbing acceleration due to the planet. The magnitudes of $\mathbf{A}_s$ and $\mathbf{P}_p$ are

$$A_s = \frac{Gm_s}{R^2} \qquad P_p = \frac{Gm_p}{r^2} \tag{8.25}$$

where we made use of the approximation given by Eq. (8.21). The ratio of the perturbing acceleration to the primary acceleration is, therefore,

$$\frac{P_p}{A_s} = \frac{\dfrac{Gm_p}{r^2}}{\dfrac{Gm_s}{R^2}} = \frac{m_p}{m_s}\left(\frac{R}{r}\right)^2 \tag{8.26}$$

The equation of motion of the planet relative to the inertial frame is

$$m_p \ddot{\mathbf{R}} = \mathbf{F}_v^{(p)} + \mathbf{F}_s^{(p)}$$

Solving for $\ddot{\mathbf{R}}$, noting that $\mathbf{F}_v^{(p)} = -\mathbf{F}_p^{(v)}$, and using Eqs. (8.18b) and (8.18c) yields

$$\ddot{\mathbf{R}} = \frac{1}{m_p}\left(\frac{Gm_v m_p}{r^3}\mathbf{r}\right) + \frac{1}{m_p}\left(-\frac{Gm_p m_s}{R^3}\mathbf{R}\right) = \frac{Gm_v}{r^3}\mathbf{r} - \frac{Gm_s}{R^3}\mathbf{R} \tag{8.27}$$

Subtracting Eq. (8.27) from Eq. (8.22) and collecting terms, we find

$$\ddot{\mathbf{R}}_v - \ddot{\mathbf{R}} = -\frac{Gm_p}{r^3}\mathbf{r}\left(1 + \frac{m_v}{m_p}\right) - \frac{Gm_s}{{R_v}^3}\left[\mathbf{R}_v - \left(\frac{R_v}{R}\right)^3\mathbf{R}\right]$$

Recalling Eq. (8.19), we can write this as

$$\ddot{\mathbf{r}} = -\frac{Gm_p}{r^3}\mathbf{r}\left(1+\frac{m_v}{m_p}\right) - \frac{Gm_s}{{R_v}^3}\left\{\mathbf{r}+\left[1-\left(\frac{R_v}{R}\right)^3\right]\mathbf{R}\right\} \tag{8.28}$$

This is the equation of motion of the vehicle relative to the planet. By using Eq. (8.21) and the fact that $m_v \ll m_p$, we can write this in approximate form as

$$\ddot{\mathbf{r}} = \mathbf{a}_p + \mathbf{p}_s \tag{8.29}$$

where

$$\mathbf{a}_p = -\frac{Gm_p}{r^3}\mathbf{r} \quad \mathbf{p}_s = -\frac{Gm_s}{R^3}\mathbf{r} \tag{8.30}$$

In this case $\mathbf{a}_p$ is the primary gravitational acceleration of the vehicle due to the planet and $\mathbf{p}_s$ is the perturbation caused by the sun. The magnitudes of these vectors are

$$a_p = \frac{Gm_p}{r^2} \quad p_s = \frac{Gm_s}{R^3}r \tag{8.31}$$

The ratio of the perturbing acceleration to the primary acceleration is

$$\frac{p_s}{a_p} = \frac{Gm_s\dfrac{r}{R^3}}{\dfrac{Gm_p}{r^2}} = \frac{m_s}{m_p}\left(\frac{r}{R}\right)^3 \tag{8.32}$$

For motion relative to the planet, the ratio p_s/a_p is a measure of the deviation of the vehicle's orbit from the Keplerian orbit arising from the planet acting by itself ($p_s/a_p = 0$). Likewise, P_p/A_s is a measure of the planet's influence on the orbit of the vehicle relative to the sun. If

$$\frac{p_s}{a_p} < \frac{P_p}{A_s} \tag{8.33}$$

then the perturbing effect of the sun on the vehicle's orbit around the planet is less than the perturbing effect of the planet on the vehicle's orbit around the sun. We say that the vehicle is therefore within the planet's sphere of influence. Substituting Eqs. (8.26) and (8.32) into Eq. (8.33) yields

$$\frac{m_s}{m_p}\left(\frac{r}{R}\right)^3 < \frac{m_p}{m_s}\left(\frac{R}{r}\right)^2$$

which means

$$\left(\frac{r}{R}\right)^5 < \left(\frac{m_p}{m_s}\right)^2$$

or

$$\frac{r}{R} < \left(\frac{m_p}{m_s}\right)^{2/5}$$

Let r_{SOI} be the radius of the sphere of influence. Within the planet's sphere of influence, defined by

$$\frac{r_{\text{SOI}}}{R} = \left(\frac{m_p}{m_s}\right)^{2/5} \tag{8.34}$$

the motion of the spacecraft is determined by its equations of motion relative to the planet (Eq. 8.28). Outside the sphere of influence, the path of the spacecraft is computed relative to the sun (Eq. 8.22).

The sphere of influence radius presented in Eq. (8.34) is not an exact quantity. It is simply a reasonable estimate of the distance beyond which the sun's gravitational attraction dominates that of a planet. The spheres of influence of all the planets and the earth's moon are listed in Table A.2.

EXAMPLE 8.3

Calculate the radius of the earth's sphere of influence.

Solution

In Table A.1 we find

$$m_{\text{earth}} = 5.974\left(10^{24}\right)\text{kg}$$

$$m_{\text{sun}} = 1.989\left(10^{30}\right)\text{kg}$$

$$R_{\text{earth}} = 149.6\left(10^{6}\right)\text{km}$$

Substituting these data into Eq. (8.34) yields

$$r_{\mathbf{SOI}} = 149.6 \times 10^{6}\left(\frac{5.974 \times 10^{24}}{1.989 \times 10^{24}}\right)^{2/5} = \boxed{925 \times 10^{6}\,\text{km}}$$

Since the radius of the earth is 6378 km,

$$r_{\text{SOI}} = 145\,\text{earth radii}$$

Relative to the earth, its sphere of influence is very large. However, relative to the sun it is tiny, as illustrated in Fig. 8.7.

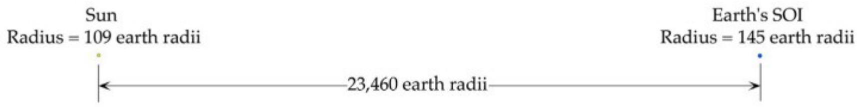

FIG. 8.7

The earth's sphere of influence and the sun, drawn to scale.

8.5 METHOD OF PATCHED CONICS

"Conics" refers to the fact that two-body, or Keplerian, orbits are conic sections with the focus at the attracting body. To study an interplanetary trajectory, we assume that when the spacecraft is outside the sphere of influence of a planet it follows an unperturbed Keplerian orbit around the sun. Because interplanetary distances are so vast, for heliocentric orbits we may neglect the size of the spheres of influence and consider them, like the planets they surround, to be just points in space coinciding with the planetary centers. Within each planetary sphere of influence, the spacecraft travels an unperturbed Keplerian path about the planet. While the sphere of influence appears as a mere speck on the scale of the solar system, from the point of view of the planet it is very large indeed and may be considered to lie at infinity.

To analyze a mission from planet 1 to planet 2 using the method of patched conics, we first determine the heliocentric trajectory, such as the Hohmann transfer ellipse discussed in Section 8.2, that will

6.3 HOHMANN TRANSFER

Walter Hohmann (1880–1945) was a German engineer whose interest in early rocketry led him to discover the orbital transfer maneuver that now bears his name. In a book published in 1925 (Hohmann, 1925), he showed that the Hohmann transfer is the most energy-efficient two-impulse maneuver for transferring between two coplanar circular orbits sharing a common focus. The Hohmann transfer is an elliptical orbit tangent to both circles on its apse line, as illustrated in Fig. 6.2. The periapsis and apoapsis of the transfer ellipse are the radii of the inner and outer circles, respectively. Obviously, only one-half of the ellipse is flown during the maneuver, which can occur in either direction, from the inner to the outer circle, or vice versa.

It may be helpful in sorting out orbit transfer strategies to use the fact that the energy of an orbit depends only on its semimajor axis a. Recall that for an ellipse (Eq. 2.80), the specific energy is negative,

$$\varepsilon = -\frac{\mu}{2a}$$

Increasing the energy requires reducing its magnitude, to make ε less negative. Therefore, the larger the semimajor axis, the more energy the orbit has. In Fig. 6.2, the energies increase as we move from the inner circle to the outer circle.

Starting at A on the inner circle, a velocity increment Δv_A in the direction of flight is required to boost the vehicle onto the higher energy elliptical trajectory. After coasting from A to B, another forward velocity increment Δv_B places the vehicle on the still higher energy, outer circular orbit. Without the latter delta-v burn, the spacecraft would, of course, remain on the Hohmann transfer ellipse and return to A. The total energy expenditure is reflected in the total delta-v requirement, $\Delta v_{\text{total}} = \Delta v_A + \Delta v_B$.

The same total delta-v is required if the transfer begins at B on the outer circular orbit. Since moving to the lower energy inner circle requires lowering the energy of the spacecraft, the Δv's must be accomplished by retrofires. That is, the thrust of the maneuvering rocket is directed opposite to the flight direction to act as a brake on the motion. Since Δv represents the same propellant expenditure regardless of the direction the thruster is aimed, when summing up Δv's, we are concerned only with their magnitudes.

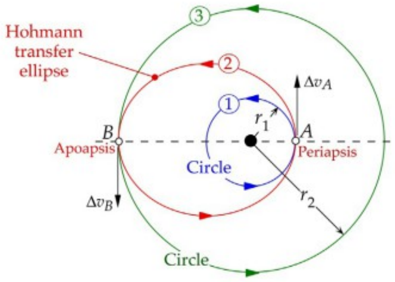

FIG. 6.2

Hohmann transfer.

Recall that the eccentricity of an elliptical orbit is found from its radius to periapsis r_p and its radius to apoapsis r_a by means of Eq. (2.84),

$$e = \frac{r_a - r_p}{r_a + r_p}$$

The radius to periapsis is given by Eq. (2.50),

$$r_p = \frac{h^2}{\mu}\frac{1}{1+e}$$

Combining these last two expressions yields

$$r_p = \frac{h^2}{\mu}\frac{1}{1+\dfrac{r_a - r_p}{r_a + r_p}} = \frac{h^2}{\mu}\frac{r_a + r_p}{2r_a}$$

Solving for the angular momentum h, we get

$$h = \sqrt{2\mu}\sqrt{\frac{r_a r_p}{r_a + r_p}} \tag{6.2}$$

This is a useful formula for analyzing Hohmann transfers, because knowing h we can find the apsidal velocities from Eq. (2.31). Note that for circular orbits ($r_a = r_p$), Eq. (6.2) yields

$$h = \sqrt{\mu r} \quad \text{(circular orbit)}$$

Alternatively, one may prefer to compute the velocities by means of the energy equation (Eq. 2.81) in the form

$$v = \sqrt{2\mu}\sqrt{\frac{1}{r} - \frac{1}{2a}} \tag{6.3}$$

This of course yields Eq. (2.63) for circular orbits.

EXAMPLE 6.1

A 2000-kg spacecraft is in a 480 km by 800 km earth orbit (orbit 1 in Fig. 6.3). Find

(a) The Δv required at perigee *A* to place the spacecraft in a 480 km by 16,000 km transfer ellipse (orbit 2).

(b) The Δv (apogee kick) required at *B* of the transfer orbit to establish a circular orbit of 16,000 km altitude (orbit 3).

(c) The total required propellant if the specific impulse is 300 s.

Solution

Since we know the perigee and apogee of all three of the orbits, let us first use Eq. (6.2) to calculate their angular momenta.

Orbit 1: $r_p = 6378 + 480 = 6858\,\text{km}$ $\quad r_a = 6378 + 800 = 7178\,\text{km}$

$$\therefore h_1 = \sqrt{2 \cdot 398{,}600}\sqrt{\frac{7178 \cdot 6858}{7178 + 6858}} = 52{,}876.5\,\text{km/s}^2 \tag{a}$$

Orbit 2: $r_p = 6378 + 480 = 6858\,\text{km}$ $\quad r_a = 6378 + 16{,}000 = 22{,}378\,\text{km}$

$$\therefore h_2 = \sqrt{2 \cdot 398{,}600}\sqrt{\frac{22{,}378 \cdot 6858}{22{,}378 + 6858}} = 64{,}689.5\,\text{km/s}^2 \tag{b}$$

Orbit 3: $r_a = r_p = 22{,}378\,\text{km}$

$$\therefore h_3 = \sqrt{398{,}600 \cdot 22{,}378} = 94{,}445.1\,\text{km/s}^2 \tag{c}$$

③
Apogee of orbit 2 (r = 22,378 km)
Circular orbit of radius 22,378 km

FIG. 6.3

Hohmann transfer between two earth orbits.

(a) The speed on orbit 1 at point *A* is

$$v_A)_1 = \frac{h_1}{r_A} = \frac{52,876}{6858} = 7.71019\text{km/s}$$

The speed on orbit 2 at point *A* is

$$v_A)_2 = \frac{h_2}{r_A} = \frac{64,689.5}{6858} = 9.43271\text{km/s}$$

Therefore, the delta-v required at point *A* is

$$\Delta v_A = v_A)_2 - v_A)_1 = \boxed{1.7225\text{km/s}}$$

(b) The speed on orbit 2 at point *B* is

$$v_B)_2 = \frac{h_2}{r_B} = \frac{64,689.5}{22,378} = 2.89076\text{km/s}$$

The speed on orbit 3 at point *B* is

$$v_B)_3 = \frac{h_3}{r_B} = \frac{94,445.1}{22,378} = 4.22044\text{km/s}$$

Hence, the apogee kick required at point *B* is

$$\Delta v_B = v_B)_3 - v_B)_2 = \boxed{1.3297\text{km/s}}$$

(c) The total delta-v requirement for this Hohmann transfer is

$$\Delta v_{\text{total}} = |\Delta v_A| + |\Delta v_B| = 1.7225 + 1.3297 = 3.0522\text{km/s}$$

According to Eq. (6.1) (converting velocity to m/s),

$$\frac{\Delta m}{m} = 1 - e^{-\frac{3052.2}{300 \cdot 9.807}} = 0.64563$$

Therefore, the mass of propellant expended is

$$\boxed{\Delta m = 0.64563 \cdot 2000 = 1291.3\text{kg}}$$

In the previous example the initial orbit of the Hohmann transfer sequence was an ellipse rather than a circle. Since no real orbit is perfectly circular, we must generalize the notion of a Hohmann transfer to include two-impulse transfers between elliptical orbits that are coaxial (i.e., share the same apse line), as shown in Fig. 6.4. The transfer ellipse must be tangent to both the initial and target ellipses 1 and 2. As can be seen, there are two such transfer orbits, 3 and 3′. It is not immediately obvious which of the two requires the lowest energy expenditure.

To find out which is the best transfer orbit in general, we must calculate the individual total delta-v requirement for orbits 3 and 3′. This requires finding the velocities at A, A', B, and B' for each pair of orbits having those points in common. We employ Eq. (6.2)to evaluate the angular momentum of each of the four orbits in Fig. 6.4.

$$h_1 = \sqrt{2\mu}\sqrt{\frac{r_A r_{A'}}{r_A + r_{A'}}} \quad h_2 = \sqrt{2\mu}\sqrt{\frac{r_B r_{B'}}{r_B + r_{B'}}} \quad h_3 = \sqrt{2\mu}\sqrt{\frac{r_A r_B}{r_A + r_B}} \quad h_{3'} = \sqrt{2\mu}\sqrt{\frac{r_{A'} r_{B'}}{r_{A'} + r_{B'}}}$$

From these we obtain the velocities,

$$\begin{array}{ll} v_A)_1 = \dfrac{h_1}{r_A} & v_A)_3 = \dfrac{h_3}{r_A} \\ v_B)_2 = \dfrac{h_2}{r_B} & v_B)_3 = \dfrac{h_3}{r_B} \\ v_{A'})_1 = \dfrac{h_1}{r_{A'}} & v_{A'})_{3'} = \dfrac{h_{3'}}{r_{A'}} \\ v_{B'})_2 = \dfrac{h_2}{r_{B'}} & v_{B'})_{3'} = \dfrac{h_{3'}}{r_{B'}} \end{array}$$

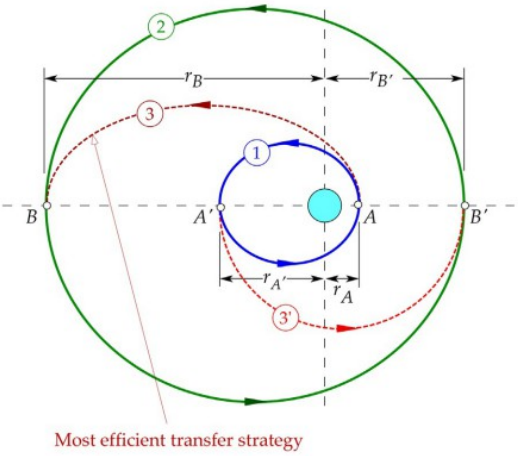

FIG. 6.4

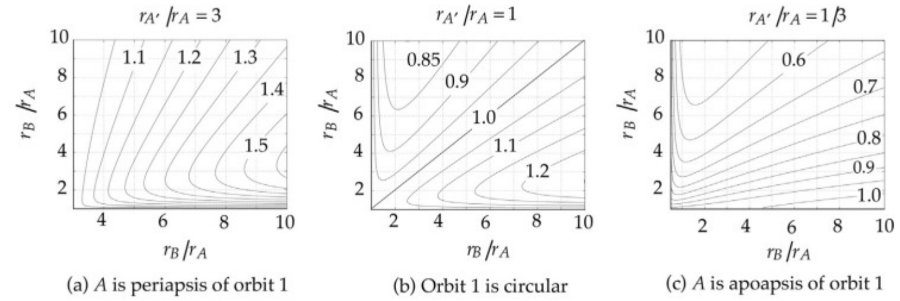
Hohmann transfers between coaxial elliptical orbits. In this illustration, $r_{A'}/r_A = 3$, $r_B/r_A = 8$, and $r_{B'}/r_A = 4$.



(a) A is periapsis of orbit 1 (b) Orbit 1 is circular (c) A is apoapsis of orbit 1

FIG. 6.5

Contour plots of $\Delta v_{\text{total}})_{3'}/\Delta v_{\text{total}})_3$ for different relative sizes of the ellipses in Fig. 6.4. Note that $r_B > r_{A'}$ and $r_{B'} > r_A$.

These lead to the delta-v's

$$\Delta v_A = \left| v_A)_3 - v_A)_1 \right| \quad \Delta v_B = \left| v_B)_2 - v_B)_3 \right| \quad \Delta v_{A'} = \left| v_{A'})_{3'} - v_{A'})_1 \right| \quad \Delta v_{B'} = \left| v_{B'})_2 - v_{B'})_{3'} \right|$$

and, finally, to the total delta-v requirement for the two possible transfer trajectories,

$$\Delta v_{\text{total}})_3 = \Delta v_A + \Delta v_B \qquad \Delta v_{\text{total}})_{3'} = \Delta v_{A'} + \Delta v_{B'}$$

If $\Delta v_{\text{total}})_{3'}/\Delta v_{\text{total}})_3 > 1$, then orbit 3 is the most efficient. On the other hand, if $\Delta v_{\text{total}})_{3'}/\Delta v_{\text{total}})_3 < 1$, then orbit 3′ is more efficient than orbit 3.

Three contour plots of $\Delta v_{\text{total}})_{3'}/\Delta v_{\text{total}})_3$ are shown in Fig. 6.5, for three different shapes of inner orbit 1 of Fig. 6.4. Fig. 6.5a is for $r_{A'}/r_A = 3$, which is the situation represented in Fig. 6.4, in which point A is the periapsis of the initial ellipse. In Fig. 6.5b $r_{A'}/r_A = 1$, which means the starting ellipse is a circle. Finally, in Fig. 6.5c $r_{A'}/r_A = 1/3$, which corresponds to an initial orbit of the same shape as orbit 1 in Fig. 6.4, but with point A being the apoapsis instead of periapsis.

Fig. 6.5a, for which $r_{A'} > r_A$, implies that if point A is the periapsis of orbit 1, then transfer orbit 3 is the most efficient. Fig. 6.5c, for which $r_{A'} < r_A$, shows that if point A' is the periapsis of orbit 1, then transfer orbit 3′ is the most efficient. Together, these results lead us to conclude that it is most efficient for the transfer orbit to begin at the periapsis on inner orbit 1, where its kinetic energy is greatest, regardless of the shape of the outer target orbit. If the starting orbit is a circle, then Fig. 6.5b shows that transfer orbit 3′ is the most efficient if $r_{B'} > r_B$. That is, from an inner circular orbit, the transfer ellipse should terminate at apoapsis of the outer target ellipse, where the speed is slowest.

If Hohmann transfer is in the reverse direction (i.e., to a lower energy inner orbit), the above analysis still applies, since the same total delta-v is required whether the Hohmann transfer runs forward or backward. Thus, from an outer circle or ellipse, to an inner ellipse the most energy-efficient transfer ellipse terminates at periapsis of the inner target orbit. If the inner orbit is a circle, the transfer ellipse should start at apoapsis of the outer ellipse.

We close this section with an illustration of the careful planning required for one spacecraft to rendezvous with another at the end of a Hohmann transfer.

are gathered and summarized in the following equations:

$$
\begin{array}{rrrrcl}
 & -\dfrac{\partial b_x}{\partial x} & -\dfrac{\partial b_y}{\partial y} & -\dfrac{\partial b_z}{\partial z} & = & 0,\\
+\dfrac{1}{c}\dfrac{\partial b_x}{\partial t} & & -\dfrac{\partial e_z}{\partial y} & +\dfrac{\partial e_y}{\partial z} & = & 0,\\
+\dfrac{1}{c}\dfrac{\partial b_y}{\partial t} & +\dfrac{\partial e_z}{\partial x} & & -\dfrac{\partial e_x}{\partial z} & = & 0,\\
+\dfrac{1}{c}\dfrac{\partial b_z}{\partial t} & -\dfrac{\partial e_y}{\partial x} & +\dfrac{\partial e_x}{\partial y} & & = & 0,
\end{array}
\tag{1.126}
$$

or in matrix form,

$$
\underbrace{\begin{pmatrix} 0 & -\boldsymbol{b}^{\mathsf{T}} \\ \boldsymbol{b} & \boldsymbol{E}_{\times} \end{pmatrix}}_{\overset{\text{def}}{=}\boldsymbol{F}_{E,b}} \gamma \underbrace{\begin{pmatrix} -\frac{1}{c}\frac{\partial}{\partial t} \\ \nabla \end{pmatrix}}_{\vec{\nabla}} = \boldsymbol{o} \in \mathbb{R}^4. \tag{1.127}
$$

The matrix $\boldsymbol{F}_{E,b}$ is called the Maxwell's matrix.

So (1.125) and (1.127) contain the Maxwell's equations in a new four-dimensional form:

$$
\boxed{\boldsymbol{F}_{B,e}\vec{\nabla} = \frac{1}{c}\vec{\boldsymbol{j}} \quad \text{and} \quad \boldsymbol{F}_{E,b}\vec{\nabla} = \boldsymbol{o}.} \tag{1.128}
$$

This form has a great advantage of being invariant when transitioning to another reference system by a Lorentz transformation, i.e. in every inertial system its keeps the same external form. But the quantities appearing in it take different values in each reference system. This is shown in the following.

1.8.2 Lorentz Transformation of the Maxwell's Equations

Multiplying (1.125) from the left with $\boldsymbol{L}^{-1}$ and inserting $\boldsymbol{L}^{-1}\boldsymbol{L} = \boldsymbol{I}$, we obtain

$$
\underbrace{\boldsymbol{L}^{-1}\boldsymbol{F}_{B,e}\boldsymbol{L}^{-1}}_{\boldsymbol{F}'_{B',e'}}\boldsymbol{L}\vec{\nabla} = \frac{1}{c}\underbrace{\boldsymbol{L}^{-1}\vec{\boldsymbol{j}}}_{\vec{\boldsymbol{j}}'}. \tag{1.129}
$$

For the new Faraday's matrix $\boldsymbol{F}'_{B',e'}$ we get

$$
\begin{aligned}
\boldsymbol{F}'_{B',e'} &= \begin{pmatrix} 0 & \boldsymbol{e}'^{\mathsf{T}} \\ -\boldsymbol{e}' & \boldsymbol{B}'_{\times} \end{pmatrix} \\
&= \begin{pmatrix} \gamma_v & \frac{\gamma_v}{c}\boldsymbol{v}^{\mathsf{T}} \\ \frac{\gamma_v}{c}\boldsymbol{v} & \boldsymbol{A}(\boldsymbol{v}) \end{pmatrix} \begin{pmatrix} 0 & \boldsymbol{e}^{\mathsf{T}} \\ -\boldsymbol{e} & \boldsymbol{B}_{\times} \end{pmatrix} \begin{pmatrix} \gamma_v & \frac{\gamma_v}{c}\boldsymbol{v}^{\mathsf{T}} \\ \frac{\gamma_v}{c}\boldsymbol{v} & \boldsymbol{A}(\boldsymbol{v}) \end{pmatrix}.
\end{aligned}
\tag{1.130}
$$

After multiplying the three matrices, we obtain for the bottom left corner vector $\boldsymbol{e}'$ with $\boldsymbol{A} = \boldsymbol{A}(\boldsymbol{v})$ and $\gamma = \gamma_v$:

$$\begin{aligned}
-\boldsymbol{e}' &= \frac{\gamma}{c}\boldsymbol{A}\boldsymbol{B}_\times \boldsymbol{v} + \frac{\gamma^2}{c^2}\boldsymbol{v}\boldsymbol{e}^\mathsf{T}\boldsymbol{v} - \gamma\boldsymbol{A}\boldsymbol{e} \\
&= \frac{\gamma}{c}\left(\boldsymbol{B}_\times \boldsymbol{v} + (\gamma-1)\frac{\boldsymbol{v}\overbrace{\boldsymbol{v}^\mathsf{T}\boldsymbol{B}_\times \boldsymbol{v}}^{0}}{v^2}\right) + \frac{\gamma^2}{c^2}\boldsymbol{v}\boldsymbol{e}^\mathsf{T}\boldsymbol{v} - \gamma\boldsymbol{e} - \frac{\gamma(\gamma-1)}{v^2}\boldsymbol{v}\boldsymbol{v}^\mathsf{T}\boldsymbol{e} \\
&= \frac{\gamma}{c}\boldsymbol{B}_\times \boldsymbol{v} - \left(\underbrace{-\frac{\gamma^2}{c^2} + \frac{\gamma^2}{v^2}}_{\frac{1}{v^2}} - \frac{\gamma}{v^2}\right)\boldsymbol{v}^\mathsf{T}\boldsymbol{e}\boldsymbol{v} - \gamma\boldsymbol{e}, \\
\boldsymbol{e}' &= \gamma\left(\boldsymbol{e} - \frac{1}{c}\boldsymbol{B}_\times \boldsymbol{v}\right) + \frac{(1-\gamma)}{v^2}\left(\boldsymbol{v}^\mathsf{T}\boldsymbol{e}\right)\boldsymbol{v},
\end{aligned} \tag{1.131}$$

i.e.

$$\boxed{\boldsymbol{e}' = \gamma\left(\boldsymbol{e} + \frac{1}{c}\boldsymbol{v} \times \boldsymbol{b}\right) + (1-\gamma)\frac{\boldsymbol{v}^\mathsf{T}\boldsymbol{e}}{v^2}\boldsymbol{v}.} \tag{1.132}$$

In the matrix $\boldsymbol{F}'_{B',e'}$ in (1.130), for the right bottom 3×3 sub-matrix $\boldsymbol{B}'_\times$ after performing the matrix multiplication we obtain

$$\boldsymbol{B}'_\times = \boldsymbol{B}_\times + \frac{(\gamma-1)}{v^2}\left(\boldsymbol{B}_\times \boldsymbol{v}\boldsymbol{v}^\mathsf{T} + \boldsymbol{v}\boldsymbol{v}^\mathsf{T}\boldsymbol{B}_\times\right) + \frac{\gamma}{c}\left(\boldsymbol{v}\boldsymbol{e}^\mathsf{T} - \boldsymbol{e}\boldsymbol{v}^\mathsf{T}\right). \tag{1.133}$$

From this matrix equation, the components of the magnetic induction vector $\boldsymbol{b}'$ can be filtered out with the help of the row or column vectors of the unit matrix ($\boldsymbol{i}_j$ is the jth column of the 3×3 identity matrix $\boldsymbol{I}_3$) as follows:

$$\boldsymbol{B}'_\times \overset{\text{def}}{=} \begin{pmatrix} 0 & -b'_z & b'_y \\ b'_z & 0 & -b'_x \\ -b'_y & b'_x & 0 \end{pmatrix}. \tag{1.134}$$

We thus obtain

$$b'_x = \boldsymbol{i}_3^\mathsf{T}\boldsymbol{B}'_\times \boldsymbol{i}_2, \tag{1.135}$$

$$b'_y = \boldsymbol{i}_1^\mathsf{T}\boldsymbol{B}'_\times \boldsymbol{i}_3, \tag{1.136}$$

$$b'_z = \boldsymbol{i}_2^\mathsf{T}\boldsymbol{B}'_\times \boldsymbol{i}_1. \tag{1.137}$$

Using (1.135) for (1.133) results in

$$\begin{aligned}
b'_x = \boldsymbol{i}_3^\mathsf{T}\boldsymbol{B}'_\times \boldsymbol{i}_2 = b_x &+ \frac{(\gamma-1)}{v^2}\left[(-b_y v_1 + b_x v_2)v_2 + v_3(-b_z v_1 + b_x v_3)\right] \\
&+ \frac{\gamma}{c}(v_3 e_y - e_z v_2).
\end{aligned} \tag{1.138}$$

Accordingly, one obtains for the two remaining components

$$\begin{aligned} b'_y = \boldsymbol{i}_1^{\mathsf{T}} \boldsymbol{B}'_{\times} \boldsymbol{i}_3 &= b_y + \frac{(\gamma - 1)}{v^2}\big[(-b_z v_2 + b_y v_3)v_3 + v_1(b_y v_1 - b_x v_2)\big] \\ &\quad + \frac{\gamma}{c}(v_1 e_z - e_x v_3) \end{aligned} \tag{1.139}$$

and

$$b'_z = \boldsymbol{i}_2^{\mathsf{T}} \boldsymbol{B}'_{\times} \boldsymbol{i}_1 = b_z + \frac{(\gamma - 1)}{v^2}\big[(b_z v_1 - b_x v_3)v_1 + v_2(b_z v_2 - b_y v_3)\big] + \frac{\gamma}{c}(v_2 e_x - e_y v_1). \tag{1.140}$$

Summarizing the last terms in (1.138), (1.139) and (1.140) results in the vector product

$$\frac{\gamma}{c}\boldsymbol{e} \times \boldsymbol{v}. \tag{1.141}$$

For the second to last summands one obtains the vector

$$\frac{(\gamma - 1)}{v^2}\begin{pmatrix} (-b_y v_1 + b_x v_2)v_2 + v_3(-b_z v_1 + b_x v_3) \\ (-b_z v_2 + b_y v_3)v_3 + v_1(b_y v_1 - b_x v_2) \\ (b_z v_1 - b_x v_3)v_1 + v_2(b_z v_2 - b_y v_3) \end{pmatrix},$$

and using $0 = b_x v_1^2 - b_x v_1^2$ in the first component, $0 = b_y v_2^2 - b_y v_2^2$ in the second, and $0 = b_z v_3^2 - b_z v_3^2$ in the third,

$$\begin{aligned} &\frac{(\gamma - 1)}{v^2}\begin{pmatrix} (-b_x v_1^2 - b_y v_1 v_2 - b_z v_1 v_3) + (b_x v_1^2 + b_x v_2^2 + b_x v_3^2) \\ (-b_x v_1 v_2 - b_y v_2^2 - b_z v_2 v_3) + (b_y v_1^2 + b_y v_2^2 + b_y v_3^2) \\ (-b_x v_1 v_3 - b_y v_2 v_3 - b_z v_3^2) + (b_z v_1^2 + b_z v_2^2 + b_z v_3^2) \end{pmatrix} \\ &= \frac{(\gamma - 1)}{v^2}\big(-\big(\boldsymbol{b}^{\mathsf{T}}\boldsymbol{v}\big)\boldsymbol{v} + v^2 \boldsymbol{b}\big). \end{aligned} \tag{1.142}$$

Equations (1.141) and (1.142), together with (1.138), (1.139) and (1.140), yield the final result

$$\boxed{\boldsymbol{b}' = \gamma\left(\boldsymbol{b} - \frac{1}{c}\boldsymbol{v} \times \boldsymbol{e}\right) + (1 - \gamma)\frac{\boldsymbol{v}^{\mathsf{T}}\boldsymbol{b}}{v^2}\boldsymbol{v}.} \tag{1.143}$$

One gets the same result for $\boldsymbol{e}'$ and $\boldsymbol{b}'$ by a Lorentz transformation of $\boldsymbol{F}_{E,b}$!

The formulas (1.132) and (1.143) are simplified considerably for small velocities $v \ll c$ because then $\gamma \approx 1$ and one obtains

$$\boldsymbol{e}' = \boldsymbol{e} + \frac{1}{c}\boldsymbol{v} \times \boldsymbol{b}$$

and

$$\boldsymbol{b}' = \boldsymbol{b} - \frac{1}{c}\boldsymbol{v} \times \boldsymbol{e}.$$

The decomposition of the electromagnetic field in an electric and magnetic field has no absolute significance. If there exists, for example, in a reference system $\mathcal{X}$ a purely electrostatic field with $\boldsymbol{b} = \boldsymbol{o}$, then, due to (1.143), a magnetic field $\boldsymbol{b}' = \frac{\gamma}{c}\boldsymbol{v} \times \boldsymbol{e} \neq \boldsymbol{o}$ exists in a reference system $\mathcal{X}'$ that moves with the speed $\boldsymbol{v}$ relative to the reference system $\mathcal{X}$. Physically this means that all charges rest in $\mathcal{X}$. But these charges move relative to $\mathcal{X}'$ with the velocity $\boldsymbol{v}$. So there exists a current in $\mathcal{X}'$ which generates a magnetic field in $\mathcal{X}'$.

The equations (1.132) and (1.143) can be summarized in one equation:

$$\boxed{\begin{pmatrix} \boldsymbol{b}' \\ \boldsymbol{e}' \end{pmatrix} = \underbrace{\left(\begin{array}{c|c} \gamma\boldsymbol{I} + (1-\gamma)\frac{\boldsymbol{v}\boldsymbol{v}^{\mathsf{T}}}{v^2} & -\frac{\gamma}{c}\boldsymbol{V}_{\times} \\ \hline \frac{\gamma}{c}\boldsymbol{V}_{\times} & \gamma\boldsymbol{I} + (1-\gamma)\frac{\boldsymbol{v}\boldsymbol{v}^{\mathsf{T}}}{v^2} \end{array}\right)}_{\boldsymbol{P}(\boldsymbol{v})} \begin{pmatrix} \boldsymbol{b} \\ \boldsymbol{e} \end{pmatrix} \in \mathbb{R}^6,} \tag{1.144}$$

with

$$\boldsymbol{V}_{\times} \overset{\text{def}}{=} \begin{pmatrix} 0 & -v_3 & v_2 \\ v_3 & 0 & -v_1 \\ -v_2 & v_1 & 0 \end{pmatrix}.$$

The symmetric 6×6-matrix $\boldsymbol{P}(\boldsymbol{v})$ occurring in (1.144) has a formal similarity with the Lorentz matrix $\boldsymbol{L}$!

It is, of course, true that $\boldsymbol{P}(-\boldsymbol{v}) = \boldsymbol{P}^{-1}(\boldsymbol{v})$, for, with

$$\boldsymbol{V}_{\times}^2 = \boldsymbol{v}\boldsymbol{v}^{\mathsf{T}} - v^2\boldsymbol{I}, \tag{1.145}$$

one obtains easily $\boldsymbol{P}(\boldsymbol{v})\boldsymbol{P}(-\boldsymbol{v}) = \boldsymbol{I}$.

In the special case when only one component of the velocity vector in the x-direction is nonzero, i.e. $\boldsymbol{v} = [v, 0, 0]^{\mathsf{T}}$, one obtains the matrix

$$\boldsymbol{P}(\boldsymbol{v}) = \left(\begin{array}{ccc|ccc} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \gamma & 0 & 0 & 0 & \frac{\gamma v}{c} \\ 0 & 0 & \gamma & 0 & -\frac{\gamma v}{c} & 0 \\ \hline 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & -\frac{\gamma v}{c} & 0 & \gamma & 0 \\ 0 & \frac{\gamma v}{c} & 0 & 0 & 0 & \gamma \end{array}\right). \tag{1.146}$$

This special symmetric 6×6-matrix can also be found in [33].

1.8.3 Electromagnetic Invariants

For the electromagnetic field quantities $\boldsymbol{e}$ and $\boldsymbol{b}$ one can form *invariants* which do not change during the transition to another inertial system. For the scalar product of the electric field strength $\boldsymbol{e}$ and the magnetic induction $\boldsymbol{b}$ we obtain

$$\begin{aligned}\boldsymbol{e}'^{\mathsf{T}}\boldsymbol{b}' &= \left(\gamma\left(\boldsymbol{e}^{\mathsf{T}} - \frac{1}{c}(\boldsymbol{v}\times\boldsymbol{b})^{\mathsf{T}}\right) + (1-\gamma)\frac{\boldsymbol{v}^{\mathsf{T}}\boldsymbol{e}}{v^2}\boldsymbol{v}^{\mathsf{T}}\right)\left(\gamma\left(\boldsymbol{b} + \frac{1}{c}\boldsymbol{v}\times\boldsymbol{e}\right)\right. \\ &\qquad \left. + (1-\gamma)\frac{\boldsymbol{v}^{\mathsf{T}}\boldsymbol{b}}{v^2}\boldsymbol{v}\right) \\ &= \gamma^2\boldsymbol{e}^{\mathsf{T}}\boldsymbol{b} + \left[2\gamma(1-\gamma) + \left(1-\gamma^2\right)\right]\frac{\boldsymbol{e}^{\mathsf{T}}\boldsymbol{v}\boldsymbol{v}^{\mathsf{T}}\boldsymbol{b}}{v^2} - \frac{\gamma^2}{c^2}\underbrace{(\boldsymbol{v}\times\boldsymbol{b})^{\mathsf{T}}(\boldsymbol{v}\times\boldsymbol{e})}_{\boldsymbol{b}^{\mathsf{T}}\boldsymbol{V}_{\times}^{\mathsf{T}}\boldsymbol{V}_{\times}\boldsymbol{e}}.\end{aligned}$$

With $\boldsymbol{V}_{\times}^{\mathsf{T}} = -\boldsymbol{V}_{\times}$ one obtains due to (1.145)

$$\boldsymbol{V}_{\times}^{\mathsf{T}}\boldsymbol{V}_{\times} = -\boldsymbol{V}_{\times}^2 = v^2\boldsymbol{I} - \boldsymbol{v}\boldsymbol{v}^{\mathsf{T}}.$$

This gives

$$\underline{\underline{\boldsymbol{e}'^{\mathsf{T}}\boldsymbol{b}'}} = \gamma^2\boldsymbol{e}^{\mathsf{T}}\boldsymbol{b} - \frac{\gamma^2}{c^2}\left(\boldsymbol{v}^{\mathsf{T}}\boldsymbol{e}\boldsymbol{v}^{\mathsf{T}}\boldsymbol{b} + v^2\boldsymbol{b}^{\mathsf{T}}\boldsymbol{e} - \boldsymbol{b}^{\mathsf{T}}\boldsymbol{v}\boldsymbol{v}^{\mathsf{T}}\boldsymbol{e}\right) = \left(\gamma^2 - \frac{\gamma^2 v^2}{c^2}\right)\boldsymbol{e}^{\mathsf{T}}\boldsymbol{b} = \underline{\underline{\boldsymbol{e}^{\mathsf{T}}\boldsymbol{b}}},$$

so the scalar product of the electric field intensity $\boldsymbol{e}$ and the magnetic induction $\boldsymbol{b}$ is invariant with respect to a Lorentz transformation!

Using a slightly long calculation, one can show that the difference of the squares of the field intensities is also invariant:

$$\underline{\underline{b'^2 - e'^2 = b^2 - e^2}}. \tag{1.147}$$

You can also arrive at electromagnetic invariants in another way, namely with the help of the invariant Faraday's matrix

$$\boldsymbol{F}_{B,e} = \begin{pmatrix} 0 & \boldsymbol{e}^{\mathsf{T}} \\ -\boldsymbol{e} & \boldsymbol{B}_{\times} \end{pmatrix}$$

and the invariant Maxwell's matrix

$$\boldsymbol{F}_{E,b} = \begin{pmatrix} 0 & -\boldsymbol{b}^{\mathsf{T}} \\ \boldsymbol{b} & \boldsymbol{E}_{\times} \end{pmatrix}.$$

With

$$\boldsymbol{F}^*_{B,e} \overset{\text{def}}{=} \boldsymbol{M}\boldsymbol{F}_{B,e}\boldsymbol{M} = \begin{pmatrix} 0 & -\boldsymbol{e}^{\mathsf{T}} \\ \boldsymbol{e} & \boldsymbol{B}_{\times} \end{pmatrix},$$

one gets, e.g.

$$\boldsymbol{F}^*_{B,e}\boldsymbol{F}_{B,e} = \begin{pmatrix} 0 & -\boldsymbol{e}^{\mathsf{T}} \\ \boldsymbol{e} & \boldsymbol{B}_{\times} \end{pmatrix}\begin{pmatrix} 0 & \boldsymbol{e}^{\mathsf{T}} \\ -\boldsymbol{e} & \boldsymbol{B}_{\times} \end{pmatrix} = \begin{pmatrix} \boldsymbol{e}^{\mathsf{T}}\boldsymbol{e} & -\boldsymbol{e}^{\mathsf{T}}\boldsymbol{B}_{\times} \\ -\boldsymbol{B}_{\times}\boldsymbol{e} & \boldsymbol{e}\boldsymbol{e}^{\mathsf{T}} + \boldsymbol{B}_{\times}\boldsymbol{B}_{\times} \end{pmatrix}$$

$$= \begin{pmatrix} e^2 & \boldsymbol{s}^\mathsf{T} \\ \boldsymbol{s} & \begin{pmatrix} e_x^2 - b_z^2 - b_y^2 & \cdots & \cdots \\ \cdots & e_y^2 - b_z^2 - b_x^2 & \cdots \\ \cdots & \cdots & e_z^2 - b_y^2 - b_x^2 \end{pmatrix} \end{pmatrix},$$

with the Poynting vector $\boldsymbol{s} \overset{\text{def}}{=} \boldsymbol{e} \times \boldsymbol{b}$. By forming the trace of this matrix product, i.e. taking the sum of the matrix elements on the main diagonal, one obtains

$$\operatorname{trace}\bigl(\boldsymbol{F}^*_{B,e} \boldsymbol{F}_{B,e}\bigr) = 2e^2 - 2b^2,$$

i.e. the above invariant in the form

$$\boxed{-\frac{1}{2}\operatorname{trace}\bigl(\boldsymbol{F}^*_{B,e} \boldsymbol{F}_{B,e}\bigr) = b^2 - e^2.} \tag{1.148}$$

One obtains the second invariant $\boldsymbol{e}^\mathsf{T} \boldsymbol{b}$ above by taking the trace of the product of the modified Faraday's matrix $\boldsymbol{F}^*_{B,e}$ and the Maxwell's matrix $\boldsymbol{F}_{E,b}$:

$$\boxed{-\frac{1}{4}\operatorname{trace}\bigl(\boldsymbol{F}^*_{B,e} \boldsymbol{F}_{E,e}\bigr) = \boldsymbol{e}^\mathsf{T} \boldsymbol{b}.} \tag{1.149}$$

Making invariants of this type later plays a role in the consideration of the singularities of the Schwarzkopf's solution of General Relativity equations.

1.8.4 Electromagnetic Forces

We want to determine the force acting on a charged particle with the charge q, which is in an electromagnetic field moving with the velocity $\boldsymbol{u}$ relative to an inertial frame $\mathcal{X}$. Let $\mathcal{X}'$ be the inertial frame in which the particle rests at the moment. In this system, due to $\boldsymbol{u}' = \boldsymbol{o}$ and $\boldsymbol{u}' \times \boldsymbol{b}' = \boldsymbol{o}$,

$$m_0 \frac{\mathrm{d}\boldsymbol{u}'}{\mathrm{d}t'} = q\boldsymbol{e}' \in \mathbb{R}^3. \tag{1.150}$$

Generally, due to the relativity principle, the Lorentz force in $\mathcal{X}$ is

$$\boldsymbol{f} = q\left(\boldsymbol{e} + \frac{1}{c}\boldsymbol{u} \times \boldsymbol{b}\right) = \frac{q}{c}[\boldsymbol{e} \mid -\boldsymbol{B}_\times] \begin{pmatrix} c \\ \boldsymbol{u} \end{pmatrix} \in \mathbb{R}^3. \tag{1.151}$$

The following law expresses how an electromagnetic field acts on a stationary charge q and current $\boldsymbol{j}$:

$$\boldsymbol{f} = q\boldsymbol{e} + \frac{1}{c}\boldsymbol{j} \times \boldsymbol{b} = \frac{1}{c}[\boldsymbol{e} \mid -\boldsymbol{B}_\times] \begin{pmatrix} cq \\ \boldsymbol{j} \end{pmatrix} \in \mathbb{R}^3. \tag{1.152}$$

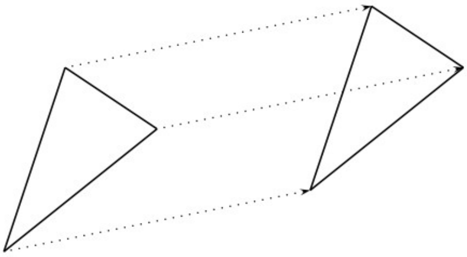
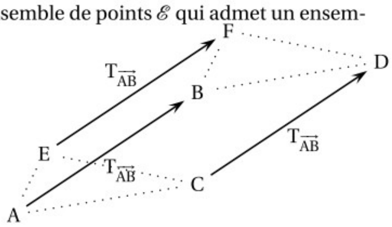
1 Espace physique et espace vectoriel

Une notion fondamentale en géométrie est celle de **déplacement**. Sans elle, il n'y a pas de moyen pour dire que ces deux triangles sont égaux (isométriques). En géométrie, les déplacements sont appelés des **translations**.



On peut considérer que l'espace physique qui nous entoure est un ensemble de points $\mathscr{E}$ qui admet un ensemble de translations $\mathscr{T}$. Chaque translation T est une bijection qui envoie chaque point A de $\mathscr{E}$ sur un autre point B de $\mathscr{E}$ de telle sorte que les **segments orientés** reliant les points à leur image soient tous de même direction, de même sens et de même longueur : une translation sera notée $T_{\overrightarrow{AB}}$ et on a $T_{\overrightarrow{AB}}(A) = B$, ou encore, d'après la figure ci-contre, $T_{\overrightarrow{AB}}(C) = D$.



F
D
$T_{\overrightarrow{AB}}$
B
$T_{\overrightarrow{AB}}$
E
$T_{\overrightarrow{AB}}$
C
A

Cette ensemble $\mathscr{T}$ a les propriétés suivantes :

(i) une translation est complètement déterminée si on connaît son action sur un seul point A, c'est-à-dire si on connaît le point B associé au point A. Ainsi donc la translation peut être caractérisée en traçant le segment [AB] et en mettant une flèche sur $\overrightarrow{AB}$, la pointe de la flèche étant en B pour indiquer que l'on va de A vers B. En langage mathématique, on dira

$$\forall X, Y \in \mathscr{E} \quad \exists \text{ une unique translation } T_{\overrightarrow{XY}} \in \mathscr{T} \text{ telle que } T_{\overrightarrow{XY}}(X) = Y$$

(ii) les translations peuvent être additionnées entre elles et multipliées par un nombre réel, de telle sorte que la somme de deux translations est encore une translation et le produit d'une translation par un nombre réel est aussi une translation :

$$T_1 + T_2 \in \mathscr{T} \quad \text{et} \quad \alpha T \in \mathscr{T}\text{, } \alpha \text{ est un nombre réel}$$

Ces opérations ont les propriétés suivantes qui sont celles d'un espace vectoriel.

Définition 1 - 1

Soit $T_1, T_2, T_3 \in \mathscr{T}$ et $\alpha, \beta \in \mathbb{R}$, alors si les éléments d'un ensemble $\mathscr{T}$ ont les propriétés

P1 $(T_1 + T_2) + T_3 = T_1 + (T_2 + T_3)$ (associativité)

P2 il existe un élément neutre 0 tel que

$$0 + T = T + 0 = T \quad \text{pour tout élément } T \in \mathscr{T}$$

P3 étant donné un élément T, il existe un élément −T tel que

$$T + (-T) = 0$$

P4 $T_1 + T_2 = T_2 + T_1$ (commutativité)

P5 $\alpha(T_1 + T_2) = \alpha T_1 + \alpha T_2$

P6 $(\alpha + \beta)T = \alpha T + \beta T$

P7 $(\alpha\beta)T = \alpha(\beta T)$

P8 pour toute translation T, on a $1 \cdot T = T$.

on dira que $\mathscr{T}$ forme **un espace vectoriel**.

Remarque

Habituellement, un espace vectoriel est désigné par la lettre V.
Si on est dans le plan, ce sera V^2 et dans l'espace V^3.
On vérifie aisément que les translations ont ces propriétés (illustrations).

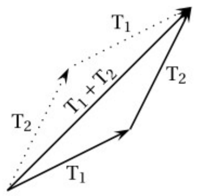


illustration de P4

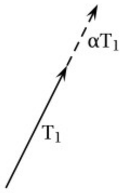

multiplication avec $\alpha > 1$

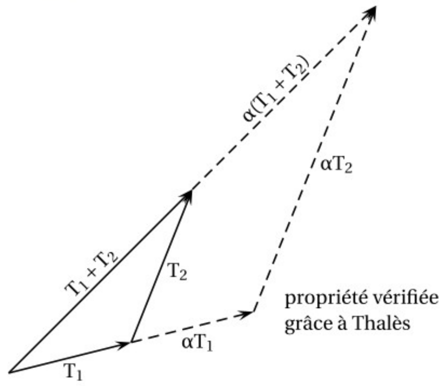

illustration de **P5**

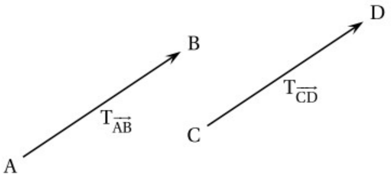
Remarques

a. la figure illustrant l'addition de deux translations montre bien qu'elle est commutative. En effet, T_1+T_2 et T_2+T_1 constituent un parallélogramme (2 paires de côtés parallèles de même longueur). C'est la raison pour laquelle on parle de la **règle du parallélogramme** pour l'addition de deux translations (ou vecteurs, cf. plus tard);

b. certaines translations sont équivalentes. Par exemple, si une translation amène un point A sur B et un point C sur D, alors les translations $T_{\overrightarrow{AB}}$ et $T_{\overrightarrow{CD}}$ sont équivalentes;



$T_{\overrightarrow{AB}} \equiv T_{\overrightarrow{CD}}$

c. si on choisit un point $O \in \mathscr{E}$ (une origine dans l'espace physique des points), alors à chaque point correspond une unique translation. En effet, soit un point A, on peut définir pour ce point une translation qui amène O sur A, notée $T_{\overrightarrow{OA}}$. Ainsi, il est possible de faire correspondre à chaque point $A \in \mathscr{E}$ une unique translation T, et réciproquement (on a une bijection entre $\mathscr{E}$ et V^3)

d. toutes les translations parallèles de même direction, de même sens et de même longueur sont équivalentes et représentent donc le même vecteur; on les appelle des **représentants de ce vecteur**. En particulier, pour chaque vecteur $\vec{v}$ il existe un unique représentant de $\vec{v}$ dont le point d'application est l'origine : $\overrightarrow{OA}$;

e. une autre manière d'exprimer la même idée est de dire que $\overrightarrow{AB}$ et $\overrightarrow{CD}$ représente le même vecteur si et seulement si ABDC est un parallélogramme;

f. un ensemble d'objets qui vérifie les propriétés P1-P8 forme un **espace vectoriel** et les éléments de cet espace, appelés des **vecteurs** sont généralement désignés par une lettre en caractère gras $\boldsymbol{v}$, ou par une lettre surmontée d'une flèche $\vec{v}$ ou encore par un couple de points représentant les extrémités d'un segment et surmonté aussi d'une flèche $\overrightarrow{AB}$. La pointe de la flèche étant en B pour indiquer que l'on va de A vers B : A étant le point d'application et B l'extrémité du vecteur;

g. ces propriétés signifient aussi que tout vecteur $\vec{v}$ obtenu à partir de deux autres $\vec{a}$ et $\vec{b}$ de la manière suivante

$$\vec{v} = \alpha \cdot \vec{a} + \beta \cdot \vec{b} \qquad \text{avec } \alpha \text{ et } \beta \text{ deux réels quelconques}$$

est un vecteur qui est dans le même espace. On dira que $\vec{v}$ est une **combinaison linéaire** des vecteurs $\vec{a}$ et $\vec{b}$.

(iii) *Dans l'espace*, il existe trois éléments T_1, T_2, T_3 qui sont **linéairement indépendants**, c.-à-d. l'équation

$$\alpha T_1 + \beta T_2 + \gamma T_3 = 0$$

n'a de solution que pour $\alpha = \beta = \gamma = 0$ (cf. activité 1 et 2). Ainsi, V est de dimension 3 et on le note V^3.

Quatre translations sont toujours linéairement dépendantes dans l'espace.

Dans le plan, on a le même type de propriétés, mais dans une dimension inférieure : il existe dans le plan seulement 2 éléments linéairement indépendants, mais pas 3.

Activité

Vecteurs générateurs du plan et de l'espace

Imaginer un robot se déplaçant dans le plan et ne pouvant se déplacer que dans deux directions ; par exemple, nord-est et sud-est. Il peut avancer à chaque fois d'un pas ou d'un multiple réel de pas (comme un demi-pas, ou trois pas, ou moins un tiers de pas). Est-ce que ce robot peut atteindre tous les points du plan dans lequel il évolue ? Quelle combinaison de pas doit-il faire pour se retrouver dans la même position ?
Si on considère le même type de problème, mais dans l'espace, combien de directions différentes un robot-oiseau doit-il pouvoir prendre pour atteindre tous les points de l'espace ?

Activité

Vecteurs linéairement dépendants

Dénotons un pas dans la direction ouest-est par le vecteur $\vec{i}$, un pas dans la direction sud-nord par $\vec{j}$ et un pas dans la direction sud-est par $\vec{l}$. Est-il possible d'exprimer un de ces trois déplacements en fonction des deux autres. Faire un dessin pour se représenter les différents déplacements !

Définition 1 - 2

Un ensemble de vecteurs sont dits linéairement dépendants si l'un des vecteurs peut être exprimé comme combinaison linéaire des autres.

Définition 1 - 3

Cas particuliers :

- Si deux vecteurs sont linéairement dépendants, on dira qu'ils sont **colinéaires**, c'est-à-dire l'un un est multiples de l'autre : $\vec{a} = \lambda \cdot \vec{b}$.
- Si trois vecteurs dans V^3 sont linéairement dépendants, on dira qu'ils sont **coplanaires**, c'est-à-dire l'un des vecteurs est une combinaison linéaire des deux autres : $\vec{c} = \alpha \cdot \vec{a} + \beta \cdot \vec{b}$.

Remarque

Si trois vecteurs $\vec{a}$, $\vec{b}$ et $\vec{c}$ sont linéairement dépendants, il doit donc être possible d'en écrire un en fonction des deux autres, par exemple

$$\vec{c} = \alpha \cdot \vec{a} + \beta \cdot \vec{b}$$

Cette égalité peut être réécrite sous la forme

$$\vec{0} = \vec{c} - \alpha \cdot \vec{a} + \beta \cdot \vec{b}$$

Inversement, si on peut écrire

$$\vec{0} = \alpha \cdot \vec{a} + \beta \cdot \vec{b} + \gamma \cdot \vec{c} \qquad \text{avec } \alpha,\ \beta,\ \gamma \text{ non tous nuls}$$

alors ces vecteurs sont linéairement dépendants, car en considérant le coefficient non nul (supposons que c'est β), il est possible d'écrire

$$\vec{b} = -\frac{\alpha}{\beta} \cdot \vec{a} - \frac{\gamma}{\beta} \cdot \vec{c}.$$

Donc, on peut poser la définition alternative pour la dépendance linéaire :

Définition 1 - 4

Un ensemble de vecteurs sont dits linéairement dépendants si on peut écrire

$$\vec{0} = \alpha \cdot \vec{a} + \beta \cdot \vec{b} + \gamma \cdot \vec{c} \qquad \text{avec } \alpha,\ \beta,\ \gamma \text{ non tous nuls}$$

de telle sorte que le terme au coefficient non nul puisse être isolé.

Du même coup, on peut donner la définition de l'**indépendance linéaire**

Définition 1 - 5

Un ensemble de trois vecteurs sont dits linéairement indépendants si l'équation

$$\vec{0} = \alpha \cdot \vec{a} + \beta \cdot \vec{b} + \gamma \cdot \vec{c}$$

n'a de solution que pour $\alpha = \beta = \gamma = 0$.

Jann Weiss, Licence Creative Commons, 2015-2016

Si l'un des coefficients pouvait être différent de 0, alors il serait possible d'isoler le terme correspondant et d'exprimer un vecteur en fonction des deux autres. Plus tard, quand les vecteurs seront donnés par leurs composantes, on verra comment tester si trois vecteurs sont linéairement indépendants.

2 Notions de base et de coordonnées

Lemme 1 - 1

Soient $\vec{a}, \vec{b}, \vec{c} \in \mathrm{V}^3$, 3 vecteurs linéairement indépendants.
Pour tout vecteur $\vec{p} \in \mathrm{V}^3$, il existe $\alpha, \beta, \gamma \in \mathbb{R}$ uniques tels que $\vec{p} = \alpha\vec{a} + \beta\vec{b} + \gamma\vec{c}$

Preuve.

$\vec{a}, \vec{b}, \vec{c}, \vec{p}$ sont linéairement dépendants (propriétés (iii))
Il existe donc $\alpha_o, \beta_o, \gamma_o, \delta_o$ non tous nuls avec

$$\alpha_o\vec{a} + \beta_o\vec{b} + \gamma_o\vec{c} + \delta_o\vec{p} = \vec{0}$$

$\delta_o \neq 0$ car si $\delta_o = 0$, alors

$$\alpha_o\vec{a} + \beta_o\vec{b} + \gamma_o\vec{c} = \vec{0}$$

et $\alpha_o, \beta_o, \gamma_o$ non tous nuls. Ce qui est impossible, car $\vec{a}, \vec{b}, \vec{c}$ sont linéairement indépendants.
Ainsi

$$\vec{p} = -\underbrace{\frac{\alpha_o}{\delta_o}}_{\alpha}\vec{a} - \underbrace{\frac{\beta_o}{\delta_o}}_{\beta}\vec{b} - \underbrace{\frac{\gamma_o}{\delta_o}}_{\gamma}\vec{c}$$

On montre encore que α, β, γ sont uniques. Supposons le contraire et qu'il existe α', β', γ' tels que

$$\begin{aligned} \vec{p} &= \alpha\vec{a} + \beta\vec{b} + \gamma\vec{c} \\ &= \alpha'\vec{a} + \beta'\vec{b} + \gamma'\vec{c} \end{aligned}$$

Alors

$$(\alpha - \alpha')\vec{a} + (\beta - \beta')\vec{b} + (\gamma - \gamma')\vec{c} = \vec{0}$$

Comme $\vec{a}, \vec{b}, \vec{c}$ sont linéairement indépendants, on a :

$$\begin{array}{lcl} \alpha - \alpha' = 0 & \text{donc} & \alpha = \alpha' \\ \beta - \beta' = 0 & \text{donc} & \beta = \beta' \\ \gamma - \gamma' = 0 & \text{donc} & \gamma = \gamma' \end{array}$$

□

Définition 1 - 6

Un ensemble de trois vecteurs linéairement indépendants de V^3 s'appelle une **base**.
α, β, γ sont les coordonnées de $\vec{p}$ dans la base en question et on peut écrire $\vec{p} = (\alpha, \beta, \gamma)$

Le choix d'une base pour V^3 permet d'identifier notre espace vectoriel avec $\mathbb{R}^3$.

Remarque

Les vecteurs qui constituent une base ne sont pas nécessairement orthogonaux entre eux, comme on peut le voir dans plusieurs exercices (exercice 1 - 10 et suivants).

Une fois qu'un espace vectoriel est muni d'une base et qu'ainsi chaque vecteur peut être caractérisé par ses coordonnées dans cette base, il reste à voir comment l'addition de vecteurs et la multiplication d'un vecteur par un scalaire (un nombre) se traduisent au niveau de ces coordonnées

Grâce aux exemples qui vont suivre, on vérifie que si $\vec{p} = (\alpha, \beta, \gamma)$ et $\vec{p'} = (\alpha', \beta', \gamma')$, alors

$$\vec{p} + \vec{p'} = (\alpha + \alpha', \beta + \beta', \gamma + \gamma')$$

et si $\nu \in \mathbb{R}$, alors

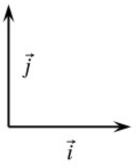
$$\nu\vec{p} = (\nu\alpha, \nu\beta, \nu\gamma)$$

mais présentons d'abord une base particulière qui est aussi la plus habituelle.

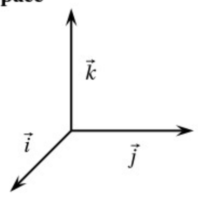
Jann Weiss, Licence Creative Commons , 2015-2016

Base standard

Plan



Espace



Vecteurs dans $\mathbb{R}^2$ Dans le graphique ci-contre, on lit, pour les différents vecteurs présentés, les coordonnées suivantes dans la base $\left(\vec{i}\,;\vec{j}\right)$

$\overrightarrow{AB} = 4\vec{i} = (4\,;0)$

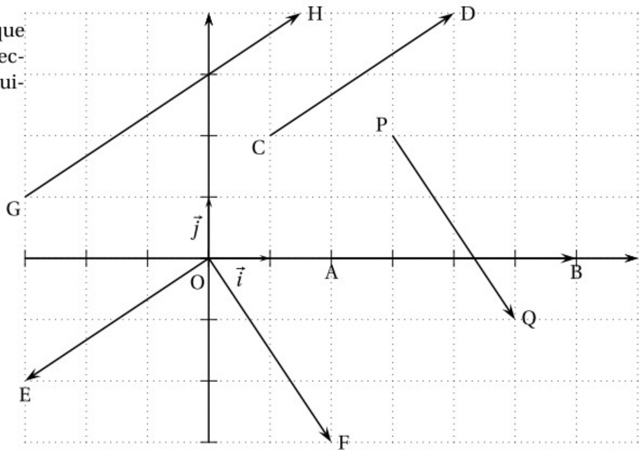
$\overrightarrow{CD} = 3\vec{i} + 2\vec{j} = (3\,;2)$

$\overrightarrow{GH} = 4.5\vec{i} + 3\vec{j} = (4.5\,;3) = 1.5\overrightarrow{CD}$

$\overrightarrow{OE} = -3\vec{i} - 2\vec{j} = (-3\,;-2)$

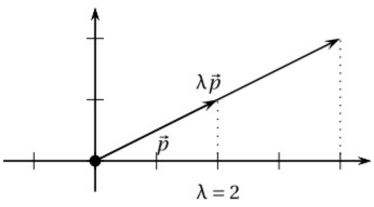
$\overrightarrow{PQ} = 2\vec{i} - 3\vec{j} = (2\,;-3)$

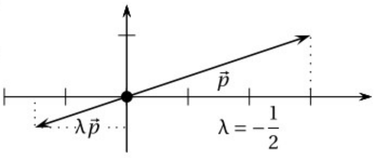
$\overrightarrow{OF} = 2\vec{i} - 3\vec{j} = (2\,;-3) = \overrightarrow{PQ}$



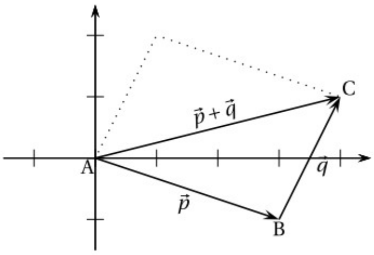
Multiplication d'un vecteur dans $\mathbb{R}^2$ par un réel Le produit d'un vecteur $\vec{p}$ par un nombre $\lambda \in \mathbb{R}$ donne un nouveau vecteur de même direction que l'original, mais dont la longueur a été multipliée par λ. Sur la figure ci-contre, on voit que par Thalès, si on multiplie les composantes du vecteur $\vec{p}$ par λ, on obtient le vecteur $\lambda\vec{p}$.

Dans les deux exemples ci-contre, on reconnaît les deux configurations de Thalès. Dans la seconde, $\vec{p} = (3\,;1)$ et $\lambda = -0.5$; ce dernier nombre représente le facteur de proportionnalité entre les côtés des deux triangles semblables, ainsi : $\lambda\vec{p} = (-1.5\,;-0,5)$.
Les propriétés de la multiplication d'un vecteur par un nombre (on dit aussi par « un scalaire ») ont été données plus haut sous **P5-P8**.





Addition de deux vecteurs dans $\mathbb{R}^2$ On sait que la somme de deux vecteurs s'obtient en effectuant successivement les translations $\vec{p}$ puis $\vec{q}$ (l'ordre n'est pas important). On obtient ainsi un parallélogramme, d'où le nom de « règle du parallélogramme » pour désigner l'addition de vecteurs. Il suffit de vérifier que cette procédure revient à additionner les composantes des vecteurs.

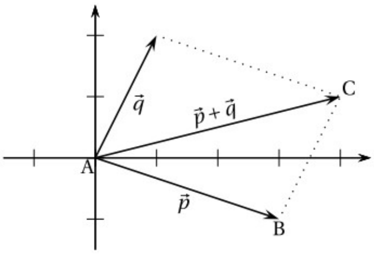


Dans l'exemple de la figure ci-contre

$$\left.\begin{aligned}\vec{p} &= (3\,;-1)\\ \vec{q} &= (1\,;2)\end{aligned}\right\}\quad \vec{p}+\vec{q} = (4\,;1)$$

ou,

$$\left.\begin{aligned}\vec{p} &= 3\vec{i}-\vec{j}\\ \vec{q} &= \vec{i}+2\vec{j}\end{aligned}\right\}\quad \begin{aligned}\vec{p}+\vec{q} &= 3\vec{i}-\vec{j}+\vec{i}+2\vec{j}\\ &= 4\vec{i}+\vec{j} = (4\,;1)\end{aligned}$$



En termes de représentants, cela signifie que l'égalité

$\boxed{\overrightarrow{AB}+\overrightarrow{BC}=\overrightarrow{AC}}$ (relation de Chasles) est vraie pour $\forall A, B, C \in \mathbb{R}$.

Remarques

- **a.** $\overrightarrow{AA}$ est le **vecteur nul** : $\vec{0} = (0\,;0)$. Il n'a pas de direction prédéfinie.
- **b.** Deux vecteurs sont opposés s'ils ont la même direction, même longueur, mais sont de sens opposés : $\overrightarrow{BA}$ est l'opposé de $\overrightarrow{AB}$. Ou encore : $\vec{p}$ et $\vec{q}$ sont opposés $\Longrightarrow \vec{p}+\vec{q}=\vec{0}$.
  Notation : $-\vec{p}$ est l'opposé de $\vec{p}$.
- **c.** cf. plus haut pour les propriétés de l'addition vectorielle **P1-P4**

Il est clair que toutes ces considérations faites dans $\mathbb{R}^2$ sont aussi valables dans $\mathbb{R}^3$. Le seul changement est que, à la différence de $\mathbb{R}^2$ où les points sont des couples, les points dans $\mathbb{R}^3$ sont des triplets : (a_1, a_2, a_3). Mais, comme il n'y a aucune raison de s'arrêter là, tout ce qui vient d'être dit est tout aussi valable pour des espaces de dimensions supérieures n où les points sont représentés par des n-uples $(a_1, \ldots, a_n)$.

2 1 Espace physique, espace vectoriel V^3 et $\mathbb{R}^3$: résumé

Nous avons vu que l'espace physique avec ses translations et une origine présente une identité de structure avec un espace vectoriel. Chaque translation $T_{\overrightarrow{AB}}$ représente un vecteur $\vec{v} = \overrightarrow{AB}$. Ce vecteur a un unique représentant dont le point d'application est l'origine : $\vec{p} = \overrightarrow{OP}$. Ainsi, chaque point P de $\mathscr{E}$ correspond à un vecteur et réciproquement :

$$\begin{aligned}\mathscr{E} &\longleftrightarrow V^3\\ P &\longleftrightarrow \text{l'unique vecteur } \vec{p} \text{ tel que } T_{\vec{p}}(O) = P\end{aligned}$$

En choisissant une base $(\vec{i}, \vec{j}, \vec{k})$ pour V^3, il devient possible d'écrire un vecteur $\vec{p}$ en fonction de cette base et ainsi de l'identifier en fonction de ses composantes qui forment un triplet

$$\vec{p} = \alpha\vec{i}+\beta\vec{j}+\gamma\vec{k} \quad \text{d'où } \vec{p} = (\alpha, \beta, \gamma)$$

Ce qui permet d'identifier V^3 avec $\mathbb{R}^3$

$$\begin{aligned}V^3 &\longleftrightarrow \mathbb{R}^3\\ \vec{p} &\longleftrightarrow (\alpha, \beta, \gamma)\end{aligned}$$

Et en mettant le tout ensemble

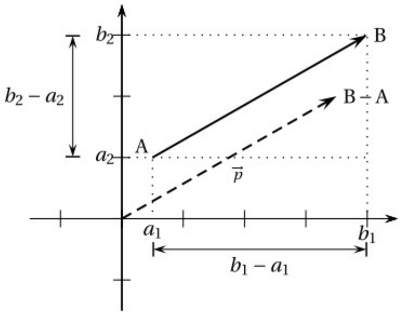
$$\begin{array}{ccccc}\mathscr{E} & \longleftrightarrow & V^3 & \longleftrightarrow & \mathbb{R}^3\\ P & \longleftrightarrow & \vec{p} = \overrightarrow{OP} & \longleftrightarrow & (\alpha, \beta, \gamma)\end{array}$$

De cette manière, en généralisant à un espace de dimension quelconque, un n-uple représente soit un point P soit un vecteur $\vec{v} = \overrightarrow{OP}$, selon l'interprétation qu'on a en tête.

Pour terminer, établissons encore le résultat suivant.

$$\boxed{\text{Deux vecteurs } \overrightarrow{\mathrm{AB}} \text{ et } \overrightarrow{\mathrm{CD}} \text{ sont équivalents si } \mathrm{B}-\mathrm{A}=\mathrm{D}-\mathrm{C}}$$

Soient deux points A(a_1, a_2) et B(b_1, b_2). Le vecteur $\overrightarrow{\mathrm{AB}}$ est équivalent à un vecteur $\vec{p}$ dont le point d'application est l'origine. L'abscisse de l'extrémité de $\vec{p}$ s'obtient en diminuant b_1 de a_1, et son ordonnée, en diminuant b_2 de a_2, c.-à-d. que son extrémité est le point B − A et les composantes du vecteur $\overrightarrow{\mathrm{AB}} = \overrightarrow{\mathrm{O(B-A)}}$ sont $(b_1 - a_1, b_2 - a_2)$.
Ainsi, si $\overrightarrow{\mathrm{CD}}$ est un vecteur équivalent à $\overrightarrow{\mathrm{AB}}$, alors on a le résultat souhaité : B − A = D − C.



3 Exercices

1 - 1

Dessiner un représentant de

$\vec{a}+\vec{b}$

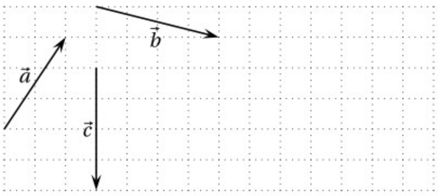
$\vec{b}-\vec{a}$

$\vec{a}-\vec{b}$

$\vec{a}+\vec{b}+\vec{c}$

$2\vec{a}-\vec{b}+\vec{c}$

$\vec{b}-2\vec{c}-2\vec{a}$



1 - 2

CLIN et OEIL sont des parallélogrammes. En utilisant les seuls points de la figure (il faut faire un dessin), écrivez plus simplement :

$\overrightarrow{\mathrm{OE}}+\overrightarrow{\mathrm{OL}}+\overrightarrow{\mathrm{NC}}$

$\overrightarrow{\mathrm{OE}}+\overrightarrow{\mathrm{IN}}+\overrightarrow{\mathrm{NC}}$

$\overrightarrow{\mathrm{IN}}+\overrightarrow{\mathrm{EO}}$

$\overrightarrow{\mathrm{OE}}+\overrightarrow{\mathrm{OL}}+\overrightarrow{\mathrm{LC}}+\overrightarrow{\mathrm{EO}}$

Remarque

Il existe plusieurs représentants pour un vecteur donné, ainsi $\overrightarrow{\mathrm{CN}}=\overrightarrow{\mathrm{IL}}=\overrightarrow{\mathrm{OE}}$

$\overrightarrow{\mathrm{CL}}=\overrightarrow{\mathrm{NI}}$

$\overrightarrow{\mathrm{CL}}=-\overrightarrow{\mathrm{IN}}$

1 - 3

$\overrightarrow{\mathrm{OA}}$ est un représentant du vecteur $\vec{a}$. $\overrightarrow{\mathrm{OB}}$ est un représentant du vecteur $\vec{b}$. Quel est le vecteur dont un représentant a son point d'application sur A *et son extrémité sur* B *?*

Remarque

On peut tirer de cet exercice une règle générale $\overrightarrow{\mathrm{AB}}=\ldots$

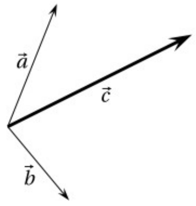
et si, à la place de O, on prend un point P quelconque $\overrightarrow{\mathrm{AB}}=\ldots$

... vecteur pointant sur l'extrémité – vecteur pointant sur l'origine ...

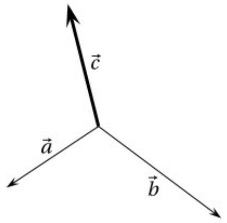
1 - 4

Exprimer le vecteur $\vec{c}$ comme combinaison linéaire de $\vec{a}$ et de $\vec{b}$ (géométriquement !) :

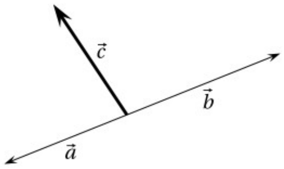
a)



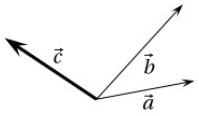
b)



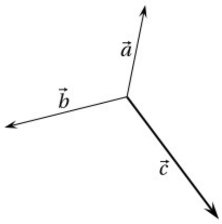
c)



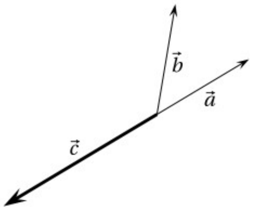
d)



e)



f)



1 - 5

On considère les points $\mathrm{A} = (-3\,;1)$ $\mathrm{B} = (1\,;3)$ $\mathrm{C} = (4\,;1)$ $\mathrm{D} = (2\,;0)$
Démontrer que $(\mathrm{AB}) /\!\!/ (\mathrm{CD})$.

Remarque

$\overrightarrow{\mathrm{AB}}$ et $\overrightarrow{\mathrm{CD}}$ sont alors dits **colinéaires** (cf. les remarques de la section 1.4)

1 - 6

A, B, C, D *sont quatre points du plan. Démontrer que* $\overrightarrow{\mathrm{AB}} + \overrightarrow{\mathrm{CD}} = \overrightarrow{\mathrm{AD}} + \overrightarrow{\mathrm{CB}}$.

1 - 7

On considère les points $\mathrm{A} = \left(\frac{7}{4}\,;-2\right)$ $\mathrm{B} = \left(\frac{1}{2}\,;\frac{9}{4}\right)$ $\mathrm{C} = (3\,;-1)$

(a) *trouver les coordonnées de* E *défini par* $\overrightarrow{\mathrm{AB}} = \overrightarrow{\mathrm{CE}}$ *;*

(b) *trouver les coordonnées de* D *tel que* ABCD *soit un parallélogramme ;*

(c) *quel est le milieu de* [ED] *?*

(d) H *est le point tel que* C *est le milieu de* [BH]
K *est le point tel que C est le milieu de* [AK]
quelles sont les coordonnées de K *et de* H *?*

(e) *écrire tous les vecteurs de la figure égaux respectivement à* $\overrightarrow{\mathrm{AB}}$, *à* $\overrightarrow{\mathrm{BE}}$, *à* $\overrightarrow{\mathrm{EK}}$.

1 - 8

Le vecteur $\vec{c}$ *défini par* $\vec{c} = 2\vec{a} + 3\vec{b}$ *est une combinaison linéaire de* $\vec{a}$ *et de* $\vec{b}$*, c'est-à-dire une somme de « multiples » (par des scalaires) des vecteurs* $\vec{a}$ *et* $\vec{b}$ *:*

a) *calculer* $\vec{c}$ *si* $\vec{a} = \begin{pmatrix} 3 \\ -1 \end{pmatrix}$ *et* $\vec{b} = \begin{pmatrix} 1 \\ 2 \end{pmatrix}$ *;*

b) *le vecteur* $\vec{d} = \begin{pmatrix} 5 \\ 3 \end{pmatrix}$ *est-il une combinaison linéaire de* $\vec{a}$ *et de* $\vec{b}$ *?*

c) *même question pour les vecteurs* $\vec{v} = \begin{pmatrix} 3 \\ -8 \end{pmatrix}$ *et* $\vec{w} = \begin{pmatrix} 10 \\ 8 \end{pmatrix}$.

1 - 9

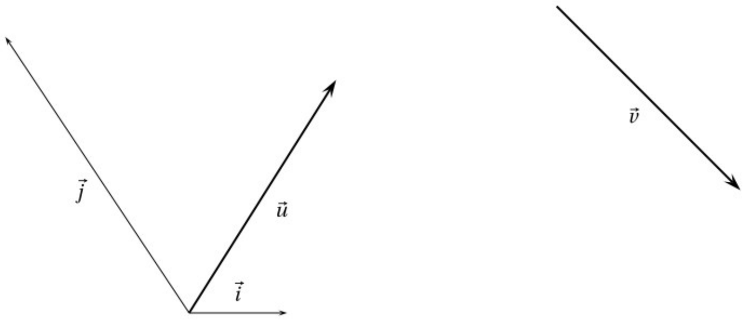
Existe-t-il deux vecteurs $\vec{a}$ *et* $\vec{b}$ *tels que* $\vec{c} = \begin{pmatrix} 10 \\ 8 \end{pmatrix}$ *ne soit pas combinaison linéaire de* $\vec{a}$ *et* $\vec{b}$ *?*

1 - 10

Soient quatre vecteurs $\overrightarrow{i}$, $\overrightarrow{j}$, $\overrightarrow{u}$ et $\overrightarrow{v}$. *Déterminer graphiquement, au dixième près*

(a) *les réels* α *et* β *tels que* $\overrightarrow{u} = \alpha\overrightarrow{i} + \beta\overrightarrow{j}$

(b) *les réels* γ *et* δ *tels que* $\overrightarrow{v} = \gamma\overrightarrow{i} + \delta\overrightarrow{j}$



Remarque

Les vecteurs $\overrightarrow{i}$ et $\overrightarrow{j}$ forment une base du plan à l'aide de laquelle on exprime les coordonnées des vecteurs $\overrightarrow{u}$ et $\overrightarrow{v}$.

1 - 11

On donne les points O, I, J, U, V, A, B.

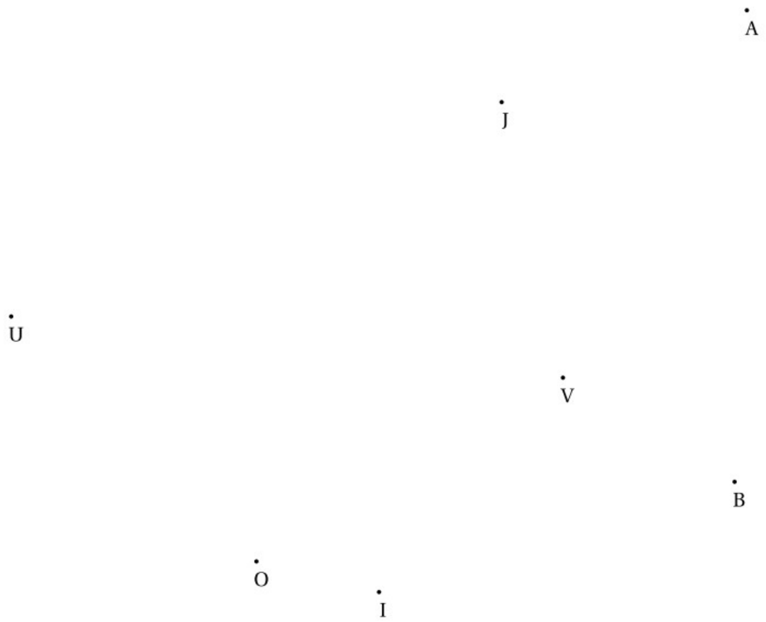
Soient $\overrightarrow{OI} = \overrightarrow{i}$, $\overrightarrow{OJ} = \overrightarrow{j}$, $\overrightarrow{OU} = \overrightarrow{u}$, $\overrightarrow{OV} = \overrightarrow{v}$.

1. (a) *Déterminer graphiquement, au dixième près, les coordonnées des points* A *et* B *dans le repère* $(O, \overrightarrow{i}, \overrightarrow{j})$.

   (b) *Exprimer le vecteur* $\overrightarrow{AB}$ *à l'aide des vecteurs* $\overrightarrow{i}$ et $\overrightarrow{j}$

2. (a) *Déterminer graphiquement, au dixième près, les coordonnées des points* A *et* B *dans le repère* $(O, \overrightarrow{u}, \overrightarrow{v})$.

   (b) *Exprimer le vecteur* $\overrightarrow{AB}$ *à l'aide des vecteurs* $\overrightarrow{u}$ et $\overrightarrow{v}$.



1 - 12

Soient O, I, J *trois points non-alignés. On appellera* $\overrightarrow{i}$ *le vecteur* $\overrightarrow{\mathrm{OI}}$, $\overrightarrow{j}$ *le vecteur* $\overrightarrow{\mathrm{OJ}}$

(a) *Construire les points* A, B, C *tels que*

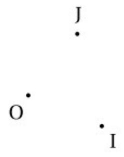
$$\overrightarrow{\mathrm{OA}} = -\overrightarrow{i} + \overrightarrow{j}, \quad \overrightarrow{\mathrm{OB}} = -2\overrightarrow{i} - \overrightarrow{j}, \quad \overrightarrow{\mathrm{OC}} = \overrightarrow{i} - 3\overrightarrow{j}$$

(b) *Soit* $\overrightarrow{u} = 2\overrightarrow{i} - 3\overrightarrow{j}$. *Construire les points* A′, B′, C′ *tels que*

$$\overrightarrow{\mathrm{AA}'} = \overrightarrow{\mathrm{BB}'} = \overrightarrow{\mathrm{CC}'} = \overrightarrow{u}$$

(c) *Exprimer les vecteurs* $\overrightarrow{\mathrm{OA}'}$, $\overrightarrow{\mathrm{OB}'}$, $\overrightarrow{\mathrm{OC}'}$ *en fonction de* $\overrightarrow{i}$ *et* $\overrightarrow{j}$.

(d) *Exprimer les vecteurs* $\overrightarrow{\mathrm{AB}}$, $\overrightarrow{\mathrm{AC}}$, $\overrightarrow{\mathrm{BC}}$ *en fonction de* $\overrightarrow{i}$ *et* $\overrightarrow{j}$.



1 - 13

Est-ce que $\vec{c} = (2\,;2\,;1)$ *(vecteur de l'espace* $\mathbb{R}^3$ *!) est combinaison linéaire de* $\vec{a} = (1\,;0\,;3)$ *et de* $\vec{b} = (0\,;-2\,;5)$ *? Même question pour* $\vec{d} = (1\,;4\,;8)$.

1 - 14

Quels sont les vecteurs de $\mathbb{R}^3$ *qui sont combinaison linéaire de* $\vec{a} = (1\,;0\,;0)$ *et* $\vec{b} = (0\,;1\,;0)$ *? (On dit aussi que ces vecteurs sont engendrés par* $\vec{a}$ *et* $\vec{b}$*)*

1 - 15

Combien faut-il de vecteurs pour engendrer l'espace $\mathbb{R}^3$ (c'est-à-dire pour engendrer n'importe quel vecteur de cet espace) ? Y a-t-il des conditions à imposer à ces vecteurs ?

   (b) $\overrightarrow{AB} \approx \begin{pmatrix} -1,2 \\ -1 \end{pmatrix}_{\vec{u},\vec{v}}$

4 Quelques considérations remarquables

(a) Soit A et B deux points distincts, α un réel et M encore un autre point. La relation $\boxed{\overrightarrow{AM} = \alpha\overrightarrow{AB}}$ traduit les propriétés suivantes :

   1) les points M, A et B sont alignées

   2) le point M a pour abscisse α dans le repère $(O, \overrightarrow{AB})$ de la droite (AB)

   Les deux vecteurs $\overrightarrow{AM}$ et $\overrightarrow{AB}$ sont aussi dits **colinéaires** : ils ont la même direction et les droites (AM) et (AB) sont parallèles.

(b) On peut aussi montrer que deux vecteurs $\vec{u}$ et $\vec{v}$ sont colinéaires si, et seulement si,

$$x_u y_v - x_v y_u = 0$$

où (x_u, y_u) et (x_v, y_v) sont les coordonnées respectives de $\vec{u}$ et $\vec{v}$ dans une base $\{\vec{i}, \vec{j}\}$. En effet, $\vec{u}$ et $\vec{v}$ sont colinéaires, si par définition, il existe un $\alpha \in \mathbb{R}$, tel que $\vec{v} = \alpha \cdot \vec{u}$, c'est-à-dire

$$\begin{pmatrix} x_v \\ y_v \end{pmatrix} = \alpha \begin{pmatrix} x_u \\ y_u \end{pmatrix} \Leftrightarrow \begin{cases} x_v &= \alpha \cdot x_u \\ y_v &= \alpha \cdot y_u \end{cases} \Leftrightarrow \begin{cases} x_v \cdot y_u &= \alpha \cdot x_u \cdot y_u \\ x_u \cdot y_v &= \alpha \cdot x_u \cdot y_u \end{cases} \Leftrightarrow x_v \cdot y_u = x_u \cdot y_v \Leftrightarrow x_v \cdot y_u - x_u \cdot y_v = 0$$

Définition 1 - 7

Le réel $x_u y_v - x_v y_u$ est appelé le **déterminant** des vecteurs $\vec{u}$ et $\vec{v}$ dans une base $\{\vec{i}, \vec{j}\}$.

Notation : $\text{dét}(\vec{u}, \vec{v}) = \begin{vmatrix} x_u & x_v \\ y_u & y_v \end{vmatrix}$ et $\begin{vmatrix} x_u & x_v \\ y_u & y_v \end{vmatrix} = x_u y_v - x_v y_u.$

Théorème 1 - 1

Deux vecteurs dans V^2 sont colinéaires si et seulement si $\text{dét}(\vec{u}, \vec{v}) = 0$.

Attention ! Ce théorème n'est valable que dans V^2 et on parle dans ce cas de « déterminant 2 × 2 ».

(c) Dans l'espace, avec trois vecteurs, il existe un opérateur similaire appelé « déterminant 3 × 3 »,

Définition 1 - 8

Le **déterminant** des vecteurs $\vec{u}$, $\vec{v}$ et $\vec{w} \in V^3$ dans une base $\{\vec{i}, \vec{j}, \vec{k}\}$ est le nombre réel :

$$\begin{aligned} \text{dét}(\vec{u}, \vec{v}, \vec{w}) = \begin{vmatrix} x_u & x_v & x_w \\ y_u & y_v & y_w \\ z_u & z_v & z_w \end{vmatrix} &= x_u \cdot \begin{vmatrix} y_v & y_w \\ z_v & z_w \end{vmatrix} - y_u \cdot \begin{vmatrix} x_v & x_w \\ z_v & z_w \end{vmatrix} + z_u \cdot \begin{vmatrix} x_v & x_w \\ y_v & y_w \end{vmatrix} \\ &= x_u y_v z_w - x_u y_w z_v - (y_u x_v z_w - y_u x_w z_v) + z_u x_v y_w - z_u x_w y_v \\ &= x_u y_v z_w + y_u z_v x_w + z_u x_v y_w - z_u y_v x_w - y_u x_v z_w - x_u z_v y_w \end{aligned}$$

avec un théorème équivalent.

Théorème 1 - 2

Trois vecteurs sont linéairement dépendants (ou coplanaires) ssi leur déterminant est nul :

$$\text{dét}(\vec{u}, \vec{v}, \vec{w}) = 0.$$

Et, si le déterminant n'est pas nul, alors les trois vecteurs sont linéairement indépendants.

Cet outil facilite grandement le calcul pour déterminer si 3 vecteurs sont linéairement dépendants ou indépendants.
En principe, pour le savoir en utilisant directement la définition, il est nécessaire de résoudre un système d'équations. Par exemple, si on a les vecteurs

$$\vec{a} = \begin{pmatrix} 2 \\ 3 \\ 1 \end{pmatrix} \quad \vec{b} = \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} \quad \vec{c} = \begin{pmatrix} 1 \\ 2 \\ 10 \end{pmatrix}$$

le système à résoudre est

$$\alpha \cdot \begin{pmatrix} 2 \\ 3 \\ 1 \end{pmatrix} + \beta \cdot \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} + \gamma \cdot \begin{pmatrix} 1 \\ 2 \\ 10 \end{pmatrix} = 0 \quad \Leftrightarrow \begin{array}{c} \text{①} \\ \text{②} \\ \text{③} \end{array} \left\{ \begin{array}{l} 2\alpha + \beta + \quad \gamma = \vec{0} \\ 3\alpha \quad + \ 2\gamma = 0 \\ \ \alpha + \beta + 10\gamma = 0 \end{array} \right.$$

① – ③ donne une nouvelle équation ④ : $\alpha - 9\gamma = 0$.
② – 3 · ③ donne : $29\gamma = 0$, d'où $\gamma = 0$ et en substituant cette valeur dans les équations précédentes, on obtient $\alpha = \beta = 0$. Ce système a pour unique solution $\alpha = \beta = \gamma = 0$, les vecteurs sont donc linéairement indépendants.

Cet exemple était facile à traiter, mais souvent les calculs donnent plus de fil à retordre. Avec le déterminant,

$$\text{dét}\left(\begin{pmatrix} 2 \\ 3 \\ 1 \end{pmatrix}, \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix}, \begin{pmatrix} 1 \\ 2 \\ 10 \end{pmatrix}\right) = 2 \cdot (0-2) - 3 \cdot (10-1) + 1 \cdot (2-0) = -4 - 27 + 2 = -29 \quad \Rightarrow \text{vecteurs lin. indépendants}$$

c'est toujours très rapide.

Remarque

Le lien entre la résolution d'un système d'équations linéaires et le déterminant est assuré par la règle dite de Cramer. Cela mérite quelques explications. Commençons par données quelques propriétés du déterminant.

(a) $\textbf{dét}(\vec{a} + \vec{b}, \vec{c}, \vec{d}) = \textbf{dét}(\vec{a}, \vec{c}, \vec{d}) + \textbf{dét}(\vec{b}, \vec{c}, \vec{d})$

Pour démontrer cette propriété, il suffit de développer le déterminant

$$\begin{aligned} \text{dét}(\vec{a} + \vec{b}, \vec{c}, \vec{d}) &= (a_1 + b_1) \cdot \begin{vmatrix} c_2 & d_2 \\ c_3 & d_3 \end{vmatrix} - (a_2 + b_2) \cdot \begin{vmatrix} c_1 & d_1 \\ c_3 & d_3 \end{vmatrix} + (a_3 + b_3) \begin{vmatrix} c_1 & d_1 \\ c_2 & d_2 \end{vmatrix} \\ = a_1 \cdot \begin{vmatrix} c_2 & d_2 \\ c_3 & d_3 \end{vmatrix} - a_2 \cdot \begin{vmatrix} c_1 & d_1 \\ c_3 & d_3 \end{vmatrix} + a_3 \cdot \begin{vmatrix} c_1 & d_1 \\ c_2 & d_2 \end{vmatrix} &+ b_1 \cdot \begin{vmatrix} c_2 & d_2 \\ c_3 & d_3 \end{vmatrix} - b_2 \cdot \begin{vmatrix} c_1 & d_1 \\ c_3 & d_3 \end{vmatrix} + b_3 \cdot \begin{vmatrix} c_1 & d_1 \\ c_2 & d_2 \end{vmatrix} \\ &= \text{dét}(\vec{a}, \vec{c}, \vec{d}) + \text{dét}(\vec{b}, \vec{c}, \vec{d}) \end{aligned}$$

On a de manière semblable

$$\text{dét}(\vec{a}, \vec{b} + \vec{c}, \vec{d}) = \text{dét}(\vec{a}, \vec{b}, \vec{c}) + \text{dét}(\vec{a}, \vec{c}, \vec{d}) \qquad \text{et} \quad \text{dét}(\vec{a}, \vec{b}, \vec{c} + \vec{d}) = \text{dét}(\vec{a}, \vec{b}, \vec{c}) + \text{dét}(\vec{a}, \vec{b}, \vec{d})$$

(b) $\textbf{dét}(\alpha \cdot \vec{a}, \vec{b}, \vec{c}) = \alpha \cdot \textbf{dét}(\vec{a}, \vec{b}, \vec{c})$

On procède de manière analogue pour démontrer cette propriété

$$\begin{aligned} \text{dét}(\alpha \cdot \vec{a}, \vec{b}, \vec{c}) &= \alpha a_1 \cdot \begin{vmatrix} b_2 & c_2 \\ b_3 & c_3 \end{vmatrix} - \alpha a_2 \cdot \begin{vmatrix} b_1 & c_1 \\ b_3 & c_3 \end{vmatrix} + \alpha a_3 \begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix} \\ &= \alpha \left(a_1 \cdot \begin{vmatrix} b_2 & c_2 \\ b_3 & c_3 \end{vmatrix} - a_2 \cdot \begin{vmatrix} b_1 & c_1 \\ b_3 & c_3 \end{vmatrix} + a_3 \cdot \begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix} \right) = \alpha \cdot \text{dét}(\vec{a}, \vec{b}, \vec{c}) \end{aligned}$$

On a de manière semblable

$$\text{dét}(\vec{a}, \alpha \cdot \vec{b}, \vec{c}) = \alpha \cdot \text{dét}(\vec{a}, \vec{b}, \vec{c}) \qquad \text{et} \quad \text{dét}(\vec{a}, \vec{b}, \alpha \cdot \vec{c}) = \alpha \cdot \text{dét}(\vec{a}, \vec{b}, \vec{c})$$

Ces deux premières propriétés font que le déterminant est multi-**linéaire**.

(c) **$\text{dét}(\vec{a},\vec{b},\vec{c}) = -\text{dét}(\vec{b},\vec{a},\vec{c})$ (propriété d'antisymétrie)**
On le démontre en développant le membre de gauche et de droite séparément :

$$\begin{aligned}
\text{dét}(\vec{a},\vec{b},\vec{c}) &= a_1\cdot\begin{vmatrix} b_2 & c_2 \\ b_3 & c_3 \end{vmatrix} - a_2\cdot\begin{vmatrix} b_1 & c_1 \\ b_3 & c_3 \end{vmatrix} + a_3\cdot\begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix}\\
&= a_1b_2c_3 - a_1b_3c_2 - a_2b_1c_3 + a_2b_3c_1 + a_3b_1c_2 - a_3b_2c_1\\
-\text{dét}(\vec{b},\vec{a},\vec{c}) &= -\left(b_1\cdot\begin{vmatrix} a_2 & c_2 \\ a_3 & c_3 \end{vmatrix} - b_2\cdot\begin{vmatrix} a_1 & c_1 \\ a_3 & c_3 \end{vmatrix} + b_3\cdot\begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix}\right)\\
&= -(b_1a_2c_3 - b_1a_3c_2 - b_2a_1c_3 + b_2a_3c_1 + b_3a_1c_2 - b_3a_2c_1)\\
&= a_1b_2c_3 - a_1b_3c_2 - a_2b_1c_3 + a_2b_3c_1 + a_3b_1c_2 - a_3b_2c_1
\end{aligned}$$

On a aussi

$$\text{dét}(\vec{a},\vec{b},\vec{c}) = -\text{dét}(\vec{a},\vec{c},\vec{b})$$

et on en tire

$$\text{dét}(\vec{c},\vec{a},\vec{b}) = -\text{dét}(\vec{a},\vec{c},\vec{b}) = -\Big(-\text{dét}(\vec{a},\vec{b},\vec{c})\Big) = \text{dét}(\vec{a},\vec{b},\vec{c})$$

(d) **$\text{dét}(\vec{a},\vec{a},\vec{c}) = 0$ (le déterminant est dit alterné)**
On le découvre en posant dans la propriété précédente (c) $\vec{b} = \vec{a}$:
$\text{dét}(\vec{a},\vec{a},\vec{c}) = -\text{dét}(\vec{a},\vec{a},\vec{c})$, d'où $\text{dét}(\vec{a},\vec{a},\vec{c}) = 0$

(e) **$\text{dét}(\vec{0},\vec{b},\vec{c}) = 0$**
On le démontre en posant dans la propriété (b) $\alpha = 0$:

$$0 = 0\cdot\text{dét}(\vec{a},\vec{b},\vec{c}) = \text{dét}(0\cdot\vec{a},\vec{b},\vec{c}) = \text{dét}(\vec{0},\vec{b},\vec{c})$$

Remarque

Dépendance linéaire et déterminant nul : ces propriétés nous permettent d'aborder la notion de dépendance linéaire avec ce nouvel outil qu'est le déterminant.

Soit 3 vecteurs linéairement dépendants $\vec{a},\vec{b},\vec{c}$ de $\mathbb{R}^3$; un des vecteurs peut donc être exprimé en fonction des 2 autres, par exemples : $\vec{c} = \alpha\cdot\vec{a} + \beta\cdot\vec{b}$. Nous avons alors :

$$\begin{aligned}
\text{dét}(\vec{a},\vec{b},\vec{c}) &= \text{dét}(\vec{a},\vec{b},\alpha\cdot\vec{a}+\beta\cdot\vec{b})\\
&= \text{dét}(\vec{a},\vec{b},\alpha\cdot\vec{a}) + \text{dét}(\vec{a},\vec{b},\beta\cdot\vec{b}) = \alpha\cdot\text{dét}(\vec{a},\vec{b},\vec{a}) + \beta\cdot\text{dét}(\vec{a},\vec{b},\vec{b}) = 0+0 = 0
\end{aligned}$$

Nous avons ainsi : **si 3 vecteurs de $\mathbb{R}^3$ sont linéairement dépendants, leur déterminant est nul**.

Nous aimerions aussi avoir la réciproque. À partir de là, avec les contraposées, on pourra affirmer « trois vecteurs sont linéairement indépendants ssi le déterminant est non-nul ».

Déterminant et indépendance linéaire, les règles de Cramer : il nous faut revenir aux systèmes d'équations linéaires pour terminer. Pour tester l'indépendance linéaire de trois vecteurs dans $\mathbb{R}^3$ à partir de la définition, il fallait poser le système

$$\alpha\vec{a} + \beta\vec{b} + \gamma\vec{c} = \vec{0}$$

qui représente un système d'équations linéaires homogène avec pour variables α,β,γ. Nous allons partir de la situation générale et prendre x, y, z comme variables. Soit le système de 3 équations à 3 inconnues

$$\vec{a}x + \vec{b}y + \vec{c}z = \vec{d} \quad\Leftrightarrow\quad \begin{aligned} a_1x + b_1y + c_1z &= d_1\\ a_2x + b_2y + c_2z &= d_2\\ a_3x + b_3y + c_3z &= d_3 \end{aligned} \qquad (\blacklozenge)$$

Nous avons

$$\begin{aligned}
\text{dét}(\vec{d},\vec{b},\vec{c}) &= \text{dét}(\vec{a}x+\vec{b}y+\vec{c}z,\vec{b},\vec{c})\\
&= x\cdot\text{dét}(\vec{a},\vec{b},\vec{c}) + y\cdot\text{dét}(\vec{b},\vec{b},\vec{c}) + z\cdot\text{dét}(\vec{c},\vec{b},\vec{c}) = x\cdot\text{dét}(\vec{a},\vec{b},\vec{c})
\end{aligned} \qquad (\bigstar)$$

D'où $x = \dfrac{\text{dét}(\vec{d},\vec{b},\vec{c})}{\text{dét}(\vec{a},\vec{b},\vec{c})}$ pour autant que $\text{dét}(\vec{a},\vec{b},\vec{c}) \neq 0$.

On trouvera de manière analogue : $y = \dfrac{\text{dét}(\vec{a},\vec{d},\vec{c})}{\text{dét}(\vec{a},\vec{b},\vec{c})}$ et $z = \dfrac{\text{dét}(\vec{a},\vec{b},\vec{d})}{\text{dét}(\vec{a},\vec{b},\vec{c})}$. (★★)

La règle de Cramer donne ainsi les solutions d'un système linéaire 3×3. En l'appliquant à un système homogène comme $\alpha\vec{a}+\beta\vec{b}+\gamma\vec{c}=\vec{0}$, avec $\vec{a},\vec{b},\vec{c}\in\mathbb{R}^3$, nous allons obtenir le résultat attendu, car tout système homogène a pour solution $x=y=z=0$ (cela se vérifie immédiatement), ici $\alpha=\beta=\gamma=0$, mais il peut admettre encore d'autres solutions. La solution est unique seulement dans le cas où $\text{dét}(\vec{a},\vec{b},\vec{c})\neq 0$, car elle est alors donnée par les formules (★★) qui suppose un déterminant non nul.

En effet, si $\text{dét}(\vec{a},\vec{b},\vec{c})=0$, la règle de Cramer (★) donne

$$\text{dét}(\vec{0},\vec{b},\vec{c})=\alpha\cdot 0 \Leftrightarrow 0=\alpha\cdot 0,$$

ce qui permet de choisir de multiples valeurs pur $\alpha\neq 0$.

Remarque

Nous pouvons maintenant affirmer que **si le déterminant des vecteurs $\vec{a},\vec{b},\vec{c}$ est non nul, alors les vecteurs sont linéairement indépendants** ou, en prenant la contraposée, si les vecteurs sont linéairement dépendants, alors le déterminant est nul.

Pour terminer, revenons au système générale (♦). Si le $\text{dét}(\vec{a},\vec{b},\vec{c})\neq 0$, ce qui est la condition pour que les 3 vecteurs soient linéairement indépendants, alors ceux-ci forment une base pour $\mathbb{R}^3$ et le vecteur $\vec{d}$ peut alors être exprimer de manière unique à l'aide de ces 3 vecteurs : $\vec{d}=\vec{a}x+\vec{b}y+\vec{c}z$.
Si par contre le déterminant est nul, alors les vecteurs $\vec{a},\vec{b},\vec{c}$ ne sont pas linéairement indépendants et ne forment donc pas une base de $\mathbb{R}^3$. Les vecteurs sont coplanaires. On a alors deux cas possibles

(a) $\vec{d}$ appartient au même plan et peut donc aussi être généré par $\vec{a},\vec{b},\vec{c}$. Toutefois, il est coplanaire avec aussi seulement deux des 3 vecteurs, c'est-à-dire que, par exemple, $\text{dét}(\vec{d},\vec{b},\vec{c})=0$. Le système a alors de multiples solutions puisque dans (★), on obtient $0=\alpha 0$, $0=\beta 0$ et $0=\gamma 0$.

(b) $\vec{d}$ n'appartient pas au même plan que $\vec{a},\vec{b},\vec{c}$ et les déterminants $A=\text{dét}(\vec{a},\vec{b},\vec{d})$, $B=\text{dét}(\vec{a},\vec{d},\vec{c})$ et $C=\text{dét}(\vec{d},\vec{b},\vec{c})=0$ sont non nuls et la règle (★) donne

$$A=\alpha\cdot 0, B=\beta\cdot 0, C=\gamma\cdot C,\quad \text{avec } A,B,C\neq 0$$

... équations qui sont sans solution !

(d) Soit $\mathscr{D}$ une droite et A et B deux points distincts tels que (AB) et $\mathscr{D}$ soient parallèles. Autrement dit, (AB) et $\mathscr{D}$ ont la même direction : nous dirons que $\overrightarrow{AB}$ est un **vecteur directeur** de $\mathscr{D}$.

(e) Soit [AB] un segment et I un point. Chacune des égalités ci-après caractérise le fait que I **est le milieu de** [AB] :

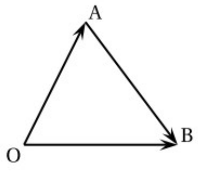
$$\boxed{\overrightarrow{AI}=\overrightarrow{IB} \quad \text{ou} \quad \overrightarrow{IA}+\overrightarrow{IB}=\vec{0} \quad ou \quad \overrightarrow{AI}=\frac{1}{2}\overrightarrow{AB}.}$$

(f) La relation de Chasles peut aussi s'écrire

$$\boxed{\overrightarrow{AB}=\overrightarrow{OB}-\overrightarrow{OA}}$$

ou encore

$$\boxed{\overrightarrow{AB}=\begin{pmatrix}b_1\\b_2\end{pmatrix}-\begin{pmatrix}a_1\\a_2\end{pmatrix}=\begin{pmatrix}b_1-a_1\\b_2-a_2\end{pmatrix}}$$

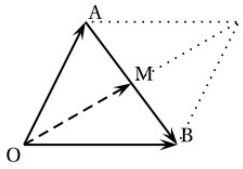


(g) M est le milieu de [AB] si et seulement si

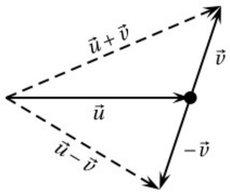
$$\overrightarrow{OM}=\frac{1}{2}(\overrightarrow{OA}+\overrightarrow{OB})$$

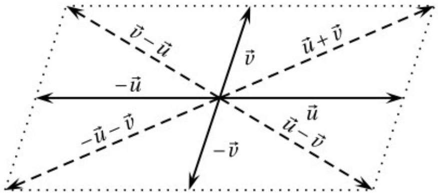
ou encore

$$\overrightarrow{OM}=\left(\frac{a_1+b_1}{2}\,;\,\frac{a_2+b_2}{2}\right)$$



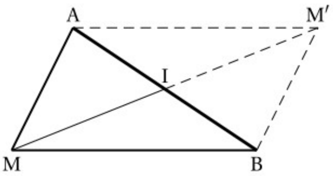
(h) Il y a quelques configurations de bases qui sont données ci-dessous





(i) Il y a deux autres configurations importantes

« le milieu I **d'un segment** [AB] **et un autre point** M **»**



Quel que soit M :

$$\boxed{\begin{array}{l}\overrightarrow{MA}+\overrightarrow{MB}=2\overrightarrow{MI}\\ \overrightarrow{MI}=\dfrac{1}{2}(\overrightarrow{MA}+\overrightarrow{MB})\end{array}}$$

Le calcul est aisé :

$$\begin{aligned}\overrightarrow{MA}+\overrightarrow{MB}&=(\overrightarrow{MI}+\overrightarrow{IA})+(\overrightarrow{MI}+\overrightarrow{IB})\\&=2\overrightarrow{MI}+\overrightarrow{IA}+\overrightarrow{IB}\end{aligned}$$

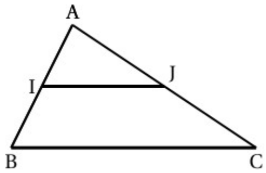
Comme I est le milieu de [AB], $\overrightarrow{IA}+\overrightarrow{IB}=\overrightarrow{0}$ et on a

$$\overrightarrow{MA}+\overrightarrow{MB}=2\overrightarrow{MI}$$

On peut aussi utiliser le fait que AMBM′ forme un parallélogramme

- $\overrightarrow{MA}+\overrightarrow{MB}=\overrightarrow{MM'}$ (règle du parallélogramme) ;
- $\overrightarrow{MM'}=2\overrightarrow{MI}$ (I est aussi le milieu de [MC])

« le théorème des milieux »



I et J sont les milieux des côtés.
On a :

$$\boxed{\overrightarrow{BC}=2\overrightarrow{IJ}}$$

(Cette relation signifie

- l'égalité BC = 2IJ
- le parallélisme de (BC) et (IJ).)

La démonstration est simple :

$$\begin{aligned}\overrightarrow{BC} = \overrightarrow{AC} - \overrightarrow{AB} &= 2\overrightarrow{AJ} - 2\overrightarrow{AI} \\ &= 2(\overrightarrow{AJ} - \overrightarrow{AI}) = 2\overrightarrow{IJ}\end{aligned}$$

construction, contain both the standard reals and actual infinitesimals; they can be used to prove theorems (for the ordinary reals) (Lightstone and Robinson [1975]).

Other approaches restrict attention to those real numbers which are explicitly "constructible" in some specific sense, perhaps by means of recursive functions of natural numbers. An efficient version of constructive analysis is due to Bishop [1967]; the corresponding real numbers are described in Myhill [1973]. Earlier, L.E.J. Brouwer developed intuitionism, with emphasis on real numbers given by choice sequences (Troelstra [1977]; see also Dummett [1977]). In my view, such requirements of constructivity tend to emphasize arithmetic at the expense of geometry. Since the real numbers should subsume *both* arithmetic and geometric aspects of mensuration, these practical uses seem better formalized by the standard axioms for the field of real numbers.

7. Vector Geometry

The real numbers provide a one-dimensional geometry—a line with a chosen origin and unit. The higher dimensional analog is vector geometry. Thus in the Euclidean plane, choose an origin 0 and a segment $0U$ representing the unit of distance. Then each point P in the plane is represented by the directed segment $0P$, called a *vector* v. Vectors $0P$ and $0Q$ can be added by the usual parallelogram law: Form the parallelogram with edges $0P$ and $0Q$, and take the diagonal vector $0R$ as the sum (Figure 1). Under this addition, the vectors form an abelian group; it is just the group of all translations of the plane (§III.7). Using the chosen unit segment $0U$, each real number r can be laid off along the line $0U$. The geometric construction of multiplication by r (Figure 3.1) then defines an operation of multiplying the vector $v = 0R$ by the real number (scalar) r to give the vector rv along the line of $0R$. If $r > 0$ it is in the direction of v; if $r < 0$, it is in the opposite direction, in both cases with $|r|$ times

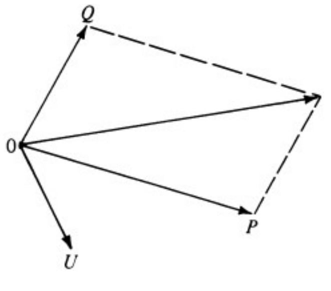

Figure 1

the length. This operation of multiplication of a vector by a scalar has the following formal properties

$$r(v + w) = rv + rw, \qquad 1v = v, \tag{1}$$

$$(r + s)v = rv + sv, \qquad (rs)v = r(sv). \tag{2}$$

for all vectors v and w and all scalars $r, s \in \mathbf{R}$. In view of these properties of addition and of scalar multiplication, we say that the vectors form a *vector space* over the real numbers.

Many geometric facts can be established readily by the use of vector algebra. For example, this algebra gives an easy proof of the theorem that the three medians of a triangle meet in a point.

Vectors may also be introduced in 3-dimensional spaces (and in higher dimensional spaces); moreover, exactly the same formulas (1) and (2) apply, whatever the dimension. More generally, a *vector space* V over a field F is an abelian group (under addition) with another operation $F \times V \to V$, written $(r,v) \mapsto rv$ for elements $r \in F$, $v \in V$, which satisfies with addition the four laws (1) and (2) above. One can also describe formally the "dimension" of such a space. In the plane, if u_1 and u_2 are two non-collinear vectors, every vector v in the plane can be written as a "linear combination" $v = x_1u_1 + x_2u_2$ with unique choices for the scalars x_1 and x_2. In three dimensions, we need three such vectors u_1, u_2 and u_3, along three "axes". More generally, vectors $u_1, \ldots, u_n$ in V are said to form a *basis* for the vector space V if every vector v in V has a unique expression

$$v = x_1u_1 + \cdots + x_nu_n ;$$

then the x_i are the *coordinates* of v relative to the basis u_i. A first theorem of vector geometry ($\doteq$ linear algebra) states that any two (finite) bases for a given vector space must have the same number of elements. This number n is the *dimension* of the space.

Vectors also provide a convenient description for certain functions transforming the plane into itself (and leaving the origin fixed): Transformations such as expansions from the origin ($v \mapsto rv$) for a fixed r, compressions on a line through the origin, and shears. All of these transformations preserve the vector operations. More generally, a *linear transformation* on V is a function t: $V \to V$ which preserves both addition of vectors and multiplication of vectors by scalars. This means that the equations

$$t(v + w) = tv + tw, \qquad t(rv) = r(tv) \tag{3}$$

hold for all vectors v and w and all scalars r. For example, a rotation about the chosen origin 0 is a linear transformation (it maps the parallelogram of addition into a parallelogram). The same notion of linear transformation applies to higher dimensional vector spaces, and is the cornerstone of the study of linear algebra and matrix theory (Chapter VII).

The general idea that some geometrical facts can be handled well by appropriate algebraic operations has now appeared in the use of real numbers for one-dimensional geometry and of vectors for higher dimensions. The addition of vectors was possible only with the choice of an origin 0. Without a choice of origin one still has some algebraic operations such as the construction of the midpoint, written $(1/2)P + (1/2)Q$, of two points P and Q or of the point $(2/3)P + (1/3)Q$ which is one third of the way from P to Q. The general such operation is the formation of the *weighted average*

$$P = w_0P_0 + w_1P_1 + \cdots + w_nP_n \tag{4}$$

of $n + 1$ points with weights real numbers w_i with sum $w_0 + \cdots + w_n = 1$. A transformation preserving such averages is called an *affine* transformation; the resulting geometry (in any number of dimensions) is *affine geometry*. It is possible to write a complete set of axioms for the weighted average operations (4), but they are cumbersome (*Algebra*, first edition). Even the simplest ternary operation $P_0 - P_1 + P_2$ of this type has not proven to be very useful. It seems more efficient to reduce to vector algebra by choosing an origin. Addition is a very convenient operation! Binary operations are much handier than ternary ones.

8. Analytic Geometry

Another and earlier reduction of plane geometry to algebra is provided by the familiar method of cartesian coordinates. Given an orientation, a choice of origin and unit, and two perpendicular coordinate axes, each point P is represented by its coordinates, a pair (x,y) of real numbers. Each line in the plane may be described as the set of those points whose coordinates satisfy a linear equation, while the distance between two points is given by the familiar formula in coordinates, derived from the Pythagorean theorem. In this way, all sort of geometric facts about the plane are handled by algebraic machinery; in effect, the plane is reduced to the cartesian product $\mathbf{R} \times \mathbf{R} = \mathbf{R}^2$ of two copies of the real line $\mathbf{R}$. However, this reduction does depend on the choice of origin *and* of axes, and one must betimes verify that truly geometric facts are independent of the choice of coordinates.

Geometry and coordinates arise first in dimensions 2 and 3. The need for higher dimensional geometry is motivated by phenomena which need specification of more than three coordinates: Events in space-time need four (position and time); in dynamics, the initial conditions for a particle need six, three for position and three for velocity. The use of such a six-dimensional *phase space* is a first example of the importance of mechanics as a motivation for mathematical developments (Chapter IX). To be sure, this example could be (but usually is not) described without explicit use of coordinates, as the product of a three-dimensional position space and another three-dimensional velocity space. A general n-dimensional Euclidean space may be constructed as the n-fold product $\mathbf{R}^n$ of real lines, with points the n-tuples of real numbers $(x_1, \ldots, x_n)$. This is a vector space over $\mathbf{R}$, with basis the n "unit vectors" $(0, \ldots, 0,1,0, \ldots, 0)$. Such use of coordinates allows for the efficient treatment of higher-dimensional phenomena in dimensions where the corresponding geometric intuitions are weak or non-existent. It serves to extend geometric ideas beyond the ordinary three dimensions.

Much of mathematical physics deals with phenomena in three dimensions and so often requires a formulation in triads of equations, one for each coordinate in $\mathbf{R}^3$. When $\mathbf{R}^3$ is regarded as a vector space, many of these equations can be written as single vector equations. This accounts for the popularity of vector analysis in Physics. It includes the use of inner products, to which we now turn.

9. Trigonometry

Trigonometry is essentially a procedure for turning angular measures into linear measures. This appear directly in the definition of the two basic trigonometric functions $\sin \theta$ and $\cos \theta$ of the angle θ. In the oriented plane take a point P on the unit circle with center at the origin 0 so that the segment $0P$ makes the given angle θ with the x coordinate axis. Then $\cos \theta$ and $\sin \theta$ are defined to be the x and y coordinates of P; since the circle has radius 1, this immediately gives the identity

$$\cos^2\theta + \sin^2\theta = 1. \tag{1}$$

This defines $\sin \theta$ and $\cos \theta$ for angles θ of all sizes (not just for an angle θ in the first quadrant, as displayed in Figure 1).

When angles are measured (in radians) by numbers t we can also think of the sine and the cosine as functions of the *number* t, so that

$$\operatorname{Sin} t = \sin(\text{angle of } t \text{ radians}). \tag{2}$$

Thus there are really two legally different functions: The Sine of a *number*, here with capital S, and the sine of an angle, with lower case s. This pedantic (but real!) difference is usually ignored. It implicitly

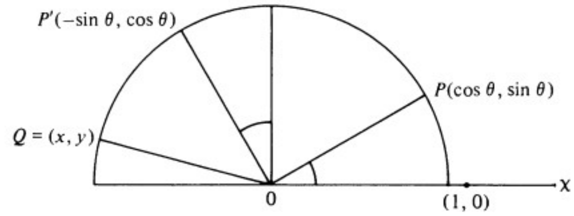

Figure 1

involves the wrapping function θ_t of §2 above. Recall that this function sends each real t to the point $P = (\cos\theta_t, \sin\theta_t)$ on the circle such that the length of the counterclockwise circular arc from (1,0) to P is congruent to t, modulo 2π. Then the definition (2) reads

$$\text{Sin } t = \sin(\theta_t), \qquad \text{Cos } t = \cos(\theta_t): \tag{3}$$

it really amounts to a composite function $t \to \theta_t \to \sin(\theta_t)$. Since the wrapping function has $\theta_{t+2\pi} = \theta_t$ we get

$$\text{Sin}(t + 2\pi) = \text{Sin}(t), \qquad \text{Cos}(t + 2\pi) = \text{Cos}(t). \tag{4}$$

In other words, Sin and Cos are periodic functions, of period 2π, as in the familiar graph of Figure 2. Now that this has been stated, we drop the S in Sin and the function θ_t; they would just get in the way of trigonometric manipulations, but we emphasize that the wrapping function accounts for radian measure and the periodicity (4) of the trigonometric functions. Indeed, the whole study of periodic functions, as carried on in Fourier analysis, concerns the expression of more or less arbitrary functions $f(t)$ of period 2π in terms of the periodic functions $\sin nt$ and $\cos nt$ for the natural numbers n.

A rotation of the circle of Figure 1 about the origin through the angle θ will carry the point (1,0) to our point P and the point (0,1) to a corresponding point P'; thus this rotation has the effect

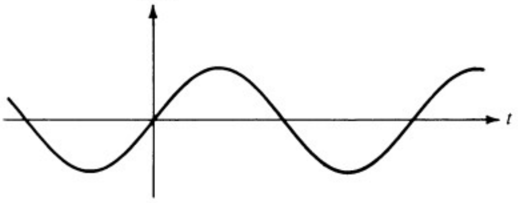

Figure 2

$$(1,0) \mapsto (\cos\theta, \sin\theta), \qquad (0,1) \mapsto (-\sin\theta, \cos\theta) \tag{5}$$

Since (1,0) and (0,1) form a basis for the 2-dimensional vector space, any point Q with coordinates (x,y) can be written as the linear combination $(x,y) = x(1,0) + y(0,1)$ of the two basis vectors. Now rotation is, as already noted, a linear transformation, so preserves linear combinations and thus by (5) has the effect

$$(x,y) \mapsto (x\cos\theta - y\sin\theta,\ x\sin\theta + y\cos\theta).$$

When one writes (x',y') for the coordinates of the rotated point, this yields the customary equations in coordinates

$$\begin{aligned} x' &= x\cos\theta - y\sin\theta, \\ y' &= x\sin\theta + y\cos\theta \end{aligned} \tag{6}$$

for a rotation $(x,y) \mapsto (x',y')$ of the plane about the origin. Also, if one takes $Q = (x,y)$ to be that point Q on the unit circle of Figure 1 for which $0Q$ makes the angle ϕ with the positive x-axis, then $x = \cos\phi$, $y = \sin\phi$. Now the rotation by θ clearly carries Q to a point Q' where $0Q'$ makes the angle $\phi + \theta$ with the positive x-axis. The coordinates (x',y') of Q' are then $\cos(\phi + \theta)$, $\sin(\phi + \theta)$ and the equations (6) for rotation become

$$\begin{aligned} \cos(\phi + \theta) &= \cos\phi\cos\theta - \sin\phi\sin\theta, \\ \sin(\phi + \theta) &= \cos\phi\sin\theta + \sin\phi\cos\theta. \end{aligned} \tag{7}$$

These "addition formulas" for the trigonometric functions are thus another expression of the relation of angular to linear measure.

This relation also accounts for the use of trigonometric functions in calculating the connections between the sides and the angles of a triangle, as suggested by the Euclidean congruence theorems. In a triangle $0AB$ with sides a, b and c, as illustrated in Figure 3, drop a perpendicular from A to the opposite side at M. If θ and ϕ are the angles of the triangle at 0 and

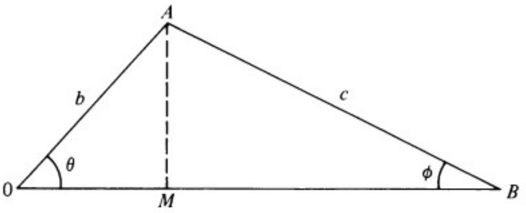

Figure 3

at B, the definition of the sine function shows that the length AM can be expressed either as $b \sin \theta$ or as $c \sin \phi$; this gives the *law of sines*: $b/c = \sin \phi / \sin \theta$. On the other hand, one may compute the length c of the side AB from the Pythagorean theorem for the right triangle AMB to be

$$c^2 = (b \sin \theta)^2 + (a - b \cos \theta)^2, \tag{8}$$

$$c^2 = a^2 + b^2 - 2ab \cos \theta.$$

This is the *law of cosines*. When $u = 0B$ and $v = 0A$ are regarded as vectors of the respective lengths $|0B| = a$, $|0A| = b$, the expression $ab \cos \theta$ which appears in (8) is called the *inner product* $u \cdot v$ of the two vectors; it is a scalar (a real number). If A has coordinates (x_1, y_1) and B coordinates (x_2, y_2), the lengths a, b, and c in (8) can be written in terms of these coordinates by the Pythagorean theorem; the formula (8) then becomes a formula for the inner product $u \cdot v$:

$$(x_1, y_1) \cdot (x_2, y_2) = x_1 x_2 + y_1 y_2. \tag{9}$$

This again is a linearization of angular phenomena.

With these ideas and formulas we have presented all of the essential concepts of trigonometry in less than 6 pages. It is curious (and troublesome) that the standard elementary presentations of trigonometry have been inflated to inordinate lengths–an inflation hardly justified by the inevitable subtlety wrapped up in the comparison of linear and angular magnitude.

In (9), the inner product is expressed in terms of a choice of coordinates. However, as in other cases, the inner product can be described in a more invariant way by suitable axioms. It has three characteristic properties: *Linearity*, *symmetry*, and *positive definiteness*, as expressed by the three equations

$$u \cdot (t_1 v_1 + t_2 v_2) = t_1 (u \cdot v_1) + t_2 (u \cdot v_2), \tag{10}$$

$$u \cdot v = v \cdot u, \tag{11}$$

$$u \cdot u \geqslant 0, \qquad u \cdot u = 0 \quad \text{only if} \quad u = 0, \tag{12}$$

valid for all vectors u, v, v_1, and v_2 and all scalars t_1 and t_2. All the properties of the inner product follow from these equations. Indeed, given these equations–for a product $u \cdot v$ of vectors in a two dimensional vector space over **R**–one can prove that there is a choice of basis and corresponding coordinates for which the given inner product is expressed by the formula (9). Such a basis is called a *normal orthogonal basis* (for the given inner product).

We will extend these ideas to higher dimensions in §VII.5.

(6 &

CHAPTER III

Geometry

This chapter is concerned with the origins of elementary plane geometry, its close relation to groups of transformations, and the notions of non-Euclidean geometry. Subsequently, n-dimensional geometry will appear with linear algebra in Chapter VII, manifolds and spaces with curvature in Chapter VIII, and topology, in its connections with complex analysis, in Chapter X. These and other aspects of geometry pervade Mathematics.

1. Spatial Activities

Geometrical figures and facts arise from a wide array of activities and observations. Some involve motion; thus in watching motion we see objects falling in vertical lines, water waves expanding in circles from a dropped stone, duneland grasses moved by the wind to describe semicircles on the sand, tree branches oscillating back and forth in the wind, long straight lines of ocean waves approaching a beach, and the like. There are also motions which we initiate and then watch–the thrown ball falling, the log rolling downhill, the circle turned into a wheel for a cart, and so on. Some activity involves construction. Thus a post or a column will stay upright in balance if it is set perpendicular to the floor as a vertical; a three-legged stool is more likely to be steady than one constructed with four legs; rods joined to form a triangle stay rigid, but rods joined in a square may wobble. Also, pieces of a board cut apart will fit together again to make up the same size board. Mapping a labyrinth or painting a scene calls for reproducing a variety of shapes, each on a smaller scale. Fitting an object inside another highlights differences in shapes. To check ahead of time that a fit will be possible may require a measurement of length or of circumference. Estimating separation at a distance requires lines of sight, angles, and triangles. These are but a few of the many activities that go into the formation of geometrical ideas.

From these activities one may disengage various figures: Circles and ovals; lines, horizontal, vertical, and perpendicular; triangles, equilateral or otherwise; squares and rectangles; cubes, cylinders, as with logs or rods, and spheres, as with oranges or balloons. One also discovers a variety of facts about these figures: A triangle is rigid because three sides (or two sides and the included angle) determine the triangle up to rigid motion. A right triangle can come in various shapes, but in every case the square constructed on the longest side is the sum of the squares on the two shorter legs (a fact said to have been useful in re-establishing property lines after the Nile had been in flood). Two different perpendiculars to the same line would never meet. Two triangles with corresponding angles equal have corresponding sides proportional—and so on.

After a considerable array of facts about geometrical figures are at hand, some connections between these facts come to light. Once the area of a triangle can be computed from the lengths of its sides, it is possible to fit four congruent triangles together so as to prove the Pythagorean theorem, by adding up the five areas in Figure 1. Or, the Pythagorean theorem can be deduced from facts about ratios of sides in similar triangles.

Explicitly (Figure 2), the perpendicular from the right angle divides the hypotenuse c in Figure 2 into pieces h and k with $h/a = a/c$ and $k/b = b/c$. Clearing of fractions, $hc = a^2$ and $kc = b^2$, so that $(h + k)c = c^2 = a^2 + b^2$, q.e.d. Many more such logical relations between geometrical facts gradually appear.

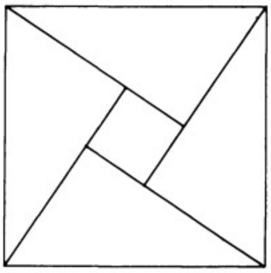

Figure 1. The Pythagorean theorem.

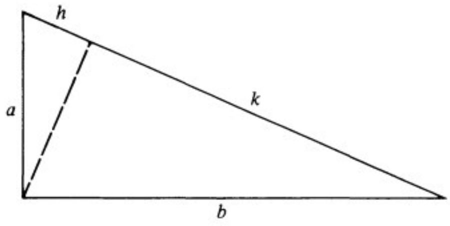

Figure 2

Nevertheless, it is truly remarkable that our experiences of spatial extent and of motion through space can be organized so completely. By taking certain figures–line, plane, segment, angle, and circle–as basic ones, and by assuming certain simple facts as axioms, other geometric figures can be constructed and other geometric facts deduced from the assumed axioms. Some of the resulting facts are surprising; for example, the three medians of a triangle meet in a point, as do the three altitudes. The resulting deductive structure of Euclidean geometry is a model of Mathematical method.

2. Proofs Without Figures

In elementary Euclidean geometry, proofs of various facts about figures are developed from the axioms, with occasional implicit use of intuitively evident properties of the figures concerned. For instance, to find the perpendicular bisector of a segment AB one constructs two circles with centers A and B and both with radius AB; these circles obviously intersect on opposite sides of the line AB, ... But what is meant by a "side" of AB and why must the circles intersect? (See Figure 1.) If *all* facts are to be deduced from axioms, then these plausible observations must also be proved from the axioms, rather than from inspection of the figure. Once this austere requirement was recognized, it turned out to be possible to add suitable new axioms to those of Euclid so that all arguments could be free of any intuitive or pictorial content. This meant that geometry was not really "about" the figures themselves, but was about certain corresponding notions defined exclusively in terms of basic notions to be taken as primitive or undefined. This austere program was systematically carried out by David Hilbert in a book, *Grundlagen der Geometrie* (B. G. Teubner, first edition 1899, twelfth edition 1977). His axioms were for both plane and solid geometry; we will examine only those for the plane. He presented the axioms in the five following groups:

Group I (Incidence Axioms). These axioms involve only three primitive notions: "point", "line", and "the point P lies on the line l". They require:

(1) Two distinct points P and Q lie on one and only one line. (Except for the meticulous logical formulation, this is the familiar requirement that "two points determine a line".)
(2) There are at least two points on every line.
(3) There are three points P, Q, R not all on a line.

With these axioms, one can define a *triangle* (the figure formed by three non-collinear points). However, one cannot yet define "right angle".

The speed of light is a

16.04.2020

maximum velocity, as relativity states, because it represents the maximum rate that information can spread through the hypergraph as it updates. And gravity — described by Einstein's general theory of relativity — emerges in the relationships between features in the hypergraph that can be interpreted as matter particles. (Particles would be small sets of linked points that persist as the hypergraph updates, something like "little lumps of space" with special properties.)

supersmall unknown particles, which he calls oligons

Such oligons, subject only to gravity, would now be hanging out in and around galaxies utterly unnotified — except for their gravitational impact.

Oligons might therefore explain why astronomers infer the existence of vast amounts of invisible "dark matter" in space.

"right rule"

That "right rule" would generate a hypergraph with our universe's specific properties:

4.7 Curvature

In ordinary plane geometry, the area of a circle is πr^2. But if the circle is drawn on the surface of a sphere of radius a, the area of the spherical region enclosed by the circle is instead:

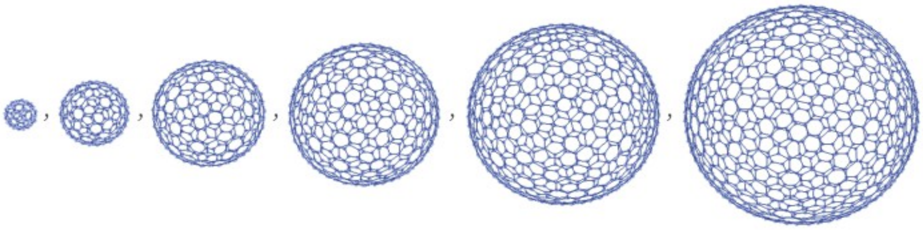
$$2\pi a^2 (1 - \cos(\frac{r}{a})) = \pi r^2 (1 - \frac{r^2}{12 a^2} + \frac{r^4}{360 a^4} - \ldots)$$

In other words, curvature in the underlying space introduces a correction to the growth rate for the area of the circle as a function of radius. And in general there is a similar correction for the volume of a d-dimensional ball in a curved space (e.g. [24][1:p1050]):

$$\frac{\pi^{d/2}}{(d/2)!} r^d (1 - \frac{r^2}{6(d+2)} R + O(r^4))$$

where here R is the Ricci scalar curvature of the space [25][26][27]. (For example, for the d-dimensional surface of a $(d+1)$-dimensional sphere of radius a, $R = \frac{(d-1)\,d}{a^2}$.)

Now consider the sequence of “sphere” graphs:



We can compute V_r for each of these graphs. Here are the log differences $\Delta(r)$ (the error bars come from the different neighborhoods associated with hexagonal and pentagonal “faces” in the graph):

Einstein–Hilbert action—thereby leading to the conclusion that $R_{\mu\nu}$ must satisfy exactly the usual vacuum Einstein equations [114][115][75][116]:

$$R_{\mu\nu} - \frac{1}{2} R\, g_{\mu\nu} = 0$$

A full derivation of this is given in [113]. Causal invariance plays a crucial role, ensuring for example that timelike directions t^i associated with different foliations give invariant results. Much like in the derivation of continuum fluid behavior from microscopic molecular dynamics (e.g. [110]), one also needs to take a variety of fairly subtle limits, and one needs sufficient intrinsic generation of effective randomness [1:7.5] to justify the use of certain statistical averages.

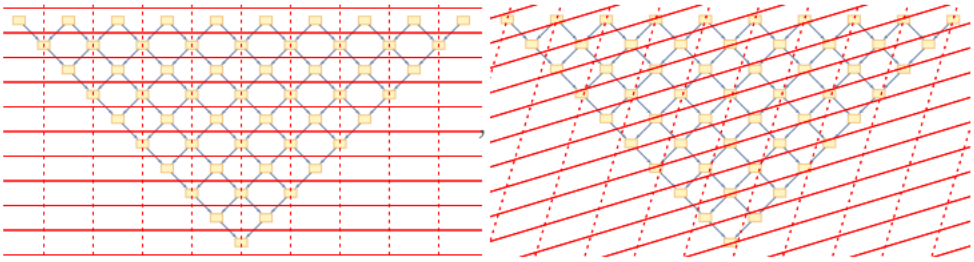
But there is a fairly simple interpretation of the result above. Imagine all the geodesics that start at a particular point in the causal graph. The further we go, the more possible geodesic paths there will be in the graph. To achieve a power law corresponding to a definite dimension, the geodesics must in a sense just "stream outwards", evenly distributed in direction.

But the Ricci tensor specifically measures the rate at which bundles of geodesics change their cross-sectional area. And as soon as this change is nonzero, it will inevitably change the local density of geodesics and eventually grow to disrupt the power law. And so the only way a fixed limiting dimension can be achieved is for the Ricci curvature to vanish, just as it does according to the vacuum Einstein equations. (Note that higher-order terms, involving for example the Weyl tensor and other components of the Riemann tensor, yield changes in the shape of bundles of geodesics, but not in their cross-sectional area, and are therefore not constrained by the requirement of fixed limiting dimension.)

8.8 Matter, Energy and Gravitation

In our models, not only space, but also everything "in space", must be represented by features of our evolving hypergraphs. There is no notion of "empty space", with "matter" in it. Instead, space itself is a dynamic construct created and maintained by ongoing updating events in the hypergraph. And what we call "matter"—as well as things like energy—must just correspond to features of the evolving hypergraph that somehow deviate from the background activity that we call "space".

Anything we directly observe must ultimately have a signature in the causal graph. And a potential hypothesis about energy and momentum is that they may simply correspond to excess "fluxes" of causal edges in time and space. Consider a simple causal graph in which we have marked spacelike and timelike hypersurfaces:

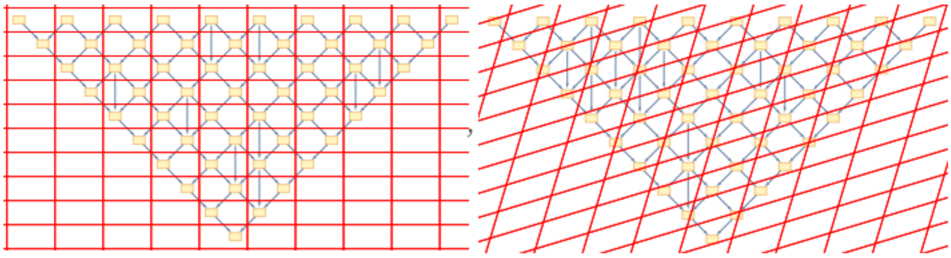


The basic idea is that the number of causal edges that cross spacelike hypersurfaces would correspond to energy, and the number that cross timelike hypersurfaces would correspond to momentum (in the spatial direction defined by a given hypersurface). Inevitably the results one gets would depend on the hypersurfaces one chooses, and so would differ from one observer to another.

And one important feature of this identification of energy and momentum is that it would explain why they follow the same relativistic transformations as time and space. In effect space and time are probing distances between nodes in the causal graph (as measured relative to a particular foliation), while momentum and energy are probing a directly dual property: the density of edges.

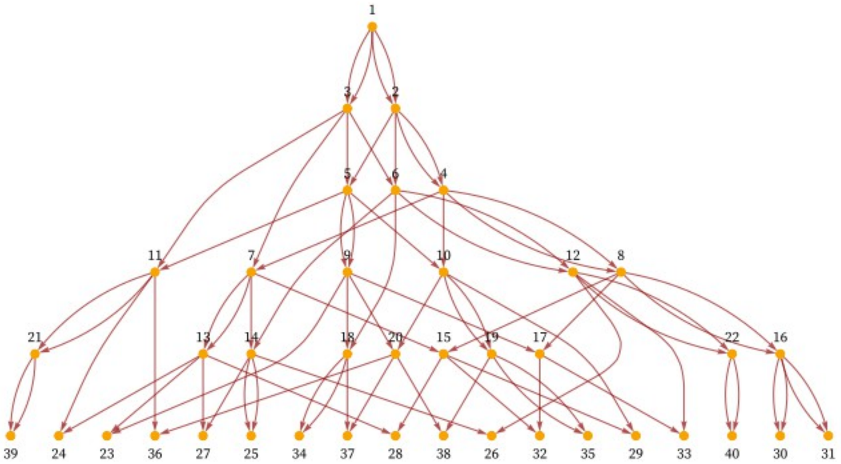
There is additional subtlety here, though, because causal edges are needed just to maintain the structure of spacetime—and whatever we measure as energy and momentum must just be some excess in the density of causal edges over the "background" corresponding to space. But even to know what we mean by density we have to have some notion of volume, but this is also itself defined in terms of edges in the causal graph.

But as a rough idealized picture, we might imagine that we have a causal graph that maintains the same overall structure, but adds some extra connections:



In our actual models, the causal graphs one gets are considerably more complicated. But one can still identify some features from the simple idealization. The basic concept is that energy and momentum add "extra causal connections" that are not "necessary" to define the basic structure of spacetime. In a sense the core thing that defines the structure of spacetime is the way that "elementary light cones" are knitted together.

Consider a causal graph like:



One can think of a set of edges like the ones indicated as in effect “outlining” the causal graph. But then there are other edges that add “extra connections”. The edges that “outline the graph” in effect maximally connect spatially separated regions—or in a sense transmit causal information at a maximum speed. The other edges one can think of as having slower speeds—so they are typically drawn closer to vertical in a rendering like the one above.

But now let us return to our simple grid idealization of the causal graph—with additional vertical edges added. Now do foliations like the ones we used above to represent inertial frames, parametrized by a velocity ratio β relative to the maximum speed (taken to be 1). Define $E(\beta)$ to be the density of causal edge crossing of the spacelike hypersurfaces, and $p(\beta)$ the corresponding quantity for timelike hypersurfaces. Then for speed 1 edges, we have (up to an overall multiplier) (cf. [111][112]):

$$E(\beta) = p(\beta) = \frac{1+\beta}{\sqrt{1-\beta^2}}$$

But in general for edges with speed α we have

$$E(\beta) = \frac{1-\alpha\,\beta}{\sqrt{1-\beta^2}},\;\; p(\beta) = \frac{\alpha-\beta}{\sqrt{1-\beta^2}}$$

which means that for any β

$$E\,(\beta)^2 - p\,(\beta)^2 \;=\; 1-\alpha^2$$

thus showing that our crossing densities transform like energy and momentum for a particle with mass $\sqrt{1-\alpha^2}$. In other words, we can potentially identify edges that are not maximum speed in the causal graph as corresponding to “matter” with nonzero rest mass. Perhaps not surprisingly, this whole setup is quite analogous to thinking about world lines of massive particles in elementary treatments of relativity.

But in our context, all of this must emerge from underlying features of the evolving hypergraph. Causal connections that transfer information at maximum speed can be thought of as arising from updating events that involve maximally separate nodes, and that are somehow always entraining "fresh" nodes. But causal connections that transfer information more slowly are associated with sequences of updating events that in effect reuse nodes. So in other words, rest mass can be thought of as being associated with local collections of nodes in the hypergraph that allow repeated updating events to occur without the involvement of other nodes.

Given this setup, it is possible to derive other features of energy, momentum and mass by methods similar to those used in typical discussions of relativity. It is first helpful to include units in the quantities we have introduced. If an elementary light cone has timeline extent T then we can consider its spacelike extent to be $c\,T$, where c is the speed of light. Within the light cone let us say that there effectively μ causal edges oriented in the timelike direction. With the inertial frame foliations used above, the contribution of these causal edges to energy and momentum will be (the factor c in the energy case comes from the spacelike extent of the light cone):

$$E(\beta) = c\,\frac{\mu}{\sqrt{1-\beta^2}} = c\,\mu\,(1+\frac{\beta^2}{2}+O(\beta^4))$$

$$p(\beta) = \mu\,\frac{\beta}{\sqrt{1-\beta^2}} = \mu\,\beta\,(\,1+O(\beta^2)\,)$$

But if we define the mass m as $\frac{\mu}{c}$ and substitute $\beta = \frac{v}{c}$, we get the standard formulas of special relativity [111][112], or to first order

$$E = m\,c^2 + \frac{1}{2}\,m\,v^2$$

$$p = m\,v$$

establishing in our model the relation $E = m\,c^2$ between energy and rest mass.

We should note that with our identification for energy and momentum, the conservation of energy becomes essentially the statement that the overall density of events in the causal network does not change as we progress through successive spacelike surfaces. And, as we will discuss later, if in effect the whole hypergraph is in some kind of dynamic equilibrium, then we can reasonably expect that this will be the case. Expansion (or, more specifically, non-uniform expansion) will lead to effective violations of energy conservation, much as it does for an expanding universe in the traditional formalism of general relativity [117][75].

In the previous subsection, we discussed the overall structure of spacetime, and we used the growth rate of the spacetime volume $C_t(X)$ as a way to assess this. But now let us ask about specific values of $C_t(X)$, complete with their "constant" multipliers. We can think of these multipliers as probing the local density of the causal graph. But deviations in this are what we have now identified as being associated with matter.

To compute $C_t(X)$ we ultimately need to be able to precisely count events in the causal graph. If the causal graph is somehow “uniform”, then it cannot contain what can be considered to be “matter”. In the setup we have defined, the presence of matter is effectively associated with “fluxes” of causal edges that reflect the non-uniform “arrangement” of nodes in the causal graph. To represent this, take $\rho\,(X)$ to be the “local density” of nodes in the causal graph. We can make a series expansion to probe deviations from uniformity in $\rho\,(X)$. And formally we can write

$$\rho(X) = \rho_0\,(\,1 + \sigma\,\delta t^\mu\,\delta t^\nu\,T_{\mu\nu}\,\ldots)$$

where the t^μ are timelike vectors used in the definition of C_t and now $T_{\mu\nu}$ is effectively a tensor that represents “fluxes of edges” in the causal graph. But these fluxes are what we have identified as energy and momentum, and when we think about how causal edges traverse spacelike and timelike hypersurfaces, $T_{\mu\nu}$ turns out to correspond exactly to the standard energy-momentum tensor of general relativity.

So now we can combine our formula for the effect of local density with our formula for the effect of curvature from the previous section to get:

$$C_t(X) = \rho_0(1 + \sigma\,\delta t^i\,\delta t^j\,T_{ij} + \ldots\,)\;t^{d+1}(1 - \frac{1}{6}\,\delta t^i\,\delta t^j\,R_{ij}\,+ \ldots)$$

But if we apply the same argument as in the previous subsection, then to maintain limiting fixed dimension we get the condition

$$R_{\mu\nu}\; - \frac{1}{2}\,R\,g_{\mu\nu} = \sigma'\,T_{\mu\nu}$$

which has exactly the form of Einstein’s equations in the presence of matter [114][115][75][116].

Just as we interpreted the curvature part of these equations in the previous subsection in terms of the change in area of geodesic bundles, we can interpret the “matter” part in terms of the change of geodesics associated with additional local connections. As an example, consider starting with a 2D hexagonal grid. Now imagine adding edges at each node. Doing this creates additional connections and additional geodesics, eventually producing something like the hyperbolic space examples in 4.2. So what the equation says is that any such effect, which would lead to negative curvature, must be compensated by positive curvature in the “background” spacetime—just as general relativity suggests.

1.4 Riemannian Metrics

We now want to introduce metric structures on differentiable manifolds. Again, we shall start from infinitesimal considerations. We would like to be able to measure the lengths of and the angles between tangent vectors. Then, one may, for example, obtain the length of a differentiable curve by integration. In a vector space such a notion of measurement is usually given by a scalar product. We thus define

Definition 1.4.1 A *Riemannian metric* on a differentiable manifold M is given by a scalar product on each tangent space T_pM which depends smoothly on the base point p. A *Riemannian manifold* is a differentiable manifold, equipped with a Riemannian metric.

In order to understand the concept of a Riemannian metric, we again need to study local coordinate representations and the transformation behavior of these expressions.

Thus, let $x = (x^1, \dots, x^d)$ be local coordinates. In these coordinates, a metric is represented by a positive definite, symmetric matrix

$$(g_{ij}(x))_{i,j=1,\dots,d}$$

Proof. Let $v \in T_qX$, (φ, U) a chart on X with $q \in U$. Let γ be any smooth curve in $\varphi(U)$ with $\gamma(0) = \varphi(q)$, $\dot{\gamma}(0) := \frac{d}{dt}\gamma(t)_{|t=0} = d\varphi(v)$, for example $\gamma(t) = \varphi(q) + td\varphi(v)$. $c := \varphi^{-1}(\gamma)$ then is a curve in X with $\dot{c}(0) = v$. Because of $X = f^{-1}(p)$,

$$f \circ c(t) = p \ \forall \ t,$$

hence $df(q) \circ \dot{c}(0) = 0$, and consequently $v = \dot{c}(0) \in \ker df(q)$. Since also $T_qX = \dim \ker df(q) = m - n$, the claim follows. □

For our example S^n, we may choose

$$f : \mathbb{R}^{n+1} \to \mathbb{R}, f(x) = |x|^2.$$

Then

$$T_xS^n = \ker df(x) = \{v \in \mathbb{R}^{n+1} : x \cdot v (= x^i v^i) = 0\}.$$

Perspectives. H. Whitney (1936) showed that any d-dimensional differentiable manifold can be embedded into $\mathbb{R}^{2d+1}$. Thus, the class of abstract differentiable manifolds is the same as the class of submanifolds of Euclidean space. Nevertheless, the abstract and intrinsic point of view offers great conceptual and technical advantages over the approach of submanifold geometry of Euclidean spaces.

1.4 Riemannian Metrics

We now want to introduce metric structures on differentiable manifolds. Again, we shall start from infinitesimal considerations. We would like to be able to measure the lengths of and the angles between tangent vectors. Then, one may, for example, obtain the length of a differentiable curve by integration. In a vector space such a notion of measurement is usually given by a scalar product. We thus define

Definition 1.4.1 A *Riemannian metric* on a differentiable manifold M is given by a scalar product on each tangent space T_pM which depends smoothly on the base point p. A *Riemannian manifold* is a differentiable manifold, equipped with a Riemannian metric.

In order to understand the concept of a Riemannian metric, we again need to study local coordinate representations and the transformation behavior of these expressions.

Thus, let $x = (x^1, \ldots, x^d)$ be local coordinates. In these coordinates, a metric is represented by a positive definite, symmetric matrix

$$(g_{ij}(x))_{i,j=1,\ldots,d}$$

(i.e. $g_{ij} = g_{ji}$ for all i, j, $g_{ij}\xi^i\xi^j > 0$ for all $\xi = (\xi^1, \ldots, \xi^d) \neq 0$), where the coefficients depend smoothly on x. The transformation formula (1.4.3) below will imply that this smoothness does not depend on the choice of coordinates. Therefore, smooth dependence on the base point as required in def. 1.4.1 can be expressed in local coordinates.

The product of two tangent vectors $v, w \in T_pM$ with coordinate representations $(v^1, \ldots, v^d)$ and $(w^1, \ldots, w^d)$ (i.e. $v = v^i \frac{\partial}{\partial x^i}, w = w^j \frac{\partial}{\partial x^j}$) then is

$$\langle v, w \rangle := g_{ij}(x(p))v^i w^j. \tag{1.4.1}$$

In particular, $\langle \frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j} \rangle = g_{ij}$.

Similarly, the length of v is given by

$$\|v\| := \langle v, v \rangle^{\frac{1}{2}}.$$

We now want to study the transformation behavior. Let $y = f(x)$ define different local coordinates. In these coordinates, v and w have representations $(\tilde{v}^1, \ldots, \tilde{v}^d)$ and $(\tilde{w}, \ldots, \tilde{w}^d)$ with $\tilde{v}^j = v^i \frac{\partial f^j}{\partial x^i}, \tilde{w}^j = w^i \frac{\partial f^j}{\partial x^i}$. Let the metric in the new coordinates be given by $h_{k\ell}(y)$.

It follows that

$$h_{k\ell}(f(x))\tilde{v}^k \tilde{w}^\ell = \langle v, w \rangle = g_{ij}(x)v^i w^j, \tag{1.4.2}$$

hence

$$h_{k\ell}(f(x)) \frac{\partial f^k}{\partial x^i} \frac{\partial f^\ell}{\partial x^j} v^i w^j = g_{ij}(x) v^i w^j,$$

and since this holds for all tangent vectors v, w,

$$h_{k\ell}(f(x)) \frac{\partial f^k}{\partial x^i} \frac{\partial f^\ell}{\partial x^j} = g_{ij}(x). \tag{1.4.3}$$

Formula (1.4.3) gives the transformation behavior of a metric under coordinate changes.

The simplest example of a Riemannian metric of course is the Euclidean one. For $v = (v^1, \ldots, v^d), w = (w^1, \ldots, w^d) \in T_x\mathbb{R}^d$, the Euclidean scalar product is simply

$$\delta_{ij} v^i w^j = v^i w^i,$$

where

$$\delta_{ij} = \begin{cases} 1 & \text{for } i = j \\ 0 & \text{for } i \neq j \end{cases}$$

is the standard Kronecker symbol.

Theorem 1.4.1 *Each differentiable manifold may be equipped with a Riemannian metric.*

Proof. Let $\{(x_\alpha, U_\alpha) : \alpha \in A\}$ be an atlas, $(\varphi_\alpha)_{\alpha \in A}$ a partition of unity subordinate to $(U_\alpha)_{\alpha \in A}$ (see Lemma 1.1.1) (for simplicity of notation, we use the same index set for (φ_α) and (U_α); this may be justified by replacing the original covering (U_α) by a locally finite refinement).

For $v, w \in T_pM$ and $\alpha \in A$ with $p \in U_\alpha$ let the coordinate representations be $(v_\alpha^1, \ldots, v_\alpha^d)$ and $(w_\alpha^1, \ldots, w_\alpha^d)$. Then we put

$$\langle v, w \rangle := \sum_{\substack{\alpha \in A \\ \text{with } p \in U_\alpha}} \varphi_\alpha(p) v_\alpha^i w_\alpha^i \, .$$

This defines a Riemannian metric. (The metric is simply obtained by piecing the Euclidean metrics of the coordinate images together with the help of a partition of unity.) □

Let now $[a, b]$ be a closed interval in $\mathbb{R}, \gamma : [a, b] \to M$ a smooth curve, where "smooth", as always, means "of class C^∞".
The *length of* γ then is defined as

$$L(\gamma) := \int_a^b \| \frac{d\gamma}{dt}(t) \| dt$$

and the *energy* of γ as

$$E(\gamma) := \frac{1}{2} \int_a^b \| \frac{d\gamma}{dt}(t) \|^2 dt \, .$$

(In physics, $E(\gamma)$ is usually called "action of γ" where γ is considered as the orbit of a mass point.) Of course, these expressions can be computed in local coordinates. Working with the coordinates $(x^1(\gamma(t)), \ldots, x^d(\gamma(t)))$ we use the abbreviation

$$\dot{x}^i(t) := \frac{d}{dt}(x^i(\gamma(t))).$$

Then

$$L(\gamma) = \int_a^b \sqrt{g_{ij}(x(\gamma(t)))\dot{x}^i(t)\dot{x}^j(t)} dt$$

and

$$E(\gamma) = \frac{1}{2} \int_a^b g_{ij}(x(\gamma(t)))\dot{x}^i(t)\dot{x}^j(t) dt.$$

We also remark for later technical purposes that the length of a (continuous and) piecewise smooth curve may be defined as the sum of the lengths of the smooth pieces, and the same holds for the energy.

On a Riemannian manifold M, the *distance* between two points p, q can be defined:

$$d(p,q) := \inf\{L(\gamma) : \gamma : [a,b] \to M \text{ piecewise smooth curve with } \gamma(a) = p, \gamma(b) = q\}.$$

We first remark, that any two points $p, q \in M$ can be connected by a piecewise smooth curve, and $d(p,q)$ therefore is always defined. Namely, let

$$E_p := \{q \in M : p \text{ and } q \text{ can be connected by a piecewise smooth curve.}\}$$

With the help of local coordinates one sees that E_p is open. But then also $M \backslash E_p = \bigcup\limits_{q \notin E_p} E_q$ is open. Since M is connected and $E_p \neq \emptyset \, (p \in E_p)$, we conclude $M = E_p$.

The distance function satisfies the usual axioms:

Lemma 1.4.1

(i) $d(p,q) \geq 0$ *for all* p, q, *and* $d(p,q) > 0$ *for all* $p \neq q$

(ii) $d(p,q) = d(q,p)$

(iii) $d(p,q) \leq d(p,r) + d(r,q)$ *(triangle inequality) for all points* $p, q, r \in M$.

Proof. (ii) and (iii) are obvious. For (i), we only have to show $d(p,q) > 0$ for $p \neq q$. For this purpose, let $x : U \to \mathbb{R}^d$ be a chart with $p \in U$. Then there exists $\varepsilon > 0$ with

$$D_\varepsilon(x(p)) := \{y \in \mathbb{R}^d : |y - x(p)| \leq \varepsilon\} \subset x(U)$$

(the bars denote the Euclidean absolute value) and

$$q \notin x^{-1}(D_\varepsilon(x(p))). \tag{1.4.4}$$

Let the metric be represented by $(g_{ij}(x))$ in our chart. Since $(g_{ij}(x))$ is positive definite and smooth, hence continuous in x and $D_\varepsilon(x(p))$ is compact, there exists $\lambda > 0$ with

$$g_{ij}(y)\xi^i\xi^j \geq \lambda|\xi|^2 \tag{1.4.5}$$

for all $y \in D_\varepsilon(x(p)), \xi = (\xi^1, \ldots, \xi^d) \in \mathbb{R}^d$. Therefore, for any curve $\gamma : [a,b] \to M$ with $\gamma(a) = p, \gamma(b) = q$

$$\begin{aligned} L(\gamma) &\geq L(\gamma \cap x^{-1}(D_\varepsilon(x(p))) \\ &\geq \lambda\varepsilon > 0, \end{aligned} \tag{1.4.6}$$

because $x(\gamma)$ by (1.4.4) has to contain a point $z \in \partial D_\varepsilon(x(p))$, i.e. a point whose Euclidean distance from $x(p)$ is ε. By (1.4.5), z then has distance from $x(p)$ at least $\lambda\varepsilon$ w.r.t. the metric (g_{ij}). □

Corollary 1.4.1 *The topology on M induced by the distance function d coincides with the original manifold topology of M.*

Proof. It suffices to show that in each chart the topology induced by d coincides with the one of $\mathbb{R}^d$, i.e. the one induced by the Euclidean distance function. Now for every x in some chart, there exists $\varepsilon > 0$ for which $D_\varepsilon(x)$ is contained in the same chart, and positive constants λ, μ with

$$\lambda|\xi|^2 \leq g_{ij}(y)\xi^i\xi^j \leq \mu|\xi|^2 \text{ for all}\, y \in D_\varepsilon(x), \xi \in \mathbb{R}^d.$$

Thus

$$\lambda|y-x| \leq d(y,x) \leq \mu|y-x| \text{ for all}\, y \in D_\varepsilon(x),$$

and thus each Euclidean distance ball contains a distance ball for d, and vice versa (with

$$B(z,\delta) := \{y \in M : d(z,y) \leq \delta\}$$

we have

$$\overset{\circ}{D}_{\lambda\delta}(x) \subset \overset{\circ}{B}(x,\delta) \subset \overset{\circ}{D}_{\mu\delta}(x), \text{ if } \mu\delta \leq \varepsilon).$$ □

We now return to the length and energy functionals.

Lemma 1.4.2 *For each smooth curve $\gamma : [a,b] \to M$*

$$L(\gamma)^2 \leq 2(b-a)E(\gamma), \tag{1.4.7}$$

and equality holds if and only if $\|\frac{d\gamma}{dt}\| \equiv$ const.

Proof. By Hölder's inequality

$$\int_a^b \|\frac{d\gamma}{dt}\|dt \leq (b-a)^{\frac{1}{2}} \left(\int_a^b \|\frac{d\gamma}{dt}\|^2 dt\right)^{\frac{1}{2}}$$

with equality precisely if $\|\frac{d\gamma}{dt}\| \equiv$ const. □

Lemma 1.4.3 *If $\gamma : [a,b] \to M$ is a smooth curve, and $\psi : [\alpha,\beta] \to [a,b]$ is a change of parameter, then*

$$L(\gamma \circ \psi) = L(\gamma).$$

Proof. Let $t = \psi(\tau)$.

$$\begin{aligned} L(\gamma\circ\psi) &= \int_\alpha^\beta \left(g_{ij}(x(\gamma(\psi(\tau))))\dot{x}^i(\psi(\tau))\dot{x}^j(\psi(\tau)) \left(\frac{d\psi}{d\tau}\right)^2\right)^{\frac{1}{2}} d\tau \\ &\quad \text{(by the chain rule)} \\ &= L(\gamma) \quad \text{(by change of variables).} \end{aligned}$$ □

Lemma 1.4.4 *The Euler-Lagrange equations for the energy E are*

$$\ddot{x}^i(t) + \Gamma^i_{jk}(x(t))\dot{x}^j(t)\dot{x}^k(t) = 0, \quad i = 1, \dots, d \tag{1.4.8}$$

with

$$\Gamma^i_{jk} = \frac{1}{2} g^{i\ell}(g_{j\ell,k} + g_{k\ell,j} - g_{jk,\ell}),$$

where

$$(g^{ij})_{i,j=1,\dots,d} = (g_{ij})^{-1} \quad (i.e.\ g^{i\ell}g_{\ell j} = \delta_{ij})$$

and

$$g_{j\ell,k} = \frac{\partial}{\partial x^k} g_{j\ell}.$$

The expressions Γ^i_{jk} are called Christoffel symbols.

Proof. The Euler-Lagrange equations of a functional

$$I(x) = \int_a^b f(t, x(t), \dot{x}(t))dt$$

are given by

$$\frac{d}{dt}\frac{\partial f}{\partial \dot{x}^i} - \frac{\partial f}{\partial x^i} = 0, \quad i = 1, \dots, d.$$

In our case, we therefore get $(E(\gamma) = \frac{1}{2}\int g_{jk}(x(t))\dot{x}^j\dot{x}^k dt)$

$$\frac{d}{dt}(g_{ik}(x(t))\dot{x}^k(t) + g_{ji}(x(t))\dot{x}^j(t)) - g_{jk,i}(x(t))\dot{x}^j(t)\dot{x}^k(t) = 0 \text{ for } i = 1, \dots, d,$$

hence

$$g_{ik}\ddot{x}^k + g_{ji}\ddot{x}^j + g_{ik,\ell}\dot{x}^\ell\dot{x}^k + g_{ji,\ell}\dot{x}^\ell\dot{x}^j - g_{jk,i}\dot{x}^j\dot{x}^k = 0.$$

Renaming some indices and using the symmetry $g_{ik} = g_{ki}$, we get

$$2g_{\ell m}\ddot{x}^m + (g_{\ell k,j} + g_{j\ell,k} - g_{jk,\ell})\dot{x}^j\dot{x}^k = 0 \quad \ell = 1, \dots, d \tag{1.4.9}$$

and from this

$$g^{i\ell}g_{\ell m}\ddot{x}^m + \frac{1}{2}g^{i\ell}(g_{\ell k,j} + g_{j\ell,k} - g_{jk,\ell})\dot{x}^j\dot{x}^k = 0 \quad i = 1, \dots, d.$$

Because of

$$g^{i\ell}g_{\ell m} = \delta_{im}, \text{ and thus } g^{i\ell}g_{\ell m}\ddot{x}^m = \ddot{x}^i$$

we obtain (1.4.8) from this. □

Definition 1.4.2 A smooth curve $\gamma = [a, b] \to M$, which satisfies (with $\dot{x}^i(t) = \frac{d}{dt}x^i(\gamma(t))$ etc.)

$$\ddot{x}^i(t) + \Gamma^i_{jk}(x(t))\dot{x}^j(t)\dot{x}^k(t) = 0 \text{ for } i = 1, \dots, d$$

is called a *geodesic*.

Thus, geodesics are the critical points of the energy functional. By Lemma 1.4.3, the length functional is invariant under parameter changes. As in the Euclidean case, one easily sees that regular curves can be parametrized by arc length. We shall attempt to minimize the length within the class of regular smooth curves, and we shall succeed and complete the program in Corollary 1.4.2 below. As the length is invariant under reparametrization by Lemma 1.4.3, therefore, if one seeks curves of shortest length, it suffices to consider curves that are parametrized by arc length. For such curves, by Lemma 1.4.2 one may minimize energy instead of length. Conversely, every critical point of the energy functional, i.e. each solution of (1.4.8), i.e. each geodesic, is parametrized proportionally to arc length.

Namely, for a solution of (1.4.8)

$$\begin{aligned}
&\frac{d}{dt}\langle \dot{x}, \dot{x}\rangle = \frac{d}{dt}(g_{ij}(x(t))\dot{x}^i(t)\dot{x}^j(t))\\
&= g_{ij}\ddot{x}^i\dot{x}^j + g_{ij}\dot{x}^i\ddot{x}^j + g_{ij,k}\dot{x}^i\dot{x}^j\dot{x}^k\\
&= -(g_{jk,\ell} + g_{\ell j,k} - g_{\ell k,j})\dot{x}^\ell\dot{x}^k\dot{x}^j + g_{\ell j,k}\dot{x}^k\dot{x}^\ell\dot{x}^j\\
&\qquad\qquad \text{by formula (1.4.9) which is equivalent to (1.4.8)}\\
&= 0, \text{ since } g_{jk,\ell}\dot{x}^\ell\dot{x}^k\dot{x}^j = g_{\ell k,j}\dot{x}^\ell\dot{x}^k\dot{x}^j\\
&\qquad\qquad \text{by interchanging the indices } j \text{ and } \ell
\end{aligned}$$

Consequently $\langle \dot{x}, \dot{x}\rangle \equiv$ const., and hence the curve is parametrized proportionally to arc length. We have shown

Lemma 1.4.5 *Each geodesic is parametrized proportionally to arc length.*

□

Theorem 1.4.2 *Let M be a Riemannian manifold, $p \in M, v \in T_pM$. Then there exist $\varepsilon > 0$ and precisely one geodesic*

$$c : [0, \varepsilon] \to M$$

with $c(0) = p, \dot{c}(0) = v$. In addition, c depends smoothly on p and v.

Proof. (1.4.8) is a system of second order ODE, and the Picard-Lindelöf Theorem yields the local existence and uniqueness of a solution with prescribed initial values and derivatives, and this solution depends smoothly on the data.

□

We note that if $x(t)$ is a solution of (1.4.8), so is $x(\lambda t)$ for any constant $\lambda \in \mathbb{R}$. Denoting the geodesic of Theorem 1.4.2 with $c(0) = p, \dot{c}(0) = v$ by c_v, we obtain

$$c_v(t) = c_{\lambda v}(\frac{t}{\lambda}) \text{ for } \lambda > 0, t \in [0, \varepsilon].$$

In particular, $c_{\lambda v}$ is defined on $[0, \frac{\varepsilon}{\lambda}]$.

Since c_v depends smoothly on v, and $\{v \in T_pM : \|v\| = 1\}$ is compact, there exists $\varepsilon_0 > 0$ with the property that for $\|v\| = 1$ c_v is defined at least on $[0, \varepsilon_0]$. Therefore, for any $w \in T_pM$ with $\|w\| \leq \varepsilon_0$, c_w is defined at least on $[0, 1]$.

Definition 1.4.3 Let M be a Riemannian manifold, $p \in M$,

$$\begin{aligned} V_p :=& \{v \in T_pM : c_v \text{ is defined on } [0,1]\} \\ \exp_p :& V_p \to M \\ & v \mapsto c_v(1) \end{aligned}$$

is called the *exponential map* of M at p.

By the preceding considerations, the domain of definition of the exponential map always at least contains a small neighborhood of $0 \in T_pM$. In general, however, V_p is not all of T_pM, as is already seen in the example of a proper, open subset of $\mathbb{R}^d$, equipped with the Euclidean metric. Nevertheless, we shall see in Theorem 1.4.7 below that for a compact Riemannian manifold, $\exp_p$ can be defined on all of T_pM.

Theorem 1.4.3 *The exponential map* $\exp_p$ *maps a neighborhood of* $0 \in T_pM$ *diffeomorphically onto a neighborhood of* $p \in M$.

Proof. Since T_pM is a vector space, we may identify T_0T_pM, the tangent space of T_pM at $0 \in T_pM$, with T_pM itself. The derivative of $\exp_p$ at 0 then becomes a map from T_pM onto itself:

$$d\exp_p(0) : T_pM \to T_pM.$$

With this identification of T_0T_pM and T_pM, for $v \in T_pM$

$$\begin{aligned} d\exp_p(0)(v) &= \frac{d}{dt} c_{tv}(1)_{|t=0} \\ &= \frac{d}{dt} c_v(t)_{|t=0} \\ &= \dot{c}_v(0) \\ &= v \end{aligned}$$

Hence

$$d\exp_p(0) = id_{|T_pM}. \tag{1.4.10}$$

In particular, $d\exp_p(0)$ has maximal rank, and by the inverse function theorem, there exists a neighborhood of $0 \in T_pM$ which is mapped diffeomorphically onto a neighborhood of $p \in M$. □

Let now $e_1, e_2, \ldots, e_d$ $(d = \dim M)$ be a basis of T_pM which is orthonormal w.r.t. the scalar product on T_pM defined by the Riemannian metric. Writing for each vector $v \in T_pM$ its components w.r.t. this basis, we obtain a map

$$\begin{aligned} \Phi &: T_pM \to \mathbb{R}^d \\ v &= v^i e_i \mapsto (v^1, \ldots, v^d). \end{aligned}$$

For the subsequent construction, we identify T_pM with $\mathbb{R}^d$ via Φ. By Theorem 1.4.3, there exists a neighborhood U of p which is mapped by $\exp_p^{-1}$ diffeomorphically onto a neighborhood of $0 \in T_pM$, hence, with our identification $T_pM \cong \mathbb{R}^d$, diffeomorphically onto a neighborhood Ω of $0 \in \mathbb{R}^d$. In particular, p is mapped to 0.

Definition 1.4.4 The local coordinates defined by the chart $(\exp_p^{-1}, U)$ are called (Riemannian) *normal coordinates* with center p.

Theorem 1.4.4 *In normal coordinates, we have for the Riemannian metric*

$$g_{ij}(0) = \delta_{ij} \tag{1.4.11}$$

$$\Gamma^i_{jk}(0) = 0 \text{ (and also } g_{ij,k}(0) = 0) \textit{ for all } i, j, k\,. \tag{1.4.12}$$

Proof. (1.4.11) directly follows from the fact that the above identification $\Phi : T_pM \cong \mathbb{R}^d$ maps an orthonormal basis of T_pM w.r.t. the Riemannian metric onto an Euclidean orthonormal basis of $\mathbb{R}^d$.

For (1.4.12), we note that in normal coordinates, the straight lines through the origin of $\mathbb{R}^d$ (or, more precisely, their portions contained in the chart image) are geodesic. Namely, the line $tv, t \in \mathbb{R}, v \in \mathbb{R}^d$, is mapped (for sufficiently small t) onto $c_{tv}(1) = c_v(t)$, where $c_v(t)$ is the geodesic, parametrized by arc length, with $\dot{c}_v(0) = v$.

Inserting now $x(t) = tv$ into the geodesic equation (1.4.8), we obtain because of $\ddot{x}(t) = 0$

$$\Gamma^i_{jk}(tv)v^j v^k = 0, \text{ for } i = 1, \ldots, d\,. \tag{1.4.13}$$

In particular at 0, i.e. for $t = 0$,

$$\Gamma^i_{jk}(0)v^j v^k = 0 \text{ for all } v \in \mathbb{R}^d, i = 1, \ldots, d\,. \tag{1.4.14}$$

We put $v = \frac{1}{2}(e_\ell + e_m)$ and obtain because of the symmetry $\Gamma^i_{jk} = \Gamma^i_{kj}$

$$\Gamma^i_{\ell m}(0) = 0 \text{ for all } i.$$

Since this holds for all ℓ, m, all $\Gamma^i_{jk}(0)$ vanish. By definition of Γ^i_{jk}, we obtain at $0 \in \mathbb{R}^d$

$$g^{i\ell}(g_{j\ell,k} + g_{k\ell,j} - g_{jk,\ell}) = 0 \;\forall\, i, j, k,$$

hence also

$$g_{jm,k} + g_{km,j} - g_{jk,m} = 0 \; \forall \, j, k, m.$$

Adding now the relation (obtained by cyclic permutation of the indices)

$$g_{kj,m} + g_{mj,k} - g_{km,j} = 0,$$

we obtain (with $g_{kj} = g_{jk}$)

$$g_{jm,k}(0) = 0, \text{ for all } j, k, m. \qquad \square$$

Later on (in Chapter 3), we shall see that in general the *second* derivatives of the metric cannot be made to vanish at a given point by a suitable choice of local coordinates. The obstruction will be given by the curvature tensor.

Further properties of Riemannian normal coordinates may best be seen by using *polar coordinates*, instead of the Euclidean ones (obtained from the map Φ). We therefore introduce on $\mathbb{R}^d$ the standard polar coordinates

$$(r, \varphi^1, \dots, \varphi^{d-1}),$$

where $\varphi = (\varphi^1, \dots, \varphi^{d-1})$ parametrizes the unit sphere S^{d-1} (the precise formula for φ will be irrelevant for our purposes), and we then obtain polar coordinates on T_pM via Φ again. We express the metric in polar coordinates and write g_{rr} instead of g_{11}, because of the special role of r. We also write $g_{r\varphi}$ instead of $g_{1\ell}, \ell \in \{2, \dots, d\}$, and $g_{\varphi\varphi}$ as abbreviation for $(g_{k\ell})_{k,\ell=2,\dots,d}$. In particular, in these coordinates at $0 \in T_pM$ (this point corresponds to $p \in M$)

$$g_{rr}(0) = 1, g_{r\varphi}(0) = 0 \tag{1.4.15}$$

by (1.4.11) and since this holds for Euclidean polar coordinates.

After these preparations, we return to the analysis of the geodesic equation (1.4.8). The lines $\varphi \equiv$ const. are geodesic when parametrized by arc length. They are given by $x(t) = (t, \varphi_0)$, φ_0 fixed, and from (1.4.8)

$$\Gamma^i_{rr} = 0 \text{ for all } i$$

(we have written Γ^i_{rr} instead of Γ^i_{11}), hence

$$g^{i\ell}(2g_{r\ell,r} - g_{rr,\ell}) = 0, \text{ for all } i,$$

thus

$$2g_{r\ell,r} - g_{rr,\ell} = 0, \text{ for all } \ell. \tag{1.4.16}$$

For $\ell = r$, we conclude

$$g_{rr,r} = 0,$$

and with (1.4.15) then

$$g_{rr} \equiv 1. \tag{1.4.17}$$

Inserting this in (1.4.16), we get

$$g_{r\varphi,r} = 0,$$

and then again with (1.4.15)

$$g_{r\varphi} \equiv 0. \tag{1.4.18}$$

We have shown

Theorem 1.4.5 *For the polar coordinates, obtained by transforming the Euclidean coordinates of* $\mathbb{R}^d$*, on which the normal coordinates with centre* p *are based, into polar coordinates, we have*

$$g_{ij} = \begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & & & \\ \vdots & & g_{\varphi\varphi}(r,\varphi) & \\ 0 & & & \end{pmatrix},$$

where $g_{\varphi\varphi}(r,\varphi)$ *is the* $(d-1)\times(d-1)$ *matrix of the components of the metric w.r.t. angular variables* $(\varphi^1,\dots,\varphi^{d-1}) \in S^{d-1}$*.* □

The polar coordinates of Theorem 1.4.5 are often called *Riemannian polar coordinates.* The situation is the same as for Euclidean polar coordinates: For example in polar coordinates on $\mathbb{R}^2$, the Euclidean metric is given by $\begin{pmatrix} 1 & 0 \\ 0 & r^2 \end{pmatrix}$. We point out once more that in contrast to Theorem 1.4.4, Theorem 1.4.5 holds not only at the origin $0 \in T_pM$, but in the whole chart.

Corollary 1.4.2 *For any* $p \in M$*, there exists* $\rho > 0$ *such that Riemannian polar coordinates may be introduced on* $B(p,\rho) := \{q \in M : d(p,q) \le \rho\}$*. For any such* ρ *and any* $q \in \partial B(p,\rho)$*, there is precisely one geodesic of shortest length (*$= \rho$*) from* p *to* q*, and in polar coordinates, this geodesic is given by the straight line* $x(t) = (t,\varphi_0)$*,* $0 \le t \le \rho$*, where* q *is represented by the coordinates* $(\rho,\varphi_0), \varphi_0 \in S^{d-1}$*. Here, "of shortest length" means that the curve is the shortest one among all curves in* M *from* p *to* q*.*

Proof. The first claim follows from Corollary 1.4.1 (and its proof) and Theorem 1.4.3. For the second claim, let $c(t) = (r(t),\varphi(t)), 0 \le t \le T$, be an arbitrary curve from p to q. $c(t)$ need not be entirely contained in $B(p,\rho)$ and may leave our coordinate neighborhood. Let

$$t_0 := \inf\{t \le T : d(x(t),p) \ge \rho\}.$$

Then $t_0 \le T$, and the curve $c_{|[0,t_0]}$ is entirely contained in $B(p,\rho)$. We shall show $L(c_{|[0,t_0]}) \ge \rho$ with equality only for a straight line in our polar coordinates. This will then imply the second claim. The proof of this inequality goes as follows:

$$\begin{aligned}
L(c_{|[0,t_0]}) &= \int_0^{t_0} (g_{ij}(c(t))\dot{c}^i\dot{c}^j)^{\frac{1}{2}}\,dt \\
&\geq \int_0^{t_0} (g_{rr}(c(t))\dot{r}\dot{r})^{\frac{1}{2}}\,dt && \text{by (1.4.18) and} \\
& && \text{since } g_{\varphi\varphi} \text{ is positive definite} \\
&= \int_0^{t_0} |\dot{r}|dt \ \geq \ \int_0^{t_0} \dot{r}dt && \text{by (1.4.17)} \\
&= \ r(t_0) \ = \ \rho && \text{by definition of } t_0,
\end{aligned}$$

and equality holds precisely if $g_{\varphi\varphi}\dot{\varphi}\dot{\varphi} \equiv 0$, in which case $\dot{\varphi}(t)$ is constant and $\dot{r} \geq 0$ and $c(t)$ thus is a straight line through the origin. □

In particular, under the assumptions of Corollary 1.4.2, the Euclidean ball

$$d_\rho(0) := \{y \in \mathbb{R}^d : |y| \leq \rho\} \subset T_pM$$

is mapped under $\exp_p$ diffeomorphically onto the Riemannian ball with the same radius,

$$B(p, \rho).$$

Corollary 1.4.3 *Let M be a compact Riemannian manifold. Then there exists $\rho_0 > 0$ with the property that for any $p \in M$, Riemannian polar coordinates may be introduced on $B(p, \rho_0)$.*

Proof. By Corollary 1.4.2, for any $p \in M$, there exists $\rho > 0$ with those properties. By Theorem 1.4.2, $\exp_p$ is smooth in p. If thus $\exp_p$ is injective and of maximal rank on a closed ball with radius ρ in T_pM, there exists a neighborhood U of p such that for all $q \in U, \exp_q$ is injective and of maximal rank on the closed ball with radius ρ in T_qM.

Since M is compact, it can be covered by finitely many such neighborhoods and we choose ρ_0 as the smallest such ρ. □

Corollary 1.4.4 *Let M be a compact Riemannian manifold. Then there exists $\rho_0 > 0$ with the property that any two points $p, q \in M$ with $d(p, q) \leq \rho_0$ can be connected by precisely one geodesic of shortest length. This geodesic depends continuously on p and q.*

Proof. ρ_0 from Corollary 1.4.3 satisfies the first claim by Corollary 1.4.2. Moreover, by the last claim of Corollary 1.4.2, the shortest geodesic from p to $q \in B(p, \rho_0)$ depends continuously on p. Exchanging the roles of p and q yields the continuous dependence on p as well. □

We explicitly point out that for any compact Riemannian manifold there is always more than one geodesic connection between any two points (This will be discussed in Chapter 5.). Only the shortest geodesic is unique, provided p and q are sufficiently close.

We now want to show the existence of shortest (geodesic) connections between any two points of arbitrary distance on a given compact Riemannian manifold.

We recall the notion of homotopy between curves:

Definition 1.4.5 Two curves γ_0, γ_1 on a manifold M with common initial and end points p and q, i.e. two continuous maps

$$\gamma_0, \gamma_1 : I = [0,1] \to M$$

with $\gamma_0(0) = \gamma_1(0) = p$, $\gamma_0(1) = \gamma_1(1) = q$, are called *homotopic* if there exists a continuous map

$$\Gamma : I \times I \to M$$

with

$$\begin{array}{lll} \Gamma(0,s) = p, & \Gamma(1,s) = q & \text{for all } s \in I \\ \Gamma(t,0) = \gamma_0(t), & \Gamma(t,1) = \gamma_1(t) & \text{for all } t \in I \end{array}$$

Two closed curves c_0, c_1 in M, i.e. two continuous maps

$$c_0, c_1 : S^1 \to M,$$

are called *homotopic*, if there exists a continuous map

$$c : S^1 \times I \to M$$

with

$$c(t,0) = c_0(t), c(t,1) = c_1(t) \quad \text{for all } t \in S^1$$

(S^1, as usual, is the unit circle parametrized by $[0, 2\pi)$.).

Lemma 1.4.6 *The concept of homotopy defines an equivalence relation on the set of all curves in M with fixed initial and end points as well as on the set of all closed curves in M.*

The *proof* is elementary. □

With the help of this concept, we now want to show the existence of geodesics:

Theorem 1.4.6 *Let M be a compact Riemannian manifold, $p, q \in M$. Then there exists a geodesic in every homotopy class of curves from p to q, and this geodesic may be chosen as a shortest curve in its homotopy class. Likewise, every homotopy class of closed curves in M contains a curve which is shortest and geodesic.*

Proof. Since the proof is the same in both cases, we shall only consider the case of closed curves.

As a preparation, we shall first show

Lemma 1.4.7 *Let M be a compact Riemannian manifold, $\rho_0 > 0$ as in Corollary 1.4.4. Let $\gamma_0, \gamma_1 : S^1 \to M$ be curves with*

$$d(\gamma_0(t), \gamma_1(t)) \leq \rho_0 \quad \textit{for all}\, t \in S^1.$$

Then γ_0 and γ_1 are homotopic.

Proof. For any $t \in S^1$ let $c_t(s) : I \to M$ be the unique shortest geodesic from $\gamma_0(t)$ to $\gamma_1(t)$ (Corollary 1.4.4), as usual parametrized proportionally to arc length. Since c_t depends continuously on its end points by Corollary 1.4.4, hence on t,

$$\Gamma(t, s) := c_t(s)$$

is continuous and yields the desired homotopy. □

Proof of Theorem 1.4.6: Let $(\gamma_n)_{n\in\mathbb{N}}$ be a minimizing sequence for arc length in the given homotopy class. Here and in the sequel, all curves are parametrized proportionally to arc length. We may assume w.l.o.g. that the curves γ_n are piecewise geodesic; namely, for each curve, we may find $t_0 = 0 < t_1 < t_2 < \ldots < t_m < t_{m+1} = 2\pi$ with the property that

$$L(\gamma_{n|[t_{j-1},t_j]}) \leq \rho_0/2$$
$$(\rho_0 \text{ as in Corollary 1.4.4) for } j = 1, \ldots, m+1 \text{ with}\, t_{m+1} := 2\pi).$$

Replacing $\gamma_{n|[t_{j-1},t_j]}$ by the shortest geodesic arc between $\gamma_n(t_{j-1})$ and $\gamma_n(t_j)$, we obtain a curve which is homotopic to and not longer than γ_n (the same argument also shows that each homotopy class does contain curves of finite length).

We may thus assume that for any γ_n there exist points $p_{0,n}, \ldots, p_{m,n}$ for which $d(p_{j-1,n}, p_{j,n}) \leq \rho_0$ ($p_{m+1,n} := p_{0,n}, j = 1, \ldots, m+1$) and for which γ_n contains the shortest geodesic arc between $p_{j-1,n}$ and $p_{j,n}$. Since the lengths of the γ_n are bounded as they constitute a minimizing sequence, we may also assume that m is independent of n. After selection of a subsequence, by the compactness of M, the points $p_{0,n}, \ldots, p_{m,n}$ converge to points $p_0, \ldots, p_m$, for $n \to \infty$. The segment of γ_n between $p_{j-1,n}$ and $p_{j,n}$ then converges to the shortest geodesic arc between p_{j-1} and p_j, for example by Corollary 1.4.4. The union of these geodesic segments yields a curve γ. By Lemma 1.4.7, γ is homotopic to the γ_n, and

$$L(\gamma) = \lim_{n\to\infty} L(\gamma_n),$$

and since the curves γ_n are minimizing sequence for the length in their homotopy class, γ is a shortest curve in this class. Therefore, γ has to be geodesic. Namely, otherwise, there would exist points p and q on γ for which one of the two segments of γ between p and q would have length at most ρ_0, but would not be geodesic. By Corollary 1.4.4, γ could then be shortened by replacing this segment by the shortest geodesic arc between p and q. By the argument

of Lemma 1.4.7, this does not change the homotopy class, and we obtain a contradiction to the minimizing property of γ.
γ thus is the desired closed geodesic. □

Corollary 1.4.5 *On any compact Riemannian manifold* M_1, *any two points* p, q *can be connected by a curve of shortest length, and this curve is geodesic.*

Proof. Minimize over all curves between p and q (and not only over those in a fixed homotopy class) as in the proof of Theorem 1.4.6. □

We also show

Theorem 1.4.7 *Let* M *be a compact Riemannian manifold. Then for any* $p \in M$, *the exponential map* $\exp_p$ *is defined on all of* T_pM, *and any geodesic may be extended indefinitely in each direction.*

Proof. For $v \in T_pM$, let

$$\Lambda := \{t \in \mathbb{R}^+ : c_v \text{ is defined on } [-t, t]\},$$

where c_v is, as usual, the geodesic with $c_v(0) = p, \dot{c}_v(0) = v$. It follows from $c_v(-t) = c_{-v}(t)$ that e_v may also be defined for negative t, at the moment at least for those with sufficiently small absolute value. Theorem 1.4.2 implies $\Lambda \neq \emptyset$. The compactness of M implies the closedness of Λ. We shall now show openness of Λ : Let c_v be defined on $[-t, t]$; for example $\dot{c}_v(t) = w \in T_{c_v(t)}M$. By Theorem 1.4.2 there exists a geodesic $\gamma_w(s)$ with $\gamma_w(0) = c_v(t), \dot{\gamma}_w(0) = \dot{c}_v(t)$, for $s \in [0, \varepsilon]$ and $\varepsilon > 0$. Putting $c_v(t+s) = \gamma_w(s)$ for $s \in [0, \varepsilon]$, we have extended c_v to $[-t, t + \varepsilon]$. Analogously, c_v may be extended in the direction of negative t. This implies openness of Λ, hence $\Lambda = \mathbb{R}^+$. The claims follow easily. □

We now want to address the question whether the results of Theorem 1.4.7 continue to hold for a more general class of Riemannian manifolds than the compact ones. Obviously, they do hold for Euclidean space which is not compact, but they do not hold for any proper open subset of Euclidean space, essentially since such a set is not complete. It will turn out that completeness will be the right condition for extending Theorem 1.4.7.

Definition 1.4.6 A Riemannian manifold M is *geodesically complete* if for all $p \in M$, the exponential map $\exp_p$ is defined on all of T_pM, or, in other words, if any geodesic $c(t)$ with $c(0) = p$ is defined for all $t \in \mathbb{R}$.

We can now state the **Theorem of Hopf-Rinow.**

Theorem 1.4.8 *Let* M *be a Riemannian manifold. The following statements are equivalent:*

(i) *M is complete as a metric space (or equivalently, it is complete as a topological space w.r.t. its underlying topology, see Corollary 1.4.1).*

(ii) *The closed and bounded subsets of M are compact.*

(iii) *There exists $p \in M$ for which $\exp_p$ is defined on all of T_pM.*

(iv) *M is geodesically complete, i.e. for every $p \in M, \exp_p$ is defined on all of T_pM.*

Furthermore, each of the statements (i) – (iv) implies

(v) *Any two points $p, q \in M$ can be joined by a geodesic of length $d(p, q)$, i.e. by a geodesic of shortest length.*

Proof. We shall first prove that if $\exp_p$ is defined on all of T_pM, then any $q \in M$ can be connected with p by a shortest geodesic. In particular, this will show the implication (iv) ⇒ (v).

For this purpose, let

$$r := d(p, q),$$

and let $\rho > 0$ be given by Corollary 1.4.2, let $p_0 \in \partial B(p, \rho)$ be a point where the continuous function $d(q, \cdot)$ attains its minimum on the compact set $\partial B(p, \rho)$. Then $p_0 = \exp_p \rho V$, for some $V \in T_pM$. We consider the geodesic

$$c(t) := \exp_p tV,$$

and we want to show that

$$c(r) = q. \tag{1.4.19}$$

$c_{|[0,r]}$ will then be a shortest geodesic from p to q.

For this purpose, let

$$I := \{t \in [0, r] : d(c(t), q) = r - t\}.$$

(1.4.19) means $r \in I$, and we shall show $I = [0, r]$ for that purpose. I is not empty, as it contains 0 by definition of r, and it is closed for continuity reasons. $I = [0, r]$ will therefore follow if we can show openness of I.

Let $t_0 \in I$. Let $\rho_1 > 0$ be the radius of Corollary 1.4.2 corresponding to the point $c(t_0) \in M$. W.l.o.g. $\rho_1 \leq r - t_0$. Let $p_1 \in \partial B(c(t_0), \rho_1)$ be a point where the continuous function $d(q, \cdot)$ assumes its minimum on the compact set $\partial B(c(t_0), \rho_1)$. Then

$$d(p, p_1) \geq d(p, q) - d(q, p_1). \tag{1.4.20}$$

Now for every curve γ from $c(t_0)$ to q, there exists some

$$\gamma(t) \in \partial B(c(t_0), \rho_1).$$

Hence

$$\begin{aligned} L(\gamma) &\geq d(c(t_0), \gamma(t)) + d(\gamma(t), q) \\ &= \rho_1 + d(\gamma(t), q) \\ &\geq \rho_1 + d(p_1, q) \quad \text{because of the minimizing property of } p_1. \end{aligned}$$

Hence also

$$d(q, c(t_0)) \geq \rho_1 + d(p_1, q) \tag{1.4.21}$$

and by the triangle inequality, we then actually must have equality. Inserting (1.4.21) into (1.4.20) and recalling $d(q, c(t_0)) = r - t_0$ gives

$$d(p, p_1) \geq r - (r - t_0 - \rho_1) = t_0 + \rho_1.$$

On the other hand, there exists a curve from p to p_1 of length $t_0 + \rho_1$; namely one goes from p to $c(t_0)$ along c and then takes the geodesic from $c(t_0)$ to p_1 of length ρ_1. That curve thus is shortest and therefore has to be geodesic as shown in the proof of Theorem 1.4.6. By uniqueness of geodesics with given initial values, it has to coincide with c, and then

$$p_1 = c(t_0 + \rho_1).$$

Since we observed that equality has to hold in (1.4.21), we get

$$d(q, c(t_0 + \rho_1)) = r - (t_0 + \rho_1),$$

hence

$$t_0 + \rho_1 \in I,$$

and openness of I follows, proving our claim.

It is now easy to complete the proof of Theorem 1.4.8:

(iv) $\Rightarrow$ (iii) is trivial

(iii) $\Rightarrow$ (ii) Let $K \subset M$ be closed and bounded. Since bounded, $K \subset B(p, r)$ for some $r > 0$. By what we have shown in the beginning, any point in $B(p, r)$ can be connected with p by a geodesic (of length $\leq r$). Hence, $B(p, r)$ is the image of the compact ball in T_pM of radius r under the continuous map $\exp_p$. Hence, $B(p, r)$ is compact itself. Since K is assumed to be closed and shown to be contained in a compact set, it must be compact itself.

(ii) $\Rightarrow$ (i) Let $(p_n)_{n \in \mathbb{N}} \subset M$ be a Cauchy sequence. It then is bounded, and, by (ii), its closure is compact. It therefore contains a convergent subsequence, and being Cauchy, it has to converge itself. This shows completeness of M.

(i) $\Rightarrow$ (iv) Let c be a geodesic in M, parametrized by arc length, and being defined on a maximal interval I. I then is nonempty, and by Theorem 1.4.2, it is also open. To show closedness, let $(t_n)_{n \in \mathbb{N}} \subset I$ converge to t.

Since

$$d(c(t_n), c(t_m)) \leq |t_n - t_m|$$

as c is parametrized by arc length, $c(t_n)$ is a Cauchy sequence, hence has a limit $p \in M$, because we assume M to be complete. Let $\rho > 0$ be as in Corollary 1.4.2. Then $B(p, \rho)$ is compact, being the image of the compact ball of radius r in T_pM under the continuous map $\exp_p$. Therefore, the argument of Corollary 1.4.3 and Corollary 1.4.4 applies to show that there exists $\rho_0 > 0$ with the property that for any point $q \in B(p, \rho)$ any geodesic starting from q can be extended at least up to length ρ_0.

Since $c(t_n)$ converges to p, for all sufficiently large m, n

$$d(c(t_n), c(t_m)) \leq |t_n - t_m| \leq \rho_0/2$$

and

$$d(c(t_n), p), d(c(t_m), p) \leq \rho_0.$$

Therefore, the shortest geodesic from $c(t_n)$ to $c(t_m)$ can be defined at least on the interval $[-\rho_0, \rho_0]$. This shortest geodesic, however, has to be a subarc of c, and c thus can be defined up to the parameter value $t_n + \rho_0$, in particular for t, showing closedness of I. □

Let now M be a differentiable submanifold of the Riemannian manifold N. The Riemannian metric of N then induces a Riemannian metric on M, by restricting the former one to $T_pM \subset T_pN$ for $p \in N$. Thus, M also becomes a Riemannian manifold.

In particular, $S^n \subset \mathbb{R}^{n+1}$ obtains a Riemannian metric. We want to compute this metric in the local chart of 1.1, namely

$$\begin{aligned} f(x^1, \ldots, x^{n+1}) &= \left(\frac{x^1}{1 - x^{n+1}}, \ldots, \frac{x^n}{1 - x^{n+1}} \right) \quad \text{for } x^{n+1} \neq 1 \\ &=: (y^1, \ldots, y^n) \in \mathbb{R}^n\,. \end{aligned}$$

In the sequel, a Latin index occuring twice in a product has to be summed from 1 to $n+1$, a Greek one from 1 to n. We compute

$$1 = x^i x^i = y^\alpha y^\alpha (1 - x^{n+1})^2 + x^{n+1} x^{n+1}$$

hence

$$x^{n+1} = \frac{y^\alpha y^\alpha - 1}{y^\alpha y^\alpha + 1}$$

and then

$$x^i = \frac{2y^i}{1 + y^\alpha y^\alpha} \quad (i = 1, \ldots, n).$$

For $g := f^{-1}$ then

$$\begin{aligned} \frac{\partial g^j}{\partial y^k} &= \frac{2\delta_{jk}}{1 + y^\alpha y^\alpha} - \frac{4y^j y^k}{(1 + y^\alpha y^\alpha)^2} \quad \text{for } j = 1, \ldots, n,\ k = 1, \ldots, n \\ \frac{\partial g^{n+1}}{\partial y^k} &= \frac{4y^k}{(1 + y^\alpha y^\alpha)^2}. \end{aligned}$$

Let a tangent vector to S^n be represented by $w = (w^1, \dots, w^n)$ in our chart. Then

$$\begin{aligned}\langle w, w\rangle &= dg(w)\cdot dg(w),\ \text{where the point denotes the Euclidean}\\ &\qquad\qquad\qquad\text{scalar product of } \mathbb{R}^{n+1}\\ &= \frac{1}{(1+y^\alpha y^\alpha)^4}\left\{4(1+y^\alpha y^\alpha)^2 w^\beta w^\beta - 16(1+y^\alpha y^\alpha)y^\beta w^\beta y^\gamma w^\gamma\right.\\ &\qquad\qquad\left. + 16 y^\beta y^\beta y^\gamma w^\gamma y^\delta w^\delta + 16 y^\beta w^\beta y^\gamma w^\gamma\right\}\\ &= \frac{4}{(1+y^\alpha y^\alpha)^2} w^\beta w^\beta.\end{aligned}$$

Thus, the metric in our chart is given by

$$g_{ij}(y) = \frac{4}{(1+|y|^2)^2}\delta_{ij}.$$

Definition 1.4.7 A diffeomorphism $h : M \to N$ between Riemannian manifolds is an *isometry* if it preserves the Riemannian metric. Thus, for $p \in M, v, w \in T_pM$, and if $\langle\cdot,\cdot\rangle_M$ and $\langle\cdot,\cdot\rangle_N$ denotes the scalar products in T_pM and $T_{h(p)}N$, resp., we have

$$\langle v, w\rangle_M = \langle dh(v), dh(w)\rangle_N.$$

A differentiable map $h : M \to N$ is a *local isometry* if for every $p \in M$ there exists a neighborhood U for which $h_{|U} : U \to h(U)$ is an isometry, and $h(U)$ is open in N.

If $(g_{ij}(p))$ and $(\gamma_{\alpha\beta}(h(p))$ are the coordinate representations of the metric, an isometry has to satisfy

$$g_{ij}(p) = \gamma_{\alpha\beta}(h(p))\frac{\partial h^\alpha(p)}{\partial x^i}\frac{\partial h^\beta(p)}{\partial x^j}.$$

A local isometry thus has the same effect as a coordinate change. Isometries leave the lengths of tangent vectors and therefore also the lengths and energies of curves invariant. Thus, critical points, i.e. geodesics, are mapped to geodesics.

With this remark, we may easily determine the geodesics of S^n. The orthogonal group $\mathrm{O}(n+1)$ operates isometrically on $\mathbb{R}^{n+1}$, and since it maps S^n into S^n, it also operates isometrically on S^n. Let now $p \in S^n, v \in T_pS^n$. Let E be the two dimensional plane through the origin of $\mathbb{R}^{n+1}$, containing v. We claim that the geodesic c_v through p with tangent vector v is nothing but the great circle through p with tangent vector v (parametrized proportionally to arc length), i.e. the intersection of S^n with E. For this, let $S \in \mathrm{O}(n+1)$ be the reflection across that E. Together with c_v, Sc_v is also a geodesic through p with tangent vector v. The uniqueness result of Theorem 1.4.2 implies $c_v = Sc_v$, and thus the image of c_v is the great circle, as claimed.

As another example, we consider the torus T^2 introduced in 1.1. We introduce a metric on T^2 by letting the projection π be a local isometry. For each chart of the form $(U, (\pi_{|U})^{-1})$, we use the Euclidean metric on $\pi^{-1}(U)$. Since the translations

$$z \mapsto z + m_1 w_1 + m_2 w_2 \quad (m_1, m_2 \in \mathbb{Z})$$

are Euclidean isometries, the Euclidean metrics on the different components of $\pi^{-1}(U)$ (which are obtained from each other by such translations) yield the same metric on U. Hence, the Riemannian metric on T^2 is well defined.

Since π is a local isometry, Euclidean geodesics of $\mathbb{R}^2$ are mapped onto geodesics of T^2. The global behavior of geodesics on such a torus is most easily studied in the case where T^2 is generated by the two unit vectors $w_1 = (1, 0)$ and $w_2 = (0, 1)$: A straight line in $\mathbb{R}^2$ which is parallel to one of the coordinate axes then becomes a geodesic on T^2 that closes up after going around once. More generally, a straight line with rational slope becomes a closed, hence periodic geodesic on T^2, while the image of one with irrational slope lies dense in T^2.

Before ending this paragraph, we want to introduce the following important notion:

Definition 1.4.8 Let M be a Riemannian manifold, $p \in M$. The *injectivity radius* of p is

$$i(p) := \sup\{\rho > 0 : \exp_p \text{ is defined on } d_\rho(0) \subset T_pM \text{ and injective}\}.$$

The *injectivity radius* of M is

$$i(M) := \inf_{p \in M} i(p).$$

For example, the injectivity radius of the sphere S^n is π, since the exponential map of any point p maps the open ball of radius π in T_pM injectively onto the complement of the antipodal point of p.

The injectivity radius of the torus just discussed is $\frac{1}{2}$, since here the exponential map is injective on the interior of a square with centre $0 \in T_pM$ and side length 1.

Perspectives. As the name suggests, the concept of a Riemannian metric was introduced by B. Riemann, in his habilitation address [254]. He also suggested to consider more generally metrics obtained by taking metrics on the tangent spaces that are not induced by a scalar product. Such metrics were first systematically investigated by Finsler and are therefore called Finsler metrics.

For a general metric space, a geodesic is defined as a curve which realizes the shortest distance between any two sufficiently close points lying on it. Those metric spaces that satisfy the conclusion of the Hopf-Rinow theorem that any two points can be connected by a shortest geodesic are called geodesic length spaces, and they are amenable to geometric constructions as demonstrated by the school of Alexandrov. See e.g. [194], [15].

A Lorentz metric on a differentiable manifold of dimension $d+1$ is given by an inner product of signature $(1, d)$ on each tangent space T_pM depending smoothly on p. A Lorentz manifold is a differentiable manifold with a Lorentz metric. The prototype is Minkowski space, namely $\mathbb{R}^{d+1}$ equipped with the inner product

$$\langle x, y\rangle = -x^0y^0 + x^1y^1 + \ldots + x^dy^d$$

for $x = (x^0, x^1, \ldots, x^d), y = (y^0, y^1, \ldots, y^d)$. Lorentz manifolds are the spaces occuring in general relativity. Let us briefly discuss some concepts. Tangent vectors V with negative, positive, vanishing $\|V\|^2 = \langle V, V\rangle$ are called time-like, space-like, and light-like, resp. Length and energy of a curve may be defined formally as in the Riemannian case, and we again obtain geodesic equations. Geodesics whose tangent vectors all have norm zero are called null geodesics. They describe the paths of light rays. (Note that in our above description of the Minkowski metric, the conventions have been chosen so that the speed of light is 1.) Submanifolds of Lorentz manifolds whose tangent vectors are all space-like are ordinary Riemannian manifolds w.r.t. the induced metric. For treatments of Lorentzian geometry, an introduction is [209]. Deeper aspects are treated in Hawking and Ellis[113].

J. Nash proved that every Riemannian manifold M can be isometrically embedded into some Euclidean space $\mathbb{R}^k$. For the proof of this result, he developed an implicit function theorem in Fréchet spaces and an iteration technique that have found other important applications. A simpler proof was found by Günther[107].

Although on a conceptual level, Nash's theorem reduces the study of Riemannian manifolds to the study of submanifolds of Euclidean spaces, in practice the intrinsic point of view has proved to be preferable (see Perspectives on 1.3).

In our presentation, we only consider finite dimensional Riemannian manifolds. It is also possible, and often very useful, to introduce infinite dimensional Riemannian manifolds. Those are locally modeled on Hilbert spaces instead of Euclidean ones. The lack of local compactness leads to certain technical complications, but most ideas and constructions of Riemannian geometry pertain to the infinite dimensional case. Such infinite dimensional manifolds arise for example naturally as certain spaces of curves on finite dimensional Riemannian manifolds. A thorough treatment is given in [159].

1.5 Vector Bundles

Definition 1.5.1 A *(differentiable) vector bundle* of rank n consists of a total space E, a base M, and a projection $\pi : E \to M$, where E and M are differentiable manifolds, π is differentiable, each "fiber" $E_x := \pi^{-1}(x)$ for $x \in M$, carries the structure of an n-dimensional (real) vector space, and the following local triviality requirement is satisfied: For each $x \in M$, there exist a neighborhood U and a diffeomorphism

$$\varphi : \pi^{-1}(U) \to U \times \mathbb{R}^n$$

with the property that for every $y \in U$

$$\varphi_y := \varphi_{|E_y} : E_y \to \{y\} \times \mathbb{R}^n$$

is a vector space isomorphism, i.e. a bijective linear map. Such a pair (φ, U) is called a *bundle chart.*

In the sequel, we shall omit the word "differentiable" for a vector bundle. Often, a vector bundle will simply be denoted by its total space.

It is important to point out that a vector bundle is by definition locally, but not necessarily globally a product of base and fiber. A vector bundle which is isomorphic to $M \times \mathbb{R}^n$ ($n =$ rank) is called trivial.

A vector bundle may be considered as a family of vector spaces (all isomorphic to a fixed model $\mathbb{R}^n$) parametrized (in a locally trivial manner) by a manifold.

Let now (E, π, M) be a vector bundle of rank n, $(U_\alpha)_{\alpha \in A}$ a covering of M by open sets over which the bundle is trivial, and $\varphi_\alpha : \pi^{-1}(U_\alpha) \to U_\alpha \times \mathbb{R}^n$ be the corresponding local trivializations. For nonempty $U_\alpha \cap U_\beta$,we obtain *transition maps*

$$\varphi_{\beta\alpha} : U_\alpha \cap U_\beta \to \mathrm{Gl}\,(n, \mathbb{R})$$

by

$$\varphi_\beta \circ \varphi_\alpha^{-1}(x, v) = (x, \varphi_{\beta\alpha}(x)v) \quad \text{for}\, x \in U_\alpha \cap U_\beta, v \in \mathbb{R}^n, \tag{1.5.1}$$

where $\mathrm{Gl}(n, \mathbb{R})$ is the general linear group of bijective linear self maps of $\mathbb{R}^n$. The transition maps express the transformation behavior of a vector in the fiber under a change of local trivialization.

The transition maps satisfy

$$\varphi_{\alpha\alpha}(x) = \mathrm{id}_{\mathbb{R}^n} \quad \text{for} \quad x \in U_\alpha \tag{1.5.2}$$
$$\varphi_{\alpha\beta}(x)\varphi_{\beta\alpha}(x) = \mathrm{id}_{\mathbb{R}^n} \quad \text{for} \quad x \in U_\alpha \cap U_\beta \tag{1.5.3}$$
$$\varphi_{\alpha\gamma}(x)\varphi_{\gamma\beta}(x)\varphi_{\beta\alpha}(x) = \mathrm{id}_{\mathbb{R}^n} \quad \text{for} \quad x \in U_\alpha \cap U_\beta \cap U_\gamma\,. \tag{1.5.4}$$

These properties are direct consequences of (1.5.1).

A vector bundle can be reconstructed from its transition maps.

Theorem 1.5.1

$$E = \coprod_{\alpha \in A} U_\alpha \times \mathbb{R}^n / \sim\,,$$

where $\amalg$ *denotes disjoint union, and the equivalence relation* $\sim$ *is defined by*

$$(x, v) \sim (y, w) :\iff x = y \text{ and } w = \varphi_{\beta\alpha}(x)v \quad (x \in U_\alpha, y \in U_\beta,\, v, w \in \mathbb{R}^n)$$

The *proof* of this fact is a straightforward verification of the properties required in Definition 1.5.1. A reader who does not want to carry this out him/herself may consult D. Husemoller, Fibre bundles, Springer, GTM 20, 1975. □

Definition 1.5.2 Let G be a subgroup of $\mathrm{Gl}(n, \mathbb{R})$, for example $\mathrm{O}(n)$ or $\mathrm{SO}(n)$, the orthogonal or special orthogonal group. We say that a vector bundle has the *structure group* G if there exists an atlas of bundle charts for which all transition maps have their values in G.

Definition 1.5.3 Let (E, π, M) be a vector bundle. A *section* of E is a differentiable map $s : M \to E$ with $\pi \circ s = \mathrm{id}_M$. The space of sections of E is denoted by $\Gamma(E)$.

We have already seen an example of a vector bundle above, namely the tangent bundle TM of a differentiable manifold M.

Definition 1.5.4 A section of the tangent bundle TM of M is called a *vector field* on M.

Let now $f : M \to N$ be a differentiable map, (E, π, N) a vector bundle over N. We want to pull back the bundle via f, i.e. construct a bundle f^*E, for which the fiber over $x \in M$ is $E_{f(x)}$, the fiber over the image of x.

Definition 1.5.5 The *pulled back bundle* f^*E is the bundle over M with bundle charts $(\varphi \circ f, f^{-1}(U))$, where (φ, U) are bundle charts of E.

We now want to extend some algebraic concepts and constructions from vector spaces to vector bundles by performing them fiberwise. For example:

Definition 1.5.6 Let (E_1, π_1, M) and (E_2, π_2, M) be vector bundles over M. Let the differentiable map $f : E_1 \to E_2$ be fiber preserving, i.e.

$$\pi_2 \circ f = \pi_1,$$

and let the fiber maps $f_x : E_{1,x} \to E_{2,x}$ be linear, i.e. vector space homomorphisms. Then f is called a *bundle homomorphism.*

Definition 1.5.7 Let (E, π, M) be a vector bundle of rank n. Let $E' \subset E$, and suppose that for any $x \in M$ there exists a bundle chart (φ, U) with $x \in U$ and

$$\varphi(\pi^{-1}(U) \cap E') = U \times \mathbb{R}^m (\subset U \times \mathbb{R}^n, m \le n).$$

The resulting vector bundle $(E', \pi_{|E'}, M)$ is called *subbundle* of E of rank m.

Let us discuss an example: $S^1 = \{x \in \mathbb{R}^2 : |x|^2 = 1\}$ is a submanifold of $\mathbb{R}^2$. If we restrict the tangent bundle $T\mathbb{R}^2$ of $\mathbb{R}^2$ to S^1, we obtain a bundle E over S^1 that is isomorphic to $S^1 \times \mathbb{R}^2$. The tangent bundle of S^1 has fiber $T_x S^1 = \{y \in \mathbb{R}^2 : x \cdot y = 0\} \subset \mathbb{R}^2$ (where the dot $\cdot$ denotes the Euclidean scalar product). TS^1 is a subbundle of $T\mathbb{R}^2|S^1$; the reader is invited to write down explicit bundle charts.

Definition 1.5.8 Let (E_1, π_1, M) and (E_2, π_2, M) be vector bundles over M. The *Cartesian product* of E_1 and E_2 is the vector bundle over M with fiber $E_{1,x} \times E_{2,x}$ and bundle charts $(\varphi_\alpha \times \psi_\beta, U_\alpha \cap V_\beta)$, where $(\varphi_\alpha, U_\alpha)$ and (ψ_β, V_β) are bundle charts for E_1 and E_2 resp., and

$$(\varphi_\alpha \times \psi_\beta)(x, (v, w)) := (\varphi_\alpha(x, v), \psi_\beta(x, w)) \quad (v \in E_{1,x}, w \in E_{2,x}).$$

Thus, the *product bundle* is simply the bundle with fiber over $x \in M$ being the product of the fibers of E_1 and E_2 over x. By this pattern, all constructions for vector spaces can be extended to vector bundles. Of particular importance for us will be dual space, exterior and tensor product. Let us briefly recall the definition of the latter:

Let V and W be vector spaces (as always over $\mathbb{R}$) of dimension m and n, resp., and let $(e_1, \dots, e_m)$ and $(f_1, \dots, f_n)$ be bases. Then $V \otimes W$ is the vector space of dimension mn spanned by the basis $(e_i \otimes f_j)_{\substack{i=1,\dots,m \\ j=1,\dots,n}}$. There exists a canonical bilinear map

$$L : V \times W \to V \otimes W$$

mapping $(a^i e_i, b^j f_j)$ onto $a^i b^j e_i \otimes f_j$

One may then also define the *tensor product* of more than two vector spaces in an associative manner.

Definition 1.5.9 Let M be a differentiable manifold, $x \in M$. The vector space dual to the tangent space $T_x M$ to $\mathbb{R}$ is called the *cotangent space* of M at the point x and denoted by $T_x^* M$. The vector bundle over M whose fibers are the cotangent spaces of M is called the *cotangent bundle* of M and denoted by $T^* M$. Elements of $T^* M$ are called *cotangent vectors,* sections of $T^* M$ are 1-*forms.*

We now want to study the transformation behavior of cotangent vectors. Let $(e_i)_{i=1,\dots,d}$ be a basis of $T_x M$ and $(\omega^j)_{j=1,\dots,d}$ the dual basis of $T_x^* M$, i.e.

$$\omega^j(e_i) = \delta_i^j = \begin{cases} 1 & \text{for } i = j \\ 0 & \text{for } i \neq j \end{cases} .$$

Moreover, let $v = v^i e_i \in T_x M$, $\eta = \eta_j \omega^j \in T_x^* M$. We have $\eta(v) = \eta_i v^i$. Let the bases (e_i) and (ω^j) be given by local coordinates, i.e.

$$e_i = \frac{\partial}{\partial x^i}, \quad \omega^j = dx^j.$$

Let now f be a coordinate change. v is transformed to

$$f_*(v) := v^i \frac{\partial f^\alpha}{\partial x^i} \frac{\partial}{\partial f^\alpha}.$$

η then has to be transformed to

$$f^*(\eta) := \eta_j \frac{\partial x^j}{\partial f^\beta} \, df^\beta$$

because in this case

$$f^*(\eta)(f_*(v)) = \eta_j \frac{\partial x^j}{\partial f^\alpha} v^i \frac{\partial f^\alpha}{\partial x^i} = \eta_i v^i = \eta(v).$$

Thus a tangent vector transforms with the functional matrix of the coordinate change whereas a cotangent vector transforms with the transposed inverse of this matrix. This different transformation behavior is expressed by the following definition:

Definition 1.5.10 A p times *contravariant* and q times *covariant* tensor on a differentiable manifold M is a section of

$$\underbrace{TM \otimes \ldots \otimes TM}_{p \text{ times}} \quad \otimes \quad \underbrace{T^*M \otimes \ldots \otimes T^*M}_{q \text{ times}} .$$

Actually, one should speak of a *tensor field,* because “tensor” often also means an element of the corresponding fibers, in the same manner, as a (tangent) vector is an element of T_xM and a vector field a section of TM.

If f is a coordinate change, a p times contravariant and q times covariant tensor is transformed p times by the matrix (df) and q times by the matrix $(df^{-1})^t$.

Lemma 1.5.1 *A Riemannian metric on a differentiable manifold M is a two times covariant (and symmetric and positive definite) tensor on M.*

Proof. From the formula (1.4.3) for the transformation behavior of a Riemannian metric. □

A Riemannian metric thus is a section of $T^*M \otimes T^*M$. We consequently write the metric in local coordinates as

$$g_{ij}(x) dx^i \otimes dx^j.$$

Theorem 1.5.2 *The tangent bundle of a Riemannian manifold M of dimension d has structure group $\mathrm{O}(d)$.*

Proof. Let (f, U) be a bundle chart for TM,

$$f : \pi^{-1}(U) \to U \times \mathbb{R}^d.$$

Let $e_1, \dots, e_d$ be the canonical basis vectors of $\mathbb{R}^d$, and let $v_1, \dots, v_d$ be the sections of $\pi^{-1}(U)$ with $f(v_i) = e_i, i = 1, \dots, d$. Applying the Gram-Schmidt orthogonalization procedure to $v_1(x), \dots, v_d(x)$ for each $x \in U$ we obtain sections $w_1, \dots, w_d$ of $\pi^{-1}(U)$ for which $w_1(x), \dots, w_d(x)$ are an orthonormal basis w.r.t. the Riemannian metric on T_xM, for each $x \in U$. By

$$\begin{aligned} f' : \pi^{-1}(U) &\to U \times \mathbb{R}^d \\ \lambda^i w_i(x) &\mapsto (x, \lambda^1, \dots, \lambda^d) \end{aligned}$$

we then get a bundle chart which maps the basis $w_1(x), \dots, w_d(x)$, i.e. an orthonormal basis w.r.t. the Riemannian metric, for each $x \in U$ onto an Euclidean orthonormal basis of $\mathbb{R}^d$. We apply this orthonormalization process for each bundle chart and obtain a new bundle atlas whose transition maps always map an Euclidean orthonormal basis of $\mathbb{R}^d$ into another such basis, and are hence in $\mathrm{O}(d)$. □

We want to point out, however, that in general there do not exist local coordinates for which $w_i(x) = \frac{\partial}{\partial x^i}$ for $i = 1, \dots, d$.

Corollary 1.5.1 *The tangent bundle of an oriented Riemannian manifold of dimension d has structure group* SO *(d).*

Proof. The orientation allows to select an atlas for which all transition maps have positive functional determinant. From this, one sees that we also may obtain transition functions for the tangent bundle with positive determinant. The orthonormalization process of Theorem 1.5.2 preserves the positivity of the determinant, and thus, in the oriented case, we obtain a new bundle atlas with transition maps in $\mathrm{SO}(d)$. □

Definition 1.5.11 Let (E, π, M) be a a vector bundle. A *bundle metric* is given by a family of scalar products on the fibers E_x, depending smoothly on $x \in M$.

In the same manner as Theorem 1.5.2, one shows

Theorem 1.5.3 *Each vector bundle (E, π, M) of rank n with a bundle metric has structure group $\mathrm{O}(n)$. In particular, there exist bundle charts $(f, U), f : \pi^{-1}(U) \to U \times \mathbb{R}^n$, for which for all $x \in U$, $f^{-1}(x, (e_1, \dots, e_n))$ is an orthonormal basis of E_x ($e_1, \dots, e_n$ is an orthonormal basis of $\mathbb{R}^n$).* □

Definition 1.5.12 The bundle charts of Theorem 1.5.3 are called *metric.*

In the same manner as Theorem 1.4.1, one shows

Theorem 1.5.4 *Each vector bundle can be equipped with a bundle metric.* □

It will be more important for us, however, that a Riemannian metric automatically induces bundle metrics on all tensor bundles over M. The metric of the cotangent bundle is given in local coordinates by

$$\langle \omega, \eta \rangle = g^{ij} \omega_i \eta_j \quad \text{for } \omega = \omega_i dx^i, \eta = \eta_i dx^i. \tag{1.5.5}$$

(We recall that (g^{ij}) is the matrix inverse to (g_{ij})).

Namely, this expression has the correct transformation behavior under coordinate changes: If $w \mapsto x(w)$ is a coordinate change, we get

$$\omega_i dx^i = \omega_i \frac{\partial x^i}{\partial w^\alpha} dw^\alpha =: \tilde{\omega}_\alpha dw^\alpha,$$

while g^{ij} is transformed into

$$h^{\alpha\beta} = g^{ij} \frac{\partial w^\alpha}{\partial x^i} \frac{\partial w^\beta}{\partial x^j},$$

and

$$h^{\alpha\beta} \tilde{\omega}_\alpha \tilde{\eta}_\beta = g^{ij} \omega_i \eta_j.$$

Moreover, we get

$$\|\omega(x)\| = \sup\{\omega(x)(v) : v \in T_x M, \|v\| = 1\}.$$

A Riemannian metric also induces an identification between TM and T^*M :

$$v = v^i \frac{\partial}{\partial x^i} \text{ corresponds to } \omega = \omega_j dx^j$$

$$\text{with} \quad \omega_j = g_{ij} v^i$$

$$\text{or} \quad v^i = g^{ij} \omega_j \, .$$

(1.5.5) may also be justified as follows:

Under this identification, to $v \in T_x M$ there corresponds a 1-form $\omega \in T_x^* M$ via

$$\omega(w) := \langle v, w \rangle \quad \text{for all } w$$

and (1.5.5) means then that

$$\|\omega\| = \|v\|.$$

For example, on $TM \otimes TM$, the metric is given by

$$\langle v \otimes w, \xi \otimes \eta \rangle = g_{ij} v^i \xi^j g_{k\ell} w^k \eta^l \tag{1.5.6}$$

($v = v^i \frac{\partial}{\partial x^i}$ etc. in local coordinates).

Definition 1.5.13 A local orthonormal basis of $T_x M$ of the type obtained in Theorem 1.5.3 is called an *(orthonormal) frame field.*

We put

$$\Lambda^p(T_x^*M) := \underbrace{T_x^*M \wedge \ldots \wedge T_x^*M}_{p \text{ times}} \quad \text{(exterior product).}$$

On $\Lambda^p(T_x^*M)$, we have two important operations: First, the exterior product by $\eta \in T_x^*M = \Lambda^1(T_x^*M)$:

$$\begin{aligned} \Lambda^p(T_x^*M) &\to \Lambda^{p+1}(T_x^*M) \\ \omega &\longmapsto \epsilon(\eta)\omega := \eta \wedge \omega. \end{aligned}$$

Second, the interior product or contraction by an element $v \in T_xM$:

$$\begin{aligned} \Lambda^p(T_x^*M) &\to \Lambda^{p-1}(T_x^*M) \\ \omega &\longmapsto \iota(v)\omega \end{aligned}$$

with

$$\begin{aligned} (\iota(v)\omega(v_1, \ldots, v_{p-1}) &:= \omega(v, v_1, \ldots, v_{p-1}) \\ &\qquad \text{for } v, v_1, \ldots, v_{p-1} \in T_xM. \end{aligned}$$

In fact, such constructions may be carried out with any vector space W and its dual W^* in place of T_x^*M and T_xM. This will be relevant in §1.8.

The vector bundle over M with fiber $\Lambda^p(T_x^*M)$ over x is then denoted by $\Lambda^p(M)$.

Definition 1.5.14 The space of sections of $\Lambda^p(M)$ is denoted by $\Omega^p(M)$, i.e. $\Omega^p(M) = \Gamma(\Lambda^p(M))$. Elements of $\Omega^p(M)$ are called *(exterior) p-forms.*

A p-form thus is a sum of terms of the form

$$\omega(x) = \eta(x) dx^{i_1} \wedge \ldots \wedge dx^{i_p}$$

where $\eta(x)$ is a smooth function and $(x^1, \ldots, x^d)$ are local coordinates.

Definition 1.5.15 The *exterior derivative* $d : \Omega^p(M) \to \Omega^{p+1}(M)$ $(p = 0, \ldots, d = \dim M)$ is defined through the formula

$$d(\eta(x) dx^{i_1} \wedge \ldots \wedge dx^{i_p}) = \frac{\partial \eta(x)}{\partial x^j} dx^j \wedge dx^{i_1} \wedge \ldots \wedge dx^{i_p}$$

and extended by linearity to all of $\Omega^p(M)$.

Lemma 1.5.2 *If* $\omega \in \Omega^p(M), \vartheta \in \Omega^q(M)$, *then* $d(\omega \wedge \vartheta) = d\omega \wedge \vartheta + (-1)^p \omega \wedge d\vartheta$.

Proof. This easily follows from the formula $\omega \wedge \vartheta = (-1)^{pq} \vartheta \wedge \omega$ and the definition of d. □

Let $f : M \to N$ be a differentiable map,

$$\omega(z) = \eta(z) dz^{i_1} \wedge \ldots \wedge dz^{i_p} \in \Omega^p(N).$$

We then define

$$f^*(\omega)(x) = \eta(f(x)) \frac{\partial f^{i_1}}{\partial x^{\alpha_1}} dx^{\alpha_1} \wedge \ldots \wedge \frac{\partial f^{i_p}}{\partial x^{\alpha_p}} dx^{\alpha_p}.$$

This obviously is the correct transformation formula for p-forms.

Lemma 1.5.3

$$d(f^*(\omega)) = f^*(d\omega).$$

Proof. This easily follows from the transformation invariance

$$\frac{\partial \eta(z)}{\partial z^j} dz^j = \frac{\partial \eta(f(x))}{\partial z^j} \frac{\partial f^j}{\partial x^\alpha} dx^\alpha = \frac{\partial \eta(f(x))}{\partial x^\alpha} dx^\alpha. \qquad \square$$

Corollary 1.5.2 *d is independent of the choice of coordinates.*

Proof. Apply Lemma 1.5.3 to a coordinate transformation f. $\square$

Theorem 1.5.5 $d \circ d = 0$.

Proof. By linearity of d, it suffices to check the asserted identity on forms of the type

$$\omega(x) = f(x) dx^{i_1} \wedge \ldots \wedge dx^{i_p}.$$

Now

$$\begin{aligned} & d \circ d(\omega(x)) \\ &= d\big(\frac{\partial f}{\partial x^j} dx^j \wedge dx^{i_1} \wedge \ldots \wedge dx^{i_p}\big) \\ &= \frac{\partial^2 f}{\partial x^j \partial x^k} dx^k \wedge dx^j \wedge dx^{i_1} \wedge \ldots \wedge dx^{i_p} \\ &= 0, \end{aligned}$$

since $\frac{\partial^2 f}{\partial x^j \partial x^k} = \frac{\partial^2 f}{\partial x^k \partial x^j}$ (f is assumed to be smooth) and

$$dx^j \wedge dx^k = -dx^k \wedge dx^j. \qquad \square$$

Let now M be a differentiable submanifold of the Riemannian manifold $N; \dim M = m, \dim N = n$. We saw already that M then also carries a Riemannian metric. For $x \in M$, we define

$$T_x^\perp M \subset T_x N$$

by

$$T_x^{\perp}M := \{v \in T_xN : \forall\, w \in T_xM : \langle v, w\rangle = 0\},$$

where $\langle .,.\rangle$, as usual, is the scalar product given by the Riemannian metric.

The spaces $T_x^{\perp}M$ are the fibers of a vector bundle $T^{\perp}M$ over M, and TM and $T^{\perp}M$ are both subbundles of $TN_{|M}$, the restriction of TN to M (in a more complicated manner: $TN_{|M} = i^*TN$, where $i : M \to N$ is the differentiable embedding of M as a submanifold of N). In order to see this, one may choose the first m basis vectors $v_1, \dots, v_m$ of $TN_{|M}$ in the orthonormalization procedure of the proof of Theorem 1.5.2 in such a manner that they locally span TM.

Then TM is also locally spanned by $w_1, \dots, w_m$ (notation as in the proof of Theorem 1.5.2), and the remaining basis vectors then span $T^{\perp}M$, and we have

$$\langle w_i, w_\alpha\rangle = 0 \text{ for } i = 1, \dots, m, \alpha = m+1, \dots, n.$$

Thus, $T^{\perp}M$ is the orthogonal complement of TM in $TN_{|M}$.

Definition 1.5.16 $T^{\perp}M$ is called the *normal bundle* of M in N.

For our example of the submanifold S^1 of $\mathbb{R}^2$, $T^{\perp}S^1$ is the subbundle of $T\mathbb{R}^2_{|S^1}$, the restriction of $T\mathbb{R}^2$ to S^1, with fiber $T_x^{\perp}S^1 = \{\lambda x : \lambda \in \mathbb{R}\} \subset \mathbb{R}^2$.

We conclude this section with a consideration of the complex case – again, we remind the reader that is needed only in particular places, like 5.2.

Definition 1.5.17 A vector bundle E over a differentiable manifold M is called a *complex vector bundle* if each fiber $E_z = \pi^{-1}(z)$ is a complex vector space, i.e., isomorphic to $z \times \mathbb{C}^k$, and if that complex structure varies smoothly, that is, the local trivializations are of the form

$$\varphi : \pi^{-1}(U) \to U \times \mathbb{C}^k.$$

We thus have transition maps

$$\varphi_{\beta\alpha} : U_\alpha \cap U_\beta \to \mathrm{Gl}\,(k, \mathbb{C}).$$

Here, in contrast to the Definition 1.1.5 of a complex manifold, we neither require that the base M be complex nor that these transition maps be holomorphic. If, however, these conditions are satisfied, that is, M is a complex manifold and the transition maps are ho lomorphic, then we have a *holomorphic vector bundle* .

On a complex manifold M, in local holomorphic coordinates, we have the 1-forms

$$dz^j := dx^j + i dy^j,\ dz^{\bar{k}} := dx^j - i dy^j$$

(recall (1.1.2)). We can then decompose the space Ω^k of k-forms into subspaces $\Omega^{p,q}$ with $p+q=k$. Namely, $\Omega^{p,q}$ is locally spanned by forms of the type

$$\omega(z) = \eta(z) dz^{i_1} \wedge \ldots \wedge dz^{i_p} \wedge dz^{\bar{j}_1} \wedge \ldots \wedge dz^{\bar{j}_q}.$$

Thus

$$\Omega^k(M) = \sum_{p+q=k} \Omega^{p,q}(M). \tag{1.5.7}$$

We can then let the differential operators

$$\partial = \frac{1}{2}\left(\frac{\partial}{\partial x^j} - i\frac{\partial}{\partial y^j}\right)(dx^j + idy^j) \quad \text{and} \quad \bar{\partial} = \frac{1}{2}\left(\frac{\partial}{\partial x^j} + i\frac{\partial}{\partial y^j}\right)(dx^j - idy^j) \tag{1.5.8}$$

operate on such a form by

$$\partial\omega = \frac{\partial\eta}{\partial z^i} dz^i \wedge dz^{i_1} \wedge \ldots \wedge dz^{i_p} \wedge dz^{\bar{j}_1} \wedge \ldots \wedge dz^{\bar{j}_q} \tag{1.5.9}$$

and

$$\bar{\partial}\omega = \frac{\partial\eta}{\partial z^{\bar{j}}} dz^{\bar{j}} \wedge dz^{i_1} \wedge \ldots \wedge dz^{i_p} \wedge dz^{\bar{j}_1} \wedge \ldots \wedge dz^{\bar{j}_q}. \tag{1.5.10}$$

The following important relations link them with the exterior derivative d:

Lemma 1.5.4 *The exterior derivative d satisfies*

$$d = \partial + \bar{\partial}. \tag{1.5.11}$$

Moreover,

$$\partial\partial = 0,\ \bar{\partial}\bar{\partial} = 0, \tag{1.5.12}$$

$$\partial\bar{\partial} = -\bar{\partial}\partial\,. \tag{1.5.13}$$

Proof. We have

$$\begin{aligned}\partial + \bar{\partial} =& \frac{1}{2}\left(\frac{\partial}{\partial x^j} - i\frac{\partial}{\partial y^j}\right)(dx^j + idy^j) + \frac{1}{2}\left(\frac{\partial}{\partial x^j} + i\frac{\partial}{\partial y^j}\right)(dx^j - idy^j)\\ =& \frac{\partial}{\partial x^j} dx^j + \frac{\partial}{\partial y^j} dy^j = d.\end{aligned}$$

Therefore,

$$0 = d^2 = (\partial + \bar{\partial})(\partial + \bar{\partial}) = \partial^2 + \partial\bar{\partial} + \bar{\partial}\partial + \bar{\partial}^2$$

and decomposing this into types yields (1.5.12) and (1.5.13). One may verify these relations also by direct computation, e.g.

$$\partial\bar{\partial} = \frac{\partial^2}{\partial z^j \partial z^{\bar{k}}} dz^j \wedge dz^{\bar{k}} = -\frac{\partial^2}{\partial z^{\bar{k}} \partial z^j} dz^{\bar{k}} \wedge dz^j = -\bar{\partial}\partial.$$

CONFORMAL MAPPINGS

This chapter is intended as a gentle introduction to the basic notions of conformal geometry. In this way we are able to introduce and discuss some concepts from differential geometry which we will need later. We meet Möbius transformations and then prove Liouville's celebrated rigidity theorem of 1850, that conformal diffeomorphisms of $\mathbf{R}^n$, $n \geq 3$, are Möbius transformations. This proof serves as a model for our subsequent proof of this theorem in much greater generality.

2.1 The Cauchy–Riemann system

Let Ω be a domain in $\mathbf{R}^n$, $n \geq 2$. A diffeomorphism $f = (f^1, f^2, \ldots, f^n)\colon \Omega \to \mathbf{R}^n$ is said to be *conformal* at a point $a \in \Omega$ if f preserves the angle at a between any pair of smooth curves passing through a. That is the angle between the image curves at $f(a)$ is the same as that between the curves at a. The map f is conformal in Ω if it is conformal at each $a \in \Omega$. A classical result one meets in any first course in complex analysis, for example §2.3 in [6], is that a conformal orientation-preserving diffeomorphism of a planar domain is holomorphic in Ω. Equivalently, f has a complex derivative at a and satisfies the Cauchy–Riemann equations,

$$\begin{aligned}\frac{\partial f^1}{\partial x_1} &= \frac{\partial f^2}{\partial x_2}\\ \frac{\partial f^1}{\partial x_2} &= -\frac{\partial f^2}{\partial x_1}\end{aligned} \tag{2.1}$$

It is our purpose in this chapter to investigate similar equations in higher dimensions. We shall see a surprising rigidity phenomenon (the Liouville theorem) which lies at the heart of multidimensional geometric function theory.

Let us now find the governing equations for conformal diffeomorphisms. Thus let γ, η: $[-1, 1] \to \Omega$ be smooth curves normalized so that $\gamma(0) = \eta(0) = a$. The tangent vectors $\zeta = \frac{d}{dt}\gamma|_{t=0}$ and $\xi = \frac{d}{dt}\eta|_{t=0}$ determine the angle θ between the two curves γ and η by the rule

$$\cos(\theta) = \frac{\langle \zeta, \xi \rangle}{|\zeta||\xi|}$$

The diffeomorphism f preserves this angle, which means that the angle between the two curves $f \circ \gamma$ and $f \circ \eta$ at $f(a)$ remains unchanged. The chain rule enables us to compute the tangent vectors to these two curves at $f(a)$:

$$\frac{d}{dt}(f \circ \gamma)|_{t=0} = Df(a)\zeta \quad \text{and} \quad \frac{d}{dt}(f \circ \eta)|_{t=0} = Df(a)\xi$$

where here and in the sequel $Df(a)$ is the *Jacobian matrix* of f,

$$Df(a) = \left[\frac{\partial f^i}{\partial x_j}(a)\right] \quad i,\ j = 1, 2, \ldots, n \tag{2.2}$$

Hence f is conformal at a if

$$\frac{\langle Df(a)\zeta,\ Df(a)\xi\rangle}{|Df(a)\zeta||Df(a)\xi|} = \frac{\langle \zeta,\ \xi\rangle}{|\zeta||\xi|} \text{ for all } \zeta,\ \xi \in \mathbb{R}^n \setminus \{0\} \tag{2.3}$$

As a matter of fact we shall only exploit this identity for orthogonal vectors via the following lemma.

Lemma 2.1.1 *Let A be a nonsingular matrix such that for all vectors ζ and ξ with $\langle \zeta, \xi\rangle = 0$, we have $\langle A\zeta, A\xi\rangle = 0$. Then $A = |\det(A)|^{1/n} O$ for some orthogonal matrix O.*

Proof We have $\langle A^t A\zeta, \xi\rangle = 0$ whenever $\langle \zeta, \xi\rangle = 0$. Fixing ζ and varying ξ in the space perpendicular to ζ, we see $A^t A\zeta$ is parallel to ζ. That is, $A^t A\zeta = \lambda(\zeta)\zeta$ for some scalar function λ. The linearity of the left-hand side of this equation shows λ to be constant. As ζ is an arbitrary non-zero vector, we conclude that $A^t A = \lambda \mathbf{I}$. Then the constant λ is easily computed by taking the determinant of both sides. □

Returning to equation (2.3), we find the hypothesis of Lemma 2.1.1 fulfilled by $Df(a)$. Denote by $J(a, f)$ the determinant of the matrix $Df(a)$, which is referred to as the *Jacobian* of f.

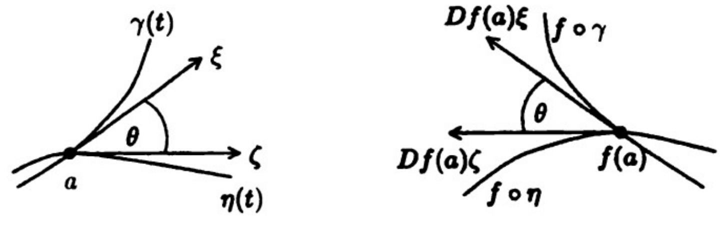

Figure 2.1 The angle between curves.

We have therefore established that an orientation-preserving conformal diffeomorphism of Ω satisfies the differential equation

$$D^t f(x) Df(x) = J(x, f)^{2/n}\mathbf{I} \quad x \in \Omega \tag{2.4}$$

It is a nice exercise to show that when $n = 2$ this system of equations reduces to the equations (2.1). It is for this reason that the system (2.4) is known in higher dimensions as the Cauchy–Riemann system.

A principal focus of this book is to study the solution to this and related equations. There are two distinctions between the higher-dimensional ($n \geq 3$) theory of these equations and the planar theory. The first is non-linearity (though strictly speaking the equations are only equivalent to a linear system in the plane) and the second is that the system is highly overdetermined. Indeed, the Cauchy–Riemann system in dimension n consists of $\frac{1}{2}(n-1)(n+2)$ independent equations for the n unknowns $f^1, f^2, \dots, f^n$ forming the components of f. That is partly why, for $n \geq 3$, the family of all solutions to this equation depends on only a finite number of real parameters. This number, as already recognized by Liouville in 1850 [204], is exactly equal to the dimension of the topological group $\mathbf{M\ddot{o}b}(n)$ of Möbius transformations of $\bar{\mathbb{R}}^n$. This dimension is $n(n+5)/2$.

2.2 The Möbius group

Let us look at some well-known solutions to the Cauchy–Riemann system. First, there are the obvious solutions $g(x) = \lambda O x$, where $\lambda \neq 0$ and O is an orthogonal transformation. Such mappings are known as *similarities*. Of course $Dg = \lambda O$. More interesting examples are furnished by reflections.

The *reflection* in a sphere $\mathbb{S}^{n-1}(a, r)$ is the mapping $g\colon \bar{\mathbb{R}}^n \to \bar{\mathbb{R}}^n$ defined by

$$g(x) = \begin{cases} a + \frac{r^2(x-a)}{|x-a|^2} & x \notin \{a, \infty\} \\ \infty & x = a \\ a & x = \infty \end{cases} \tag{2.5}$$

It is clear that $g \circ g = \mathbf{I}$ and $g(x) = x$ if and only if $x \in \mathbb{S}^{n-1}(a, r)$. For $x \notin \{a, \infty\}$ we compute the Jacobian matrix of g to be

$$Dg(x) = \frac{r^2}{|x-a|^2}\left(I - 2\frac{x-a}{|x-a|} \otimes \frac{x-a}{|x-a|}\right) \tag{2.6}$$

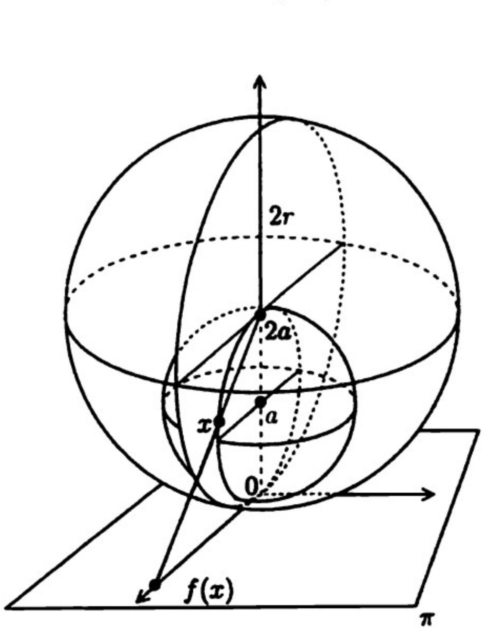

Figure 2.2 The stereographic projection of the sphere $\mathbb{S}^{n-1}(a, r)$, $r = |a|$, is the restriction of the inversion in $\mathbb{S}^{n-1}(2a, 2r)$.

In particular, the Jacobian determinant is negative:

$$J(x, g) = -r^{2n}|x - a|^{-2n} \tag{2.7}$$

and

$$D^t g(x) Dg(x) = \frac{r^4}{|x - a|^4}\mathbf{I} \tag{2.8}$$

Thus every reflection in a sphere is orientation-reversing and conformal. Recall that the reflection h in a hyperplane $\Pi = \{x \in \mathbb{R}^n : \langle x, a\rangle = t\}$ of $\mathbb{R}^n$ is an orientation-reversing isometry and that the Möbius group $\mathbf{M\ddot{o}b}(n)$ is generated by reflections in spheres and hyperplanes. Every reflection g satisfies the Cauchy–Riemann system (2.4) as is easy to see from (2.7) and (2.8). The following observation is a simple consequence of the chain rule:

Suppose f: $\Omega_1 \to \Omega_2$ and g: $\Omega_2 \to \Omega_3$ are C^1 solutions to the Cauchy–Riemann system. Then $f \circ g$: $\Omega_1 \to \Omega_3$ is also a C^1 solution. If in addition f is a diffeomorphism, then f^{-1}: $\Omega_2 \to \Omega_1$ is a solution as well.

Thus the space of diffeomorphic solutions to the Cauchy–Riemann system on domains in $\mathbb{R}^n$ form a pseudo-group which contains the Möbius transformations, since $\mathbf{M\ddot{o}b}(n)$ is generated by reflections. We now begin to study all solutions to the Cauchy–Riemann system.

2.3 The Liouville theorem (smooth case)

Later we will discuss very weak solutions of the differential equations (2.4). For now we will have to be satisfied with the following theorem, [162].

Theorem 2.3.1 *Every solution* $f \in C^3(\Omega, \mathbb{R}^n)$, $n \geq 3$, *to the Cauchy–Riemann system* $D^t f(x) Df(x) = |J(x, f)|^{2/n}\mathbf{I}$, *where* $J(x, f)$ *does not change sign in* Ω, *has the form*

$$f(x) = b + \frac{\alpha\, A(x-a)}{|x-a|^{\epsilon}} \tag{2.9}$$

In this formula the arbitrary parameters are $a \in \mathbb{R}^n \backslash \Omega$, $b \in \mathbb{R}^n$, $\alpha \in \mathbb{R}$, A *is an orthogonal matrix, and* ϵ *is either* 0 *or* 2.

The idea of the proof is to differentiate the Cauchy–Riemann system twice to obtain an equation for the Jacobian determinant. It is instructive to place the computation within the more global framework of Riemannian geometry. We do this with a restricted degree of generality but with the more general system of equations

$$D^t f(x) Df(x) = G(x) \tag{2.10}$$

where $G(x) = [g_{ij}(x)]$ is a twice continuously differentiable function with values in the space of positive definite symmetric $n \times n$ matrices. The reader familiar with Riemannian geometry may recognize G as none other than the pullback of the Euclidean metric tensor (represented in standard coordinates) via the diffeomorphism f. We shall put off a precise discussion of this topic for the moment.

2.4 Curvature

Following the general philosophy of Cartan in dealing with overdetermined nonlinear systems, we want to eliminate f from the system of equations (2.10) by differentiation and substitution to obtain equations for G only. These of course turn out to be the curvatures of G. System (2.10) can be rewritten as

$$Df(x) G^{-1}(x) D^t f(x) = \mathbf{I} \tag{2.11}$$

where $G^{-1}(x) = [g^{ij}(x)]$ is the inverse of G.

Henceforth we follow Einstein's summation convention. Accordingly terms with repeated indices are to be summed from 1 *to* n.

In terms of the coordinate functions $f = (f^1, f^2, \ldots, f^n)$ both systems (2.10) and (2.11) can be written as

$$f_i^\alpha f_j^\alpha = g_{ij} \quad \text{or} \quad g^{\nu\mu} f_\nu^i f_\mu^j = \delta_{ij} \tag{2.12}$$

where δ_{ij} is the usual Kronecker symbol. Here we have reserved the use of lower indices on f to indicate partial differentiation with respect to a given variable, thus

$$Df = \left[\frac{\partial f^i}{\partial x_j}\right] = \left[f^i_j\right]$$

and with the further notation $f^i_{jk} = \frac{\partial^2 f^i}{\partial x_j \partial x_k}$ and so forth.

Differentiate the first system of equations at (2.12) with respect to the variable x_k and then permute the indices to obtain the three equations

$$\begin{aligned} f^\alpha_{ik} f^\alpha_j + f^\alpha_i f^\alpha_{jk} &= \frac{\partial g_{ij}}{\partial x_k} \\ f^\alpha_{ij} f^\alpha_k + f^\alpha_i f^\alpha_{jk} &= \frac{\partial g_{ik}}{\partial x_j} \\ -f^\alpha_{ij} f^\alpha_k - f^\alpha_j f^\alpha_{ik} &= -\frac{\partial g_{ij}}{\partial x_i} \end{aligned}$$

which we sum to obtain

$$2 f^\alpha_i f^\alpha_{jk} = \frac{\partial g_{ij}}{\partial x_k} + \frac{\partial g_{ik}}{\partial x_j} - \frac{\partial g_{jk}}{\partial x_i} \tag{2.13}$$

To compute the second-order derivatives of f we multiply by $f^l_\nu g^{\nu i}$ and use the second system of equations in (2.12) to find

$$f_{jk} = \Gamma^\nu_{jk} f_\nu \tag{2.14}$$

where Γ^ν_{jk} are the familiar *Christoffel symbols* of G, that is

$$2\Gamma^\nu_{jk} = g^{i\nu}\left(\frac{\partial g_{ij}}{\partial x_k} + \frac{\partial g_{ik}}{\partial x_j} - \frac{\partial g_{jk}}{\partial x_i}\right) \tag{2.15}$$

Notice that one immediate consequence of this is that if G is a constant matrix, then f is a linear transformation. In particular, conformal mappings with constant determinant are linear transformations, in fact scalar multiples of an orthogonal transformation. Next we differentiate equation (2.14) with respect to the variable x_l, $l = 1, 2, \ldots, n$, to obtain

$$\begin{aligned} f_{jkl} &= f_\nu \frac{\partial \Gamma^\nu_{jk}}{\partial x_l} + f_{\nu l} \Gamma^\nu_{jk} \\ &= \left(\frac{\partial \Gamma^\nu_{jk}}{\partial x_l} + \Gamma^\mu_{jk} \Gamma^\nu_{\mu l}\right) f_\nu \end{aligned}$$

where we have used (2.12) once again. If f is three times continuously differentiable, then f_{jkl} does not change with the permutation of indices. Permute k and l to see that

$$\left(\frac{\partial \Gamma^{\nu}_{jk}}{\partial x_l} - \frac{\partial \Gamma^{\nu}_{jl}}{\partial x_k} + \Gamma^{\mu}_{jk}\Gamma^{\nu}_{\mu l} - \Gamma^{\mu}_{jl}\Gamma^{\nu}_{\mu k}\right) f_{\nu} = 0 \tag{2.16}$$

Finally, we observe that the vectors f_{ν}, $\nu = 1, 2, \ldots, n$, are linearly independent. Hence

$$R^{\nu}_{jlk} = 0 \tag{2.17}$$

where R^{ν}_{jlk} is the *Riemannian curvature tensor*

$$R^{\nu}_{jlk} = \frac{\partial \Gamma^{\nu}_{jk}}{\partial x_l} - \frac{\partial \Gamma^{\nu}_{jl}}{\partial x_k} + \Gamma^{\mu}_{jk}\Gamma^{\nu}_{\mu l} - \Gamma^{\mu}_{jl}\Gamma^{\nu}_{\mu k} \tag{2.18}$$

We now recall two other important differential expressions from Riemannian geometry: the *Ricci curvature tensor*,

$$R_{ij} = R^{\nu}_{i\nu j} \tag{2.19}$$

and the *scalar curvature*

$$R = g^{\nu\mu} R_{\nu\mu} \tag{2.20}$$

The matrix function $G = G(x)$ is said to be *conformally Euclidean* if there is a scalar function $\lambda = \lambda(x)$ such that

$$g_{ij}(x) = e^{\lambda(x)}\delta_{ij} \tag{2.21}$$

The curvatures of a conformally Euclidean matrix are computed as follows. First the Christoffel symbols,

$$2\Gamma^{l}_{ij} = \lambda_i\delta_{jl} + \lambda_j\delta_{il} - \lambda_l\delta_{ij} \tag{2.22}$$

where the lower indices on λ denote partial differentiation. Next the curvature tensor

$$\begin{aligned} 4R^{l}_{ijk} = {} & 2\lambda_{ij}\delta_{kl} - 2\lambda_{lj}\delta_{ik} + 2\lambda_{lk}\delta_{ij} - 2\lambda_{ik}\delta_{jl} \\ & - \lambda_i\lambda_j\delta_{kl} + \lambda_l\lambda_j\delta_{ik} - \lambda_l\lambda_k\delta_{ij} + \lambda_i\lambda_k\delta_{jl} \\ & + \lambda_\nu\lambda_\nu\delta_{jk}\delta_{il} - \lambda_\nu\lambda_\nu\delta_{ik}\delta_{jl} \end{aligned}$$

and the Ricci tensor

$$4R_{ik} = 2(2-n)\lambda_{ik} - 2\lambda_{\nu\nu}\delta_{ik} + (n-2)\lambda_i\lambda_k - (n-2)\lambda_\nu\lambda_\nu\delta_{ik}$$

This yields the scalar curvature

$$\frac{4e^{\lambda}}{n-1}R = (2-n)|\nabla\lambda|^2 - 4\Delta\lambda \tag{2.23}$$

2.5 Computing the Jacobian

We are now in a position to compute the Jacobian determinant of any C^3 solution to the Cauchy–Riemann system. There is no loss of generality in assuming that $J(x, f) \geq 0$ in Ω for we may otherwise compose f with an orientation-reversing orthogonal transformation.

Lemma 2.5.1 *In each dimension $n \geq 3$ we have that either $J(x, f)$ is a constant function, or that*

$$J(x, f) = r^{2n}|x-a|^{-2n} \tag{2.24}$$

for some $r > 0$ and some $a \in \mathbb{R}^n \setminus \Omega$.

Proof Suppose that $J(x, f)$ is not constant. Fix one of the components of the open set $\{x \in \Omega : J(x, f) > 0\}$ and denote it by Ω^+. Our first aim is to show that formula (2.24) holds in Ω^+ and therefore that Ω^+ is a relatively closed subset of Ω, from which we will deduce $\Omega^+ = \Omega$. Let us set

$$\lambda(x) = \frac{2}{n}\log J(x, f) \quad x \in \Omega^+ \tag{2.25}$$

Let us now write the Cauchy–Riemann system as

$$D^t f(x) Df(x) = e^{\lambda(x)}\mathbf{I} \quad x \in \Omega^+$$

As the matrix function $G(x) = e^{\lambda(x)}\mathbf{I}$ is conformally flat its Ricci curvature vanishes. In particular, the scalar curvature $R = 0$. When $R = 0$ we see $4\Delta\lambda = (2-n)|\nabla\lambda|^2$ and we may simplify the formula for the Ricci tensor to

$$8R_{ij} = (n-2)\left[2\frac{\partial\lambda}{\partial x_i}\frac{\partial\lambda}{\partial x_j} - 4\frac{\partial^2\lambda}{\partial x_i\partial x_j} - |\nabla\lambda|^2\delta_{ij}\right] \tag{2.26}$$

Note the consequence that in two dimensions the conformally flat matrix $G = e^{\lambda}\mathbf{I}$ has vanishing scalar curvature if and only if λ is harmonic. Supposing now that $n \geq 3$, the assumption that G is Ricci flat, $R_{ij} = 0$, reads as

$$4\frac{\partial^2\lambda}{\partial x_i\partial x_j} = 2\frac{\partial\lambda}{\partial x_i}\frac{\partial\lambda}{\partial x_j} - |\nabla\lambda|^2\delta_{ij} \tag{2.27}$$

4
Laplacian comparison theorem

Let M be a complete m-dimensional manifold. Suppose p is a fixed point in M and let us consider the distance function $r_p(x) = r(p, x)$ to p. When there is no ambiguity, the subscript will be deleted and we will simply write $r(x)$. The distance function in general is not smooth due to the presence of cut-points. However, it can be seen that it is a Lipschitz function with Lipschitz constant 1. In particular, we have

$$|\nabla r|^2 = 1$$

almost everywhere on M. Though r might not be a C^2 function, one can still estimate its Laplacian in the sense of distribution.

Theorem 4.1 *Let M be a complete m-dimensional Riemannian manifold with Ricci curvature bounded from below by*

$$\mathcal{R}_{ij} \geq (m-1)K$$

for some constant K. Then the Laplacian of the distance function satisfies

$$\Delta r(x) \leq \begin{cases} (m-1)\sqrt{K}\cot(\sqrt{K}r) & \text{for} \quad K > 0, \\ (m-1)r^{-1} & \text{for} \quad K = 0, \\ (m-1)\sqrt{-K}\coth(\sqrt{-K}r) & \text{for} \quad K < 0 \end{cases}$$

in the sense of distribution.

Proof For a smooth function f, let $x \in M$ be a point such that $\nabla f(x) \neq 0$. Then locally the level surface N of f through the point x is a smooth hypersurface. Let $\{e_1, \ldots, e_{m-1}\}$ be an orthonormal frame tangent to N, and let e_m be the unit normal vector to N. The Laplacian of f at x is defined to be

$$\begin{aligned}
\Delta f(x) &= \sum_{i=1}^{m-1}(e_i e_i - \nabla_{e_i} e_i) f(x) + (e_m e_m - \nabla_{e_m} e_m) f(x) \\
&= \sum_{i=1}^{m-1}(e_i e_i - (\nabla_{e_i} e_i)^t) f(x) \\
&\quad - \sum_{i=1}^{m-1}(\nabla_{e_i} e_i)^n f(x) + (e_m e_m - \nabla_{e_m} e_m) f(x) \\
&= \Delta_N f(x) + \overrightarrow{H} f(x) + (e_m e_m - \nabla_{e_m} e_m) f(x) \\
&= \overrightarrow{H} f(x) + (e_m e_m - \nabla_{e_m} e_m) f(x),
\end{aligned}$$

where Δ_N denotes the Laplacian of N with respect to the induced metric and $\overrightarrow{H}$ denotes the mean curvature vector of N. If we take $f = r$, then for a point x which is not in the cut-locus of p, we have $N = \partial B_p(r)$. Moreover, the unit normal vector $e_m = \partial/\partial r$. Hence, we have

$$\Delta r(x) = H(x),$$

where $H(x)$ is the mean curvature of $\partial B_p(r)$ with respect to $\partial/\partial r$. Therefore according to Corollary 2.2 the theorem is true for those points that are not in the cut-locus of p.

Using the same notation as in Theorem 2.1, let us denote

$$\bar{H}(r) = \begin{cases} (m-1)\sqrt{K}\cot(\sqrt{K}r) & \text{for} \quad K > 0, \\ (m-1)r^{-1} & \text{for} \quad K = 0, \\ (m-1)\sqrt{-K}\coth(\sqrt{-K}r) & \text{for} \quad K < 0. \end{cases}$$

To show that Δr has the desired estimate in the sense of distribution, it suffices to show that for any nonnegative compactly supported smooth function ϕ we have

$$\int_M (\Delta\phi)\, r \le \int_M \phi\, \bar{H}(r).$$

In terms of polar normal coordinates at p, we can write

$$\int_M \phi\, \bar{H}(r) = \int_0^\infty \int_{C(r)} \phi\, \bar{H}(r)\, J(\theta, r)\, d\theta\, dr.$$

On the other hand, for each $\theta \in S_p(M)$ if we let $R(\theta)$ be the maximum value of $r > 0$ such that the geodesic $\gamma(s) = \exp_p(s\theta)$ minimizes up to $s = r$, then by Fubini's theorem we can write

$$\int_0^\infty \int_{C(r)} \phi\, \bar{H}(r)\, J(\theta, r)\, d\theta\, dr = \int_{S_p(M)} \int_0^{R(\theta)} \phi\, \bar{H}(r)\, J(\theta, r)\, dr\, d\theta.$$

However, for $r < R(\theta)$, we have

$$\begin{aligned} \bar{H}(r)\, J(\theta, r) &\geq H(\theta, r)\, J(\theta, r) \\ &= \frac{\partial}{\partial r} J(\theta, r). \end{aligned}$$

Therefore,

$$\begin{aligned} \int_M \phi\, \bar{H}(r) &\geq \int_{S_p(M)} \int_0^{R(\theta)} \phi\, \frac{\partial J}{\partial r}\, dr\, d\theta \\ &= -\int_{S_p(M)} \int_0^{R(\theta)} \frac{\partial \phi}{\partial r}\, J\, dr\, d\theta + \int_{S_p(M)} [\phi\, J]_0^{R(\theta)}\, d\theta \\ &= -\int_M \frac{\partial \phi}{\partial r} + \int_{S_p(M)} \phi(\theta, R(\theta))\, J(\theta, R(\theta))\, d\theta \\ &\geq -\int_M \langle \nabla \phi, \nabla r \rangle, \end{aligned}$$

where we have used the facts that both ϕ and J are nonnegative and $J(\theta, 0) = 0$. On the other hand, since r is Lipschitz, we conclude that

$$-\int_M \langle \nabla \phi, \nabla r \rangle = \int_M (\Delta \phi) r,$$

which proves the theorem. □

We are now ready to prove a structural theorem for manifolds with nonnegative Ricci curvature. Let us first define the notions of a line and a ray in a Riemannian manifold.

Definition 4.2 A line is a normal geodesic $\gamma : (-\infty, \infty) \longrightarrow M$ such that any of its finite segments $\gamma|_a^b$ is a minimizing geodesic.

Definition 4.3 A ray is a half-line $\gamma_+ : [0, \infty) \longrightarrow M$, which is a normal minimizing geodesic.

Theorem 4.4 (Cheeger–Gromoll [CG2]) *Let M be a complete, m-dimensional, manifold with nonnegative Ricci curvature. If there exists a* *line in M, then M is isometric to $\mathbb{R} \times N$, the product of a real line and an $(m-1)$-dimensional manifold N with nonnegative Ricci curvature.*

Proof Let $\gamma_+ : [0, \infty) \longrightarrow M$ be a ray in M. One defines the Buseman function β_+ with respect to γ_+ by

$$\beta_+(x) = \lim_{t\to\infty} (t - r(\gamma_+(t), x)).$$

We observe that β_+ is a Lipschitz function with Lipschitz constant 1. Moreover, by the Laplacian comparison theorem,

$$\begin{aligned}\Delta\beta_+(x) &\geq -\lim_{t\to\infty} (m-1) r(\gamma_+(t), x)^{-1}\\ &= 0\end{aligned}$$

in the sense of distribution. If γ is a line, then $\gamma_+(t) = \gamma(t)$ and $\gamma_-(t) = \gamma(-t)$ for $t \geq 0$ are rays. The corresponding Buseman functions β_+ and β_- are subharmonic in the sense of distribution. In particular, $\beta_- + \beta_+$ is also subharmonic on M. On the other hand, since γ is a line, the triangle inequality implies that

$$\begin{aligned}2t &= r(\gamma(-t), \gamma(t))\\ &\leq r(\gamma(-t), x) + r(\gamma(t), x).\end{aligned}$$

Hence

$$t - r(\gamma_-(t), x) + t - r(\gamma_+(t), x) \leq 0,$$

and by taking the limit as $t \to \infty$ we have

$$\beta_-(x) + \beta_+(x) \leq 0.$$

Moreover, it is also clear that

$$\beta_-(x) + \beta_+(x) = 0$$

for all x on γ. However, by the strong maximum principle, since the subharmonic function $\beta_- + \beta_+$ has an interior maximum, it must be identically constant. In particular, both β_- and β_+ are harmonic and $\beta_- \equiv -\beta_+$. By regularity theory, β_+ is a smooth harmonic function with $|\nabla\beta_+| \leq 1$, and $|\nabla\beta_+| \equiv 1$ on the geodesic γ. For simplicity, let us write $\beta = \beta_+$. The Bochner formula gives

$$\begin{aligned}\Delta|\nabla\beta|^2 &= 2\beta_{ij}^2 + 2\mathcal{R}_{ij}\,\beta_i\,\beta_j + 2\langle\nabla\beta, \nabla\Delta\beta\rangle\\ &\geq 0. \qquad (4.1)\end{aligned}$$

Hence by the fact that $|\nabla\beta|^2$ achieves its maximum in the interior of M, the maximum principle for subharmonic functions again implies that $|\nabla\beta|^2 \equiv 1$ on M. Substituting this into (4.1) yields $\beta_{ij} \equiv 0$, and $\nabla\beta$ is a parallel vector field on M. This implies that M must split, which proves the theorem. □

Corollary 4.5 *Let M be a complete m-dimensional Riemannian manifold with nonnegative Ricci curvature. If M has at least two ends, then there exists a compact $(m-1)$-dimensional manifold N of nonnegative Ricci curvature such that*

$$M = \mathbb{R} \times N.$$

Proof The assumption that M has at least two ends implies that there exists a compact set $D \subset M$ such that $M \setminus D$ has at least two unbounded components. Hence there are two unbounded sequences of points $\{x_i\}_{i=1}^{\infty}$ and $\{y_i\}_{i=1}^{\infty}$, such that the minimal geodesics γ_i joining x_i to y_i must intersect D. By the compactness of D, if $p_i \in \gamma_i \cap D$ and $v_i = \gamma_i'(p_i)$, then by passing through a subsequence we have $p_i \to p$ and $v_i \to v$ for some $p \in D$ and $v \in T_pM$. We now claim that the geodesic $\gamma : (-\infty, \infty) \longrightarrow M$ given by the initial conditions $\gamma(0) = p$ and $\gamma'(0) = v$ is a line.

To see this, let us consider an arbitrary segment $\gamma|_{[a,b]}$ of γ. By the continuity of the initial conditions of the second order ordinary differential equation, we know that $\gamma_i|_{[a,b]} \to \gamma|_{[a,b]}$ because $(p_i, v_i) \to (p, v)$. However, by the assumption, $\gamma_i|_{[a,b]}$ are minimizing geodesics, hence $\gamma|_{[a,b]}$ is also minimizing, and γ is a line.

Theorem 4.4 now implies that $M = \mathbb{R} \times N$. The compactness of N follows from the assumption that M has at least two ends. □

Another application of the Laplacian comparison theorem is the eigenvalue comparison theorem of Cheng.

Theorem 4.6 (Cheng [Cg1]) *Let M be a compact Riemannian manifold of dimension m and ∂M be the boundary of M. Assume that the Ricci curvature of M is bounded by*

$$\mathcal{R}_{ij} \geq (m-1)K$$

for some constant K. Let us consider $\bar{M}$ to be the simply connected space form with constant curvature K. Let $\mu_1(M)$ be the first nonzero eigenvalue of the Dirichlet Laplacian on M and i be the inscribe radius of M. If $\bar{B}(i)$ is a *geodesic ball in $\bar{M}$ with radius i and $\mu_1(\bar{B}(i))$ is its first Dirichlet eigenvalue, then*

$$\mu_1(M) \leq \mu_1(\bar{B}(i)).$$

When $\partial M = \emptyset$, let $\lambda_1(M)$ be the first nonzero eigenvalue of the Laplacian and d be the diameter of M. If $\bar{B}(d/2)$ is a geodesic ball in $\bar{M}$ with radius $d/2$ and $\mu_1\left(\bar{B}\,(d/2)\right)$ is its first Dirichlet eigenvalue, then

$$\lambda_1(M) \leq \mu_1\left(\bar{B}\left(\frac{d}{2}\right)\right).$$

Proof Let us first consider the case when M has boundary. Let $B_p(i)$ be an inscribed ball in M. By the monotonicity of eigenvalues, it suffices to show that

$$\mu_1(B_p(i)) \leq \mu_1(\bar{B}(i)).$$

Let $\bar{u}$ be the first Dirichlet eigenfunction on $\bar{B}(i)$. By the uniqueness of $\bar{u}$, we may assume that $\bar{u} \geq 0$. If we let $\bar{p} \in \bar{B}(i)$ be its center and $\bar{r}$ be the distance function to $\bar{p}$, then $\bar{u}(\bar{r})$ must be a function of $\bar{r}$ alone. By the facts that $\bar{u} \geq 0$ and $\bar{u}(i) = 0$, the strong maximum principle implies that $(\partial\bar{u}/\partial\bar{r})(i) < 0$. If there is some value of $\bar{r} < i$ such that $\partial\bar{u}/\partial\bar{r} > 0$, then this would imply that $\bar{u}$ has a interior local minimum. However, this violates the strong maximum principle. Hence, $\bar{u}' = \partial\bar{u}/\partial\bar{r} \leq 0$.

Let us define a Lipschitz function on $B_p(i)$ by $u(r) = \bar{u}(r)$, where r denotes the distance function to p. Clearly, u satisfies the Dirichlet boundary condition. Computing the Laplacian of u gives

$$\begin{aligned}\Delta u &= \bar{u}'\Delta r + \bar{u}''|\nabla r|^2 \\ &\geq \bar{u}'\Delta r + \bar{u}''.\end{aligned}$$

On the other hand, if we let $\bar{\Delta}$ be the Laplacian on $\bar{M}$, then

$$\begin{aligned}-\mu_1(\bar{B}(i))\,\bar{u} &= \bar{\Delta}\bar{u} \\ &= \bar{u}'\bar{\Delta}\bar{r} + \bar{u}''.\end{aligned}$$

By Theorem 4.1 and the fact that $\bar{u}' \leq 0$, we conclude that

$$\Delta u \geq -\mu_1(\bar{B}(i))\,u$$

in the sense of distribution. Hence, by the Rayleigh principle for eigenvalues, we conclude that

$$\begin{aligned}\mu_1(B_p(i)) &\leq \frac{\int_{B_p(i)} |\nabla u|^2}{\int_{B_p(i)} u^2} \\ &= \frac{-\int_{B_p(i)} u\Delta u}{\int_{B_p(i)} u^2} \\ &\leq \mu_1(\bar{B}(i)).\end{aligned}$$

To prove the upper bound for the case when M has no boundary, we consider the disjoint balls $B_p(d/2)$ and $B_q(d/2)$ centered at a pair of points p and q which realize the diameter. By the above estimate,

$$\mu_1\left(B_p\left(\frac{d}{2}\right)\right) \leq \mu_1\left(\bar{B}\left(\frac{d}{2}\right)\right)$$

and

$$\mu_1\left(B_q\left(\frac{d}{2}\right)\right) \leq \mu_1\left(\bar{B}\left(\frac{d}{2}\right)\right).$$

We now claim that $\lambda_1(M) \leq \max\{\mu_1(M_1), \mu_1(M_2)\}$ for any disjoint pair of open subsets $M_1, M_2 \subset M$. This will establish the theorem by setting $M_1 = B_p(d/2)$ and $M_2 = B_q(d/2)$.

To prove the claim, let u_1 and u_2 be nonnegative first Dirichlet eigenfunctions on M_1 and M_2 respectively. By multiplying u_i by a constant, we may assume that $\int_{M_i} u_i = 1$ for $i = 1, 2$. Let us define a Lipschitz function on M by

$$u = \begin{cases} u_1 & \text{on} \quad M_1, \\ -u_2 & \text{on} \quad M_2, \\ 0 & \text{on} \quad M \setminus (M_1 \cup M_2). \end{cases}$$

Clearly, $\int_M u = 0$, hence after applying the Rayleigh principle, we have

$$\begin{aligned}\lambda_1(M)\left(\int_{M_1} u_1^2 + \int_{M_2} u_2^2\right) &= \lambda_1(M)\int_M u^2 \\ &\leq \int_M |\nabla u|^2 \\ &= \int_{M_1} |\nabla u_1|^2 + \int_{M_2} |\nabla u_2|^2\end{aligned}$$

$$= \mu_1(M_1) \int_{M_1} u_1^2 + \mu_1(M_2) \int_{M_2} u_2^2$$

$$\leq \max\{\mu_1(M_1), \mu_1(M_2)\} \left(\int_{M_1} u_1^2 + \int_{M_2} u_2^2 \right).$$

This establishes the claim. □

2

Volume comparison theorem

In this chapter, we will develop a volume comparison theorem originally proved by Bishop (see [BC]). Let $p \in M$ be a point in a complete Riemannian manifold of dimension m. In terms of polar normal coordinates at p, we can write the volume element as

$$J(\theta, r)dr \wedge d\theta,$$

where $d\theta$ is the area element of the unit $(m-1)$-sphere. The Gauss lemma asserts that the area element of submanifold $\partial B_p(r)$, which is the boundary of the geodesic ball of radius r, is given by $J(\theta, r)d\theta$. By the first and second variational formulas (1.5) and (1.6), if $x = (\theta, r)$ is not in the cut-locus of p, we have

$$\begin{aligned} J'(\theta, r) &= \frac{\partial J}{\partial r}(\theta, r) \\ &= H(\theta, r)\, J(\theta, r) \end{aligned} \tag{2.1}$$

and

$$\begin{aligned} J''(\theta, r) &= \frac{\partial^2 J}{\partial r^2}(\theta, r) \\ &= -\sum_{i,j=1}^{m-1} h_{ij}^2(\theta, r)\, J(\theta, r) - \mathcal{R}_{rr}(\theta, r)\, J(\theta, r) + H^2(\theta, r)\, J(\theta, r), \end{aligned} \tag{2.2}$$

where $\mathcal{R}_{rr} = \mathcal{R}(\partial/\partial r, \partial/\partial r)$, $H(\theta, r)$, and $(h_{ij}(\theta, r))$ denote the Ricci curvature in the radial direction, the mean curvature and the second fundamental form of $\partial B_p(r)$ at the point $x = (\theta, r)$ with respect to the unit normal vector $\partial/\partial r$, respectively.

Using the inequalities

$$\begin{aligned}\sum_{i,j=1}^{m-1} h_{ij}^2 &\geq \sum_{i=1}^{m-1} h_{ii}^2 \\ &\geq \frac{\left(\sum_{i=1}^{m-1} h_{ii}\right)^2}{m-1} \\ &= \frac{H^2}{m-1} \end{aligned} \tag{2.3}$$

and (2.1), we can estimate (2.2) by

$$\begin{aligned} J'' &\leq \frac{m-2}{m-1} H^2\, J - \mathcal{R}_{rr}\, J \\ &= \frac{m-2}{m-1} (J')^2\, J^{-1} - \mathcal{R}_{rr}\, J. \end{aligned} \tag{2.4}$$

Since any smooth metric is locally Euclidean, we have the initial conditions

$$J(\theta, r) \sim r^{m-1}$$

and

$$J'(\theta, r) \sim (m-1) r^{m-2}$$

as $r \to 0$. Let us point out that if M is a simply connected constant curvature space form with constant sectional curvature K, then all the above inequalities become equalities. In particular (2.4) becomes

$$J'' = \frac{m-2}{m-1} (J')^2\, J^{-1} - (m-1) K\, J.$$

Theorem 2.1 (Bishop [BC]) *Let M be a complete Riemannian manifold of dimension m, and p be a fixed point of M. Let us assume that the Ricci curvature tensor of M at any point x is bounded below by $(m-1)K(r(p,x))$ for some function K depending only on the distance from p. If $J(\theta, r)\, d\theta$ is the area element of $\partial B_p(r)$ as defined above and $\bar{J}(r)$ is the solution of the ordinary differential equation*

$$\bar{J}'' = \frac{m-2}{m-1} (\bar{J}')^2\, \bar{J}^{-1} - (m-1) K\, \bar{J}$$

with initial conditions

$$\bar{J}(r) \sim r^{m-1}$$

and

$$\bar{J}'(r) \sim (m-1)r^{m-2},$$

as $r \to 0$, *then within the cut-locus of* p *the function* $J(\theta, r)/\bar{J}(r)$ *is a nonincreasing function of* r. *Also, if* $\bar{H}(r) = \bar{J}'/\bar{J}$, *then* $H(\theta, r) \leq \bar{H}(r)$ *whenever* (θ, r) *is within the cut-locus of* p. *In particular, if* K *is a constant, then* $\bar{J}d\theta$ *corresponds to the area element of the sphere of radius* r *in the simply connected space form of constant curvature* K.

Proof By setting $f = J^{1/(m-1)}$, (2.1) and (2.4) can be written as

$$f' = \frac{1}{m-1} H\, f$$

and

$$\begin{aligned} f'' &\leq \frac{-1}{m-1} \mathcal{R}_{rr}\, f \\ &\leq -K\, f. \end{aligned}$$

The initial conditions become

$$f(\theta, 0) = 0$$

and

$$f'(\theta, 0) = 1.$$

Let $\bar{f} = \bar{J}^{1/(m-1)}$ be the corresponding function defined using $\bar{J}$. The function $\bar{f}$ satisfies

$$\begin{aligned} \bar{f}'' &= -K\, \bar{f}, \\ \bar{f}(0) &= 0, \end{aligned}$$

and

$$\bar{f}'(0) = 1.$$

Observe that when K is a constant, the function $\bar{f} > 0$ for all values of $r \in (0, \infty)$ when $K \leq 0$, and for $r \in (0, \pi/\sqrt{K})$ when $K > 0$. In general, $\bar{f} > 0$

on an interval $(0, a)$ for some $a > 0$. At those values of r we can define

$$F(\theta, r) = \frac{f(\theta, r)}{\bar{f}(r)}.$$

We have

$$F' = \bar{f}^{-2}\,(f'\,\bar{f} - f\,\bar{f}')$$

and

$$\begin{aligned} F'' &= \bar{f}^{-1}\,f'' - 2\bar{f}^{-2}\,f'\,\bar{f}' - \bar{f}^{-2}\,f\,\bar{f}'' + 2\bar{f}^{-3}\,f\,(\bar{f}')^2 \\ &\le -2\bar{f}^{-1}\,\bar{f}'\,F', \end{aligned}$$

hence

$$\begin{aligned} (\bar{f}^2 F')' &= \bar{f}^2(F'' + 2\bar{f}^{-1}\,\bar{f}'\,F') \\ &\le 0. \end{aligned}$$

Integrating from ϵ to r yields

$$\begin{aligned} F'(r) &\le F'(\epsilon)\,\bar{f}^2(\epsilon)\,\bar{f}^{-2}(r) \\ &= (\bar{f}(\epsilon)\,f'(\epsilon) - f(\epsilon)\,\bar{f}'(\epsilon))\,\bar{f}^{-2}(r). \end{aligned}$$

Letting $\epsilon \to 0$, the initial conditions of f and $\bar{f}$ imply that

$$F'(r) \le 0.$$

In particular, $\bar{f}\,f' - \bar{f}'\,f \le 0$, implying

$$H(\theta, r) \le \bar{H}(r).$$

Moreover, that F is a nonincreasing function of r implies that $J(\theta, r)/\bar{J}(r)$ is also a nonincreasing function of r. □

By computing the area element and the mean curvature of the constant curvature space form explicitly, we have the following corollary.

Corollary 2.2 *Under the assumption of Theorem 2.1, if K is a constant, then*

$$H \le \begin{cases} (m-1)\sqrt{K}\cot\left(\sqrt{K}r\right) & \textit{for} \quad K > 0, \\ (m-1)r^{-1} & \textit{for} \quad K = 0, \\ (m-1)\sqrt{-K}\coth\left(\sqrt{-K}r\right) & \textit{for} \quad K < 0, \end{cases}$$

and

$$\frac{J(\theta, r)}{\bar{J}(r)}$$

is a nonincreasing function of r, where

$$\bar{J}(r) = \begin{cases} \left(\frac{1}{\sqrt{K}}\right)^{m-1} \sin^{m-1}\left(\sqrt{K}r\right) & \text{for} \quad K > 0, \\ r^{m-1} & \text{for} \quad K = 0, \\ \left(\frac{1}{\sqrt{-K}}\right)^{m-1} \sinh^{m-1}\left(\sqrt{-K}r\right) & \text{for} \quad K < 0. \end{cases}$$

Let us take this opportunity to point out that this estimate implies that when $K > 0$, there must be a cut-point along any geodesic which has length $\pi/\sqrt{K}$. In particular, this proves Myers' theorem.

Corollary 2.3 (Myers) *Let M be an m-dimensional complete Riemannian manifold with Ricci curvature bounded from below by*

$$\mathcal{R}_{ij} \geq (m-1)K$$

for some constant $K > 0$. Then M must be compact with diameter d bounded from above by

$$d \leq \frac{\pi}{\sqrt{K}}.$$

Corollary 2.4 *Let M be an m-dimensional complete Riemannian manifold with Ricci curvature bounded from below by a constant $(m-1)K$. Suppose $\bar{M}$ is an m-dimensional simply connected space form with constant sectional curvature K. Let $A_p(r)$ be the area of the boundary of the geodesic ball $\partial B_p(r)$ centered at $p \in M$ of radius r and $\bar{A}(r)$ be the area of the boundary of a geodesic ball $\partial \bar{B}(r)$ of radius r in $\bar{M}$. Then for $0 \leq r_1 \leq r_2 < \infty$, we have*

$$A_p(r_1)\,\bar{A}(r_2) \geq A_p(r_2)\,\bar{A}(r_1). \tag{2.5}$$

If we let $V_p(r)$ and $\bar{V}(r)$ be the volumes of $B_p(r)$ and $\bar{B}(r)$, respectively, then for $0 \leq r_1 \leq r_2, r_3 \leq r_4 < \infty$ we have

$$\left(V_p(r_2) - V_p(r_1)\right)\left(\bar{V}(r_4) - \bar{V}(r_3)\right) \geq \left(V_p(r_4) - V_p(r_3)\right)\left(\bar{V}(r_2) - \bar{V}(r_1)\right). \tag{2.6}$$

Proof Let us define $C(r)$ to be a subset of the unit tangent sphere $S_p(M)$ at p such that for all $\theta \in C(r)$ the geodesic given by $\gamma(s) = \exp_p(s\theta)$ is minimizing up to $s = r$. Clearly for $r_1 \leq r_2$ we have $C(r_2) \subset C(r_1)$. By Theorem 2.1, we have

$$J(\theta, r_1)\, \bar{J}(r_2) \geq J(\theta, r_2)\, \bar{J}(r_1)$$

for $\theta \in C(r_2)$. Integrating over $C(r_2)$ yields

$$\begin{aligned} \int_{C(r_2)} J(\theta, r_1)\, d\theta\, \bar{J}(r_2) &\geq \int_{C(r_2)} J(\theta, r_2)\, d\theta\, \bar{J}(r_1) \\ &= A_p(r_2)\, \bar{J}(r_1). \end{aligned}$$

On the other hand,

$$\begin{aligned} A_p(r_1) &= \int_{C(r_1)} J(\theta, r_1)\, d\theta \\ &\geq \int_{C(r_2)} J(\theta, r_1)\, d\theta. \end{aligned}$$

Taking this together with the fact that

$$\bar{A}(r) = \alpha_{m-1}\, \bar{J}(r)$$

with α_{m-1} being the area of the unit $(m-1)$-sphere, we conclude (2.5).

To see (2.6), we first assume that $r_1 \leq r_2 \leq r_3 \leq r_4$ and we simply integrate the inequality

$$A_p(t_1)\, \bar{A}(t_2) \geq A_p(t_2)\, \bar{A}(t_1)$$

over $r_1 \leq t_1 \leq r_2$ and $r_3 \leq t_2 \leq r_4$. For the case when $r_1 \leq r_3 \leq r_2 \leq r_4$, we write

$$\begin{aligned} &\big(V_p\,(r_2) - V_p(r_1)\big)\big(\bar{V}(r_4) - \bar{V}(r_3)\big) \\ &\quad = \big(V_p(r_3) - V_p(r_1)\big)\big(\bar{V}(r_2) - \bar{V}(r_3)\big) \\ &\qquad + \big(V_p(r_3) - V_p(r_1)\big)\big(\bar{V}(r_4) - \bar{V}(r_2)\big) \\ &\qquad + \big(V_p(r_2) - V_p(r_3)\big)\big(\bar{V}(r_2) - \bar{V}(r_3)\big) \\ &\qquad + \big(V_p(r_2) - V_p(r_3)\big)\big(\bar{V}(r_4) - \bar{V}(r_2)\big) \end{aligned}$$

$$\begin{aligned}
&\geq \big(V_p(r_2) - V_p(r_3)\big)\big(\bar{V}(r_3) - \bar{V}(r_1)\big) \\
&\quad + \big(V_p(r_4) - V_p(r_2)\big)\big(\bar{V}(r_3) - \bar{V}(r_1)\big) \\
&\quad + \big(V_p(r_2) - V_p(r_3)\big)\big(\bar{V}(r_2) - \bar{V}(r_3)\big) \\
&\quad + \big(V_p(r_4) - V_p(r_2)\big)\big(\bar{V}(r_2) - \bar{V}(r_3)\big) \\
&= \big(V_p(r_4) - V_p(r_3)\big)\big(\bar{V}(r_2) - \bar{V}(r_1)\big).
\end{aligned} \qquad \square$$

Let us point out that equality in (2.6) holds if and only if $C(r_1) = C(r_4)$ and $J(\theta, r) = \bar{J}(r)$ for all $0 \leq r \leq r_4$ and $\theta \in C(r_1)$. In particular, if $r_1 = 0$, then $J(\theta, r) = \bar{J}(r)$ for all $r \leq r_4$ and $\theta \in S_p(M)$. This implies that $B_p(r_4)$ is isometric to $\bar{B}(r_4)$.

Theorem 2.5 *Let M be an m-dimensional complete Riemannian manifold with nonnegative Ricci curvature. Then the volume growth of M must satisfy the following estimates:*

(1) *(Bishop) If α_{m-1} is the area of the unit $(m-1)$-sphere, then*

$$V_p(\rho) \leq \frac{\alpha_{m-1}}{m}\,\rho^m$$

for all $p \in M$ and $\rho \geq 0$.

(2) *(Yau [Y2]) For all $p \in M$, there exists a constant $C(m) > 0$ depending only on m, such that*

$$V_p(\rho) \geq C\, V_p(1)\, \rho$$

for all $\rho > 2$.

Proof Applying (2.6) to $r_1 = 0 = r_3$ and $r_4 = r$, we have

$$V_p(r_2)\,\bar{V}(r) \geq V_p(r)\,\bar{V}(r_2).$$

Observing that

$$\lim_{r_2 \to 0} \frac{V_p(r_2)}{\bar{V}(r_2)} = 1,$$

the upper bound follows.

To prove the lower bound, let $x \in \partial B_p(1+\rho)$. Then (2.6) and the curvature assumption imply that

$$V_x(2+\rho) - V_x(\rho) \leq V_x(\rho)\,\frac{(2+\rho)^m - \rho^m}{\rho^m}. \tag{2.7}$$

However, since the distance between p and x is $r(p,x)=1+\rho$, we have $B_p(1)\subset(B_x(2+\rho)\setminus B_x(\rho))$, hence

$$V_p(1)\le V_x(2+\rho)-V_x(\rho). \tag{2.8}$$

Since $B_x(\rho)\subset B_p(1+2\rho)$, we have

$$V_x(\rho)\le V_p(1+2\rho),$$

therefore combining this with (2.7) and (2.8), we conclude that

$$V_p(1)\le V_p(1+2\rho)\,\frac{(2+\rho)^m-\rho^m}{\rho^m}.$$

The lower bounded follows by observing that

$$\frac{(2+\rho)^m-\rho^m}{\rho^m}=C\,\rho^{-1}$$

for $\frac{1}{2}\rho\to\infty$. □

We would like to remark that if we assume that for a sufficiently small $\epsilon>0$ the Ricci curvature has a lower bound of the form

$$\mathcal{R}_{ij}(x)\ge-\epsilon(1+r(p,x))^{-2},$$

then one can show that M must have infinite volume. On the other hand, if the Ricci curvature is bounded from below by

$$\mathcal{R}_{ij}(x)\ge-C_0(1+r(p,x))^{-2-\delta}$$

for some constants $C_0,\delta>0$, then the upper bound is also valid and is of the form

$$V_p(r)\le Cr^m,$$

where $C(C_0,\delta,m)>0$ is a constant depending on C_0, δ and m.

It is also a good exercise to show that if a complete manifold has Ricci curvature bounded from below by

$$\mathcal{R}_{ij}\ge\epsilon r(p,x)^{-2}$$

for some constant $\epsilon>\frac{1}{4}$ and for all $r>1$, then M must be compact.

The next theorem shows that when the upper bound of the diameter given by Myers' theorem is achieved, then the manifold must be isometrically a sphere.

Theorem 2.6 (Cheng [Cg1]) *Let M be a complete m-dimensional Riemannian manifold with Ricci curvature bounded from below by*

$$\mathcal{R}_{ij} \geq (m-1)K$$

for some constant $K > 0$. If the diameter d of M satisfies

$$d = \frac{\pi}{\sqrt{K}},$$

then M is isometric to the standard sphere of radius $1/\sqrt{K}$.

Proof By scaling, we may assume that $K = 1$. Let p and q be a pair of points in M which realize the diameter. The volume comparison theorem implies that

$$V_p(d) \leq V_p\left(\frac{d}{2}\right) \frac{\bar{V}(d)}{\bar{V}\,(d/2)}.$$

The assumption that $d = \pi/\sqrt{K}$ implies that

$$\frac{\bar{V}(d)}{\bar{V}\,(d/2)} = 2,$$

hence

$$V_p(d) \leq 2V_p\left(\frac{d}{2}\right).$$

Similarly, we have

$$V_q(d) \leq 2V_q\left(\frac{d}{2}\right).$$

However, by the triangle inequality and the fact that $d = r(p,q)$, we have $B_p(d/2) \cap B_q(d/2) = \emptyset$. Therefore,

$$\begin{aligned} 2V(M) &= V_p(d) + V_q(d) \\ &\leq 2\left(V_p\left(\frac{d}{2}\right) + V_q\left(\frac{d}{2}\right)\right) \\ &\leq 2V(M), \end{aligned}$$

where $V(M)$ denotes the volume of M. This implies that the inequalities in the volume comparison theorem are in fact equalities. Hence by the remark following Corollary 2.4 M must be the standard sphere. □

2.4 The Projective Space

The aim of this section is to present certain explicit calculations for the projective space $\mathbb{P}^n$. We shall describe sections of the holomorphic line bundles $\mathcal{O}(k)$ on $\mathbb{P}^n$ and show that the canonical bundle $K_{\mathbb{P}^n}$ of the projective space $\mathbb{P}^n$ is isomorphic to the line bundle $\mathcal{O}(-n-1)$. It will turn out that everything can be expressed in polynomials, which turns complex geometry for $\mathbb{P}^n$ into complex algebraic geometry.

In order to determine all holomorphic sections of $\mathcal{O}(k)$, let us first recall that $\mathcal{O}(-1)$ is the holomorphic line bundle which is naturally embedded into the trivial vector bundle $\mathcal{O}^{\oplus n+1}$ such that the fibre of $\mathcal{O}(-1)$ over $\ell \in \mathbb{P}^n$ is $\ell \subset \mathbb{C}^{n+1}$ (cf. Proposition 2.2.6).

We will also use the following observation. If E is a holomorphic subbundle of F, then the inclusion $E \subset F$ naturally defines an inclusion of all tensor products $E^{\otimes k} \subset F^{\otimes k}$. In particular, for $k > 0$ the line bundle $\mathcal{O}(-k)$ is a subbundle of $\mathbb{P}^n \times (\mathbb{C}^{n+1})^{\otimes k}$.

Any homogeneous polynomial $s \in \mathbb{C}[z_0, \ldots, z_n]_k$ of degree k defines a linear map $(\mathbb{C}^{n+1})^{\otimes k} \to \mathbb{C}$. This gives rise to a holomorphic map $\mathbb{P}^n \times (\mathbb{C}^{n+1})^{\otimes k} \to \mathbb{C}$ which is linear on any fibre of the projection to $\mathbb{P}^n$. The restriction to $\mathcal{O}(-k)$ thus provides a holomorphic section of $\mathcal{O}(k)$. This way we associate to any homogeneous polynomial s of degree k a global holomorphic section of $\mathcal{O}(k)$, which will also be called s (cf. Exercise 2.2.8).

Proposition 2.4.1 *For $k \geq 0$ the space $H^0(\mathbb{P}^n, \mathcal{O}(k))$ is canonically isomorphic to the space $\mathbb{C}[z_0, \ldots, z_n]_k$ of all homogeneous polynomials of degree k.*

Proof. Note that the section associated to a non-trivial polynomial $0 \neq s \in \mathbb{C}[z_0, \ldots, z_n]_k$ is not trivial. Indeed, the composition $\mathcal{O}(-1) \subset \mathbb{P}^n \times \mathbb{C}^{n+1} \to \mathbb{C}^{n+1}$ is surjective and, therefore, any polynomial s that induces the trivial section of $\mathcal{O}(k)$ defines a trivial map $\mathbb{C}^{n+1} \to \mathbb{C}$, i.e. $s = 0$. Since the map $\mathbb{C}[z_0, \ldots, z_n]_k \to H^0(\mathbb{P}^n, \mathcal{O}(k))$ is clearly linear, it suffices to show surjectivity.

Let $0 \neq t \in H^0(\mathbb{P}^n, \mathcal{O}(k))$. Choose a non-trivial $0 \neq s_0 \in H^0(\mathbb{P}^n, \mathcal{O}(k))$ induced by a homogeneous polynomial of degree k and consider the meromorphic function $F := t/s_0 \in K(\mathbb{P}^n)$ (cf. Remark 2.3.24). Composing with the projection $\mathbb{C}^{n+1} \setminus \{0\} \to \mathbb{P}^n$ yields a meromorphic map $\tilde{F} \in K(\mathbb{C}^{n+1} \setminus \{0\})$. Moreover, $G := s_0 \cdot \tilde{F}$ is a holomorphic function $\mathbb{C}^{n+1} \setminus \{0\} \to \mathbb{C}$, which, due to Hartogs' theorem 1.1.4, can be extended to a holomorphic function $G : \mathbb{C}^{n+1} \to \mathbb{C}$. By definition of $\tilde{F}$ and G, this function is homogeneous of degree k, i.e. $G(\lambda \cdot z) = \lambda^k \cdot G(z)$ for $\lambda \in \mathbb{C}$ and $z \in \mathbb{C}^{n+1}$.

Using the power series expansion of G in $z = 0$ this proves that G is a homogeneous polynomial s of degree k. Clearly, the section of $\mathcal{O}(k)$ induced by G equals $t \in H^0(\mathbb{P}^n, \mathcal{O}(k))$. □

It should be obvious from the proof that the isomorphism described above is compatible with the multiplicative structure, i.e. we obtain a ring isomorphism

$$R(\mathbb{P}^n, \mathcal{O}(1)) = \bigoplus_{k\geq 0} H^0(\mathbb{P}^n, \mathcal{O}(k)) \cong \mathbb{C}[z_0, \ldots, z_n].$$

Applying Exercise 2.2.5 the proposition also yields

Corollary 2.4.2 *For $k < 0$ the line bundle $\mathcal{O}(k)$ admits no global holomorphic sections, i.e. $H^0(\mathbb{P}^n, \mathcal{O}(k)) = 0$.* □

The higher cohomology groups of $\mathcal{O}(k)$ will be computed in Example 5.2.5 by applying the Kodaira vanishing theorem.

Let us next construct an isomorphism $K_{\mathbb{P}^n} \cong \mathcal{O}(-n-1)$. This can be done by a direct cocycle calculation or by using the Euler sequence. We shall discuss both. Using the adjunction formula, the isomorphism $K_{\mathbb{P}^n} \cong \mathcal{O}(-n-1)$ will enable us to compute the Kodaira dimension of hypersurfaces and complete intersections.

First, let us recall the standard open covering of $\mathbb{P}^n$ (see page 56). Let U_i be the open set

$$U_i := \{(z_0 : \ldots : z_n) \mid z_i \neq 0\} \subset \mathbb{P}^n.$$

Then $\mathbb{P}^n = \bigcup_{i=0}^n U_i$ and the maps

$$\varphi_i : U_i \longrightarrow \mathbb{C}^n, \quad (z_0 : \ldots : z_n) \longmapsto \left(\tfrac{z_0}{z_i}, \ldots, \widehat{\tfrac{z_i}{z_i}}, \ldots, \tfrac{z_n}{z_i}\right)$$

are biholomorphic. For $i > j$ the transition map

$$\varphi_{ij} = \varphi_i \circ \varphi_j{}^{-1} : \{(w_1, \ldots, w_n) \mid w_i \neq 0\} \longmapsto \{(w_1, \ldots, w_n) \mid w_j \neq 0\}$$

is the composition of

$$\tilde{\varphi}_{ij}(w_1, \ldots, w_n) = (w_i^{-1}w_1, \ldots, w_i^{-1}w_{i-1}, w_i^{-1}, w_i^{-1}w_{i+1}, \ldots, w_i^{-1}w_n)$$

and the permutation $(j+1, i)$, the signature of which is $(-1)^{i-j-1}$.

Proposition 2.4.3 *The canonical bundle $K_{\mathbb{P}^n}$ is isomorphic to $\mathcal{O}(-n-1)$.*

Proof. By definition $K_{\mathbb{P}^n} \cong \det(\mathcal{T}^*_{\mathbb{P}^n})$, where the holomorphic tangent bundle $\mathcal{T}_{\mathbb{P}^n}$ is uniquely determined by its cocycle $\{J(\varphi_{ij}) \circ \varphi_j : U_i \cap U_j \to \mathrm{Gl}(n, \mathbb{C})\}$. Thus, it suffices to show that the line bundle associated to the cocycle $\{\det(J(\varphi_{ij})) \circ \varphi_j\}$ is isomorphic to $\mathcal{O}(n+1)$. Using the above remark, we have

$$\det(J(\varphi_{ij})) = (-1)^{i-j-1}\det\left(\frac{\partial \tilde{\varphi}^k_{ij}}{\partial w_\ell}\right)_{k,\ell},$$

where $\tilde{\varphi}_{ij} = (\tilde{\varphi}^1_{ij}, \ldots, \tilde{\varphi}^n_{ij})$.

The matrix $\left(\frac{\partial\bar{\varphi}_{ij}^k}{\partial w_\ell}\right)_{k,\ell}$ is easily identified as

$$\begin{pmatrix}
w_i^{-1} & 0 & \cdot\,\cdot & 0 & -\frac{w_1}{w_i^2} & 0 & \cdot\quad\cdot & 0 \\
0 & w_i^{-1} & \cdot\,\cdot & 0 & -\frac{w_2}{w_i^2} & 0 & \cdot\quad\cdot & 0 \\
\cdot & & & & & & & \cdot \\
\cdot & & & & & & & \cdot \\
0 & \cdot & \cdot\,\cdot & w_i^{-1} & -\frac{w_{i-1}}{w_i^2} & 0 & \cdot\quad\cdot & 0 \\
 & & & & -\frac{1}{w_i^{-2}} & 0 & \cdot\quad\cdot & 0 \\
0 & \cdot & \cdot\,\cdot & 0 & -\frac{w_{i+1}}{w_i^2} & w_i^{-1} & \cdot\quad\cdot & 0 \\
 & & & & & & & \\
0 & \cdot & \cdot\,\cdot & 0 & -\frac{w_n}{w_i^2} & 0 & \cdot\quad\cdot & w_i^{-1}
\end{pmatrix}$$

Hence, $\det\left(\frac{\partial\bar{\varphi}_{ij}^k}{\partial w_\ell}\right) = -w_i^{-(n+1)}$ and, therefore,

$$\det(J(\varphi_{ij}))\circ\varphi_j = (-1)^{i-j}w_i^{-(n+1)}\circ\varphi_j = (-1)^{i-j}(z_i/z_j)^{-(n+1)}.$$

On the other hand, $\mathcal{O}(-1)$ is the line bundle $\{(\ell, z) \mid z \in \ell\} \subset \mathbb{P}^n \times \mathbb{C}^{n+1}$, to which is associated the cocycle $\{z_i/z_j\}$ (cf. Proposition 2.2.6). Thus, $\mathcal{O}(n+1)$ corresponds to the cocycle $\{(z_j/z_i)^{n+1}\}$. The two cocyles $\{(z_j/z_i)^{n+1}\}$ and $\{(-1)^{i-j}(z_i/z_j)^{-(n+1)}\}$ define isomorphic line bundles, for they only differ by the boundary of the cocycle $\{\eta_i \equiv (-1)^i : U_i \to \mathbb{C}^* \subset \mathcal{O}^*\}$. □

Recall that any short exact sequence $0 \to E \to F \to G \to 0$ of holomorphic vector bundles (or locally free sheaves), induces a canonical isomorphism $\det(F) \cong \det(E)\otimes\det(G)$ (cf. viii) of Example 2.2.4). Thus, the above proposition is also a consequence of the following one.

Proposition 2.4.4 (Euler sequence) *On $\mathbb{P}^n$ there exists a natural short exact sequence of holomorphic vector bundles*

$$\begin{tikzcd} 0 \arrow[r] & \mathcal{O} \arrow[r] & \bigoplus_{j=0}^n \mathcal{O}(1) \arrow[r] & \mathcal{T}_{\mathbb{P}^n} \arrow[r] & 0. \end{tikzcd}$$

Proof. The inclusion $\mathcal{O} \subset \bigoplus_{j=0}^n \mathcal{O}(1)$ is obtained from the natural inclusion $\mathcal{O}(-1) \subset \bigoplus_{j=0}^n \mathcal{O}$ (cf. Proposition 2.2.6) by twisting with $\mathcal{O}(1)$ (cf. Exercise 2.2.4). It suffices to show that the kernel of the dual map $\bigoplus_{j=0}^n \mathcal{O}(-1) \to \mathcal{O}$ is canonically isomorphic to $\Omega_{\mathbb{P}^n}$. (Here we use that a sequence of holomorphic vector bundles $0 \to E \to F \to G \to 0$ is exact if and only if $0 \to G^* \to F^* \to E^* \to 0$ is exact.)

The proof of the identification of $\Omega_{\mathbb{P}^n}$ with the kernel is a little tedious. Using the standard trivialization of $\bigoplus_{j=0}^n \mathcal{O}(-1)|_{U_i}$ we will identify $\Omega_{\mathbb{P}^n}|_{U_i}$ in a natural way with the kernel of the surjection $\bigoplus_{j=0}^{n}\mathcal{O}(-1)\to\mathcal{O}$ over U_i. The proof concludes by showing that these inclusions glue.

First note that for any local holomorphic function $f: U\to\mathbb{C}$, where $U\subset X$ is an open subset of an arbitrary manifold X the differential $df=\partial f$ is a section of $\Omega_X|_U$ (cf. Exercise 2.2.10 or Section 2.6). Moreover, if $\varphi: U_i\cong\varphi(U_i)\subset\mathbb{C}^n$ is a local coordinate system, then $\Omega_X|_U=\bigoplus_{k=1}^{n}(d\varphi^k)\cdot\mathcal{O}_U$. In our situation $\Omega_{\mathbb{P}^n}|_{U_i}=\bigoplus_{i\neq k=0}^{n}d\left(\frac{z_k}{z_i}\right)\cdot\mathcal{O}_{U_i}$.

Since $\mathcal{O}(-1)|_{U_i}$ is canonically trivialized by $(\ell,z)\mapsto z_i$, one has a natural diagonal trivialization $\psi_i(\ell,z^0,\ldots,z^n)=(\ell,z_i^0,\ldots,z_i^n)$ of $\bigoplus_{k=0}^{n}\mathcal{O}(-1)|_{U_i}$. In this trivialization the surjection $\varphi:\bigoplus\mathcal{O}(-1)\to\mathcal{O}$ is the map

$$\varphi_i(\ell,w_0,\ldots,w_n)=\sum_{k=0}^{n}w_k\frac{z_k}{z_i}.$$

Hence, the map

$$\phi_i:\Omega_{\mathbb{P}^n}|_{U_i}=\bigoplus_{k=0}^{n}d\left(\tfrac{z_k}{z_i}\right)\cdot\mathcal{O}_{U_i}\longrightarrow\bigoplus_{k=0}^{n}\mathcal{O}_{U_i},\quad d\left(\tfrac{z_k}{z_i}\right)\longmapsto e_k-\tfrac{z_k}{z_i}e_i,$$

where e_k is the k-th unit vector in $\bigoplus_{k=0}^{n}\mathcal{O}$, identifies $\Omega_{\mathbb{P}^n}|_{U_i}$ with the kernel of φ_i.

Let us now check that $\phi_i(d\left(\frac{z_k}{z_i}\right))=(\psi_i\psi_j^{-1})(\phi_j(d\left(\frac{z_k}{z_i}\right)))$. Here we use

$$d\left(\frac{z_k}{z_i}\right)=d\left(\frac{z_k}{z_j}\right)\frac{z_j}{z_i}-\frac{z_k}{z_i}\frac{z_j}{z_i}d\left(\frac{z_i}{z_j}\right).$$

Thus,

$$\phi_j\left(d\left(\frac{z_k}{z_i}\right)\right)=\frac{z_j}{z_i}\left(e_k-\frac{z_k}{z_j}e_j\right)-\frac{z_k}{z_i}\frac{z_j}{z_i}\left(e_i-\frac{z_i}{z_j}e_j\right)=\frac{z_j}{z_i}\left(e_k-\frac{z_k}{z_i}e_i\right).$$

Since $\psi_i\psi_j^{-1}$ is given by multiplication with $\frac{z_i}{z_j}$, this concludes the proof. ☐

Remark 2.4.5 The dual of the Euler sequence twisted by $\mathcal{O}(1)$ takes the form

$$0\longrightarrow\Omega_{\mathbb{P}^n}(1)\longrightarrow\bigoplus_{j=0}^{n}\mathcal{O}\longrightarrow\mathcal{O}(1)\longrightarrow 0. \tag{2.1}$$

Let us think of $\mathbb{P}^n$ more invariantly as $\mathbb{P}(V)$ with V a complex vector space of dimension $n+1$. In particular, V^* is naturally identified with the space of homogeneous linear forms on V and, therefore, $V^*=H^0(\mathbb{P}(V),\mathcal{O}(1))$. The exact sequence (2.1) can in this context be written as

$$0\longrightarrow\Omega_{\mathbb{P}(V)}(1)\longrightarrow V^*\otimes\mathcal{O}\longrightarrow\mathcal{O}(1)\longrightarrow 0,$$

where the surjection $V^*\otimes\mathcal{O}\to\mathcal{O}(1)$ is the evaluation map.

The advantage of writing the Euler sequence coordinate free is that it lends itself to important generalizations in the relative context, but we only mention this in passing:

If E is a holomorphic vector bundles over X, any fibre $\pi^{-1}(x)$ of the projection $\pi : \mathbb{P}(E) \to X$ is a complex projective space $\mathbb{P}(E(x))$ which comes with the Euler sequence

$$\begin{tikzcd} 0 \arrow[r] & \Omega_{\mathbb{P}(E(x))}(1) \arrow[r] & E(x)^* \otimes \mathcal{O} \arrow[r] & \mathcal{O}(1) \arrow[r] & 0. \end{tikzcd}$$

It turns out that these sequences can be glued to the *relative Euler sequence*

$$\begin{tikzcd} 0 \arrow[r] & \Omega_\pi \otimes \mathcal{O}_\pi(1) \arrow[r] & \pi^* E^* \arrow[r] & \mathcal{O}_\pi(1) \arrow[r] & 0, \end{tikzcd}$$

where $\mathcal{O}_\pi(1)$ is the (dual of the) relative tautological bundle (see Exercise 2.4.9) and $\mathcal{T}_\pi = \Omega_\pi^*$ is the relative tangent bundle defined as the kernel of $\mathcal{T}_{\mathbb{P}(E)} \to \pi^*\mathcal{T}_X$.

Corollary 2.4.6 *One has* $\mathrm{kod}(\mathbb{P}^n) = -\infty$.

Proof. Since the line bundles $\mathcal{O}(d)$ have global sections for $d \geq 0$, none of the powers $K_{\mathbb{P}^n}^{\otimes m} = \mathcal{O}(-m(n+1))$ for $m > 0$ admits non-trivial global sections (Corollary 2.4.2). Thus, the canonical ring $R(\mathbb{P}^n)$ is isomorphic to $\mathbb{C}$. □

This yields in particular an example of a complex compact manifold with $\mathrm{kod}(X) < a(X)$. Other examples are provided by projective complex tori.

In order to compute the canonical bundle of hypersurfaces in $\mathbb{P}^n$, or more generally of complete intersections, we will need one more result. The following works for any complex manifold Y and not just the projective space.

Proposition 2.4.7 *Let X be a smooth hypersurface of a complex manifold Y defined by a section $s \in H^0(Y, L)$ of some holomorphic line bundle L on Y. Then $\mathcal{N}_{X/Y} \cong L|_X$ and thus $K_X \cong (K_Y \otimes L)|_X$.*

Proof. First observe the following fact: Let $\varphi = (\varphi^1, \ldots, \varphi^n)$ be a holomorphic map $U \to \mathbb{C}^n$ of some connected open neighbourhood $U \subset \mathbb{C}^n$ of the origin, such that $\varphi^n(z_1, \ldots, z_{n-1}, 0) = 0$ for all $(z_1, \ldots, z_{n-1}, 0) \in U$. Then $\varphi^n(z) = z_n \cdot h(z_1, \ldots, z_n)$, where $h(z_1, \ldots, z_n)$ is a power series in $z_1, \ldots, z_n$. Hence,

$$\frac{\partial \varphi^n}{\partial z_k}(z_1, \ldots, z_{n-1}, 0) = \begin{cases} 0 & \text{for } k = 1, \ldots, n-1 \\ h(z_1, \ldots z_{n-1}, 0) & \text{for } k = n \end{cases}$$

Let us apply this to our situation. We may fix local coordinates $\varphi_i : U_i \cong \varphi_i(U_i) \subset \mathbb{C}^n$, such that $\varphi_i(U_i \cap X) = \{(z_1, \ldots, z_n) \in \varphi_i(U_i) \mid z_n = 0\}$. Thus, the transition maps $\varphi_{ij} : \varphi_j(U_i \cap U_j) \cong \varphi_i(U_i \cap U_j)$ have the above property.

This yields

$$J(\varphi_{ij})|_X = \begin{pmatrix} J(\varphi_{ij}|_X) & * \\ 0 & \frac{\partial \varphi_{ij}^n}{\partial z_n}|_X \end{pmatrix}$$

By Proposition 2.2.17, the normal bundle $\mathcal{N}_{X/Y}$ corresponds to the cocycle $\{\frac{\partial \varphi_{ij}^n}{\partial z_n} \circ \varphi_j|_X\}$.

On the other hand, due to Proposition 2.3.18, one has $L \cong \mathcal{O}(X)$ and, therefore, L corresponds to the cocycle $\{\frac{s_i}{s_j}\}$, where s_i and s_j are local equations of X on U_i respectively U_j. Thus, $s_i = \varphi_i^n$. Hence, for $x \in X$ with $\varphi_j(x) = (z_1, \ldots z_{n-1}, 0)$ one has

$$\begin{aligned} \frac{s_i}{s_j}(x) &= \frac{\varphi_i^n}{\varphi_j^n}(x) = \frac{(\varphi_{ij} \circ \varphi_j)^n}{\varphi_j^n}(x) \\ &= \left(\frac{\varphi_{ij}^n}{z_n} \circ \varphi_j\right)(x) = h(z_1, \ldots, z_{n-1}, 0) \\ &= \frac{\partial \varphi_{ij}^n}{\partial z_n}(z_1, \ldots, z_{n-1}, 0) = \left(\frac{\partial \varphi_{ij}^n}{\partial z_n} \circ \varphi_j\right)(x). \end{aligned}$$

Therefore, both line bundles $\mathcal{O}(X)|_X$ and $\mathcal{N}_{X/Y}$ are given by the same cocycle.

The last assertion follows from the adjunction formula 2.2.17. □

Remark 2.4.8 Note that the isomorphism $\mathcal{N}_{Y/X} \cong \mathcal{O}(X)|_X$ can locally be described as the map induced by $\mathcal{T}_Y \twoheadrightarrow \mathcal{O}(X)|_X$, $\frac{\partial}{\partial z} \mapsto \frac{\partial s}{\partial z_i}|_X$.

Corollary 2.4.9 *If $X \subset \mathbb{P}^n$ is a smooth hypersurface of degree d, i.e. defined by a section $s \in H^0(\mathbb{P}^n, \mathcal{O}(d))$, then $K_X \cong \mathcal{O}(d-n-1)|_X$.* □

Exercises

2.4.1 Show that the canonical bundle K_X of a complete intersection $X = Z(f_1) \cap \ldots \cap Z(f_k) \subset \mathbb{P}^n$ is isomorphic to $\mathcal{O}(\sum \deg(f_i) - n - 1))|_X$. What can you deduce from this for the Kodaira dimension of X?

2.4.2 Are there holomorphic vector fields on $\mathbb{P}^n$, i.e. global sections of $\mathcal{T}_{\mathbb{P}^n}$, which vanish only in a finite number of points? If yes, in how many?

2.4.3 Compute the Kodaira dimension of the following smooth hypersurfaces: i) $Z\left(\sum_{i=0}^2 x_i^2\right) \subset \mathbb{P}^2$, ii) $Z\left(\sum_{i=0}^2 x_i^3\right) \subset \mathbb{P}^2$, iii) $Z\left(\sum_{i=0}^3 x_i^3\right) \subset \mathbb{P}^3$, and iv) $Z\left(\sum_{i=0}^4 x_i^5\right) \subset \mathbb{P}^4$.

2.4.4 Show that $H^0(\mathbb{P}^n, \Omega_{\mathbb{P}^n}^q) = 0$ for $q > 0$.

2.4.5 The surface $\Sigma_n = \mathbb{P}(\mathcal{O}_{\mathbb{P}^1} \oplus \mathcal{O}_{\mathbb{P}^1}(n))$ is called the n-th *Hirzebruch surface.* Show that Σ_n is isomorphic to the hypersurface $Z(x_0^n y_1 - x_1^n y_2) \subset \mathbb{P}^1 \times \mathbb{P}^2$, where $(x_0 : x_1)$ and $(y_0 : y_1 : y_2)$ are the homogeneous coordinates of $\mathbb{P}^1$ respectively $\mathbb{P}^2$.

2.4.6 Describe the tangent, cotangent, and canonical bundle of $\mathbb{P}^n \times \mathbb{P}^m$.

2.4.7 Determine all complete intersections $X = H_1 \cap \ldots \cap H_{n+m-2} \subset \mathbb{P}^n \times \mathbb{P}^m$ with $H_i \in |p_1^*\mathcal{O}(d_i) \otimes p_2^*\mathcal{O}(e_i)|$, $d_i, e_i > 0$ with trivial canonical bundle.

2.4.8 Let $Y \subset X$ be a smooth hypersurface in a complex manifold X of dimension n and let α be a meromorphic section of K_X with at most simple poles along Y. Locally one can write $\alpha = h \cdot \frac{dz_1}{z_1} \wedge dz_2 \wedge \ldots \wedge dz_n$ with z_1 defining Y. One sets $\mathrm{Res}_Y(\alpha) = (h \cdot dz_2 \wedge \ldots \wedge dz_n)|_Y$.

a) Show that $\mathrm{Res}_Y(\alpha)$ is well defined and that it yields an element in $H^0(Y, K_Y)$.

b) Consider α as an element in $H^0(X, K_X \otimes \mathcal{O}(Y))$ and compare the definition of the residue with the adjunction formula: $K_Y \cong (K_X \otimes \mathcal{O}(Y))|_Y$.

c) Consider a smooth hypersurface $Y \subset \mathbb{P}^n$ defined by a homogeneous polynomial $f \in H^0(\mathbb{P}^n, \mathcal{O}(n+1))$. Prove that $\alpha := \sum (-1)^i z_i f^{-1} dz_0 \wedge \ldots \wedge \widehat{dz_i} \wedge \ldots \wedge dz_n$ is a meromorphic section of $K_{\mathbb{P}^n}$ with simple poles along Y. Furthermore, show that $\mathrm{Res}_Y(\alpha) \in H^0(Y, K_Y)$ defines a holomorpic volume form on Y, i.e. a trivializing section of K_Y.

2.4.9 Let E be a holomorphic vector bundle on a complex manifold X. Construct the relative tautological holomorphic line bundle $\mathcal{O}_\pi(-1)$ on $\mathbb{P}(E)$. Here, $\pi : \mathbb{P}(E) \to X$ denotes the projection and the fibre $\mathcal{O}_\pi(-1)(\ell)$ for a line $\ell \subset E(x)$ representing a point $\ell \in \pi^{-1}(x)$ should be, by construction, identified with ℓ.

2.4.10 This exercise generalizes the Euler sequence to Grassmannians. Show that on $\mathrm{Gr}_k(V)$ there exists a natural short exact sequence (the tautological sequence) of holomorphic vector bundles

$$\begin{tikzcd} 0 \arrow[r] & S \arrow[r] & \mathcal{O} \otimes V \arrow[r] & Q \arrow[r] & 0 \end{tikzcd}$$

such that over a point $w \in \mathrm{Gr}_k(V)$ corresponding to $W \subset V$ the inclusion $S(w) \subset (\mathcal{O} \otimes V)(w) = V$ is just $W \subset V$. Moreover, prove that $\mathrm{Hom}(S, Q)$ is isomorphic to the holomorphic tangent bundle of $\mathrm{Gr}_k(V)$. Observe that this generalize what has been said about the Euler sequence on $\mathbb{P}^n$ which corresponds to the case $k = 1$

2.4.11 Let X be a complex manifold and let $\mathcal{O}_X \otimes V \twoheadrightarrow E$ be a surjection of vector bundles where V is a vector space and E is a vector bundle of rank k. Show that there exists a natural morphism $\varphi : X \to \mathrm{Gr}_k(V)$ with $\varphi^*(\mathcal{O} \otimes V \to Q) = \mathcal{O}_X \otimes V \to E$. Proposition 2.3.26 is the special case $k = 1$. Compare the Euler sequence with the tautological sequence introduced in the previous exercise via the Plücker embedding.

4.3 Curvature

In the previous paragraph we introduced the notion of a connection generalizing the exterior differential to sections of vector bundles. Indeed, by definition a connection satisfies the Leibniz rule. However, in general a connection ∇ need not satisfy $\nabla^2 = 0$, i.e. ∇ is not a differential. The obstruction for a connection to define a differential is measured by its curvature. This concept will be explained now.

The reader familiar with the basic concepts in Riemannian geometry will find the discussion similar to the treatment of the curvature of a Riemannian manifold. As before, we shall also study what happens in the presence of additional structures, e.g. hermitian and holomorphic ones.

Let E be a vector bundle on a manifold M endowed with a connection $\nabla : \mathcal{A}^0(E) \to \mathcal{A}^1(E)$. Then a natural extension

$$\nabla : \mathcal{A}^k(E) \longrightarrow \mathcal{A}^{k+1}(E)$$

is defined as follows: If α is a local k-form on M and s is a local section of E then

$$\nabla(\alpha \otimes s) = d(\alpha) \otimes s + (-1)^k \alpha \wedge \nabla(s).$$

Observe that for $k = 0$ this is just the Leibniz formula (4.2) which also ensures that the extension is well-defined, i.e. $\nabla(\alpha \otimes (f \cdot s)) = \nabla(f\alpha \otimes s)$ for any local function f. Moreover, a generalized Leibniz rule also holds for this extension, i.e. for any section t of $\mathcal{A}^\ell(E)$ and any k-form β one has

$$\nabla(\beta \wedge t) = d(\beta) \wedge t + (-1)^k \beta \wedge \nabla(t).$$

Indeed, if $t = \alpha \otimes s$ then

$$\begin{aligned} \nabla(\beta \wedge t) &= \nabla((\beta \wedge \alpha) \otimes s) = d(\beta \wedge \alpha) \otimes s + (-1)^{k+\ell}(\beta \wedge \alpha) \otimes \nabla(s) \\ &= d(\beta) \wedge t + (-1)^k((\beta \wedge d(\alpha)) \otimes s + (-1)^\ell(\beta \wedge \alpha) \otimes \nabla(s)) \\ &= d(\beta) \wedge t + (-1)^k \beta \wedge \nabla(t) \end{aligned}$$

Definition 4.3.1 The *curvature* F_∇ of a connection ∇ on a vector bundle E is the composition

$$F_\nabla := \nabla \circ \nabla : \mathcal{A}^0(E) \longrightarrow \mathcal{A}^1(E) \longrightarrow \mathcal{A}^2(E).$$

Usually, the curvature F_∇ will be considered as a global section of $\mathcal{A}^2(\mathrm{End}(E))$, i.e. $F_\nabla \in \mathcal{A}^2(M, \mathrm{End}(E))$. This is justified by the following result.

Lemma 4.3.2 *The curvature homomorphism* $F_\nabla : \mathcal{A}^0(E) \to \mathcal{A}^2(E)$ *is* $\mathcal{A}^0$-*linear.*

Proof. For a local section s of E and a local function f on M one computes

$$\begin{aligned} F_\nabla(f\cdot s) &= \nabla(\nabla(f\cdot s)) = \nabla\left(df\otimes s + f\cdot\nabla(s)\right)\\ &= \underbrace{d^2(f)}_{0}\otimes s\underbrace{-df\wedge\nabla(s)+df\wedge\nabla(s)}_{0}+f\cdot\nabla(\nabla(s))\\ &= f\cdot F_\nabla(s)\end{aligned}$$

□

Examples 4.3.3 i) Let us compute the curvature of a connection on the trivial bundle $M\times\mathbb{C}^r$. If ∇ is the trivial connection, i.e. $\nabla = d$, then $F_\nabla = 0$.

Any other connection is of the form $\nabla = d + A$, where A is a matrix of one-forms. For a section s one obtains $F_\nabla(s) = (d+A)(d+A)(s) = (d+A)(d(s)+A\cdot s) = d^2(s)+d(A\cdot s)+A\cdot d(s)+A(A(s)) = d(A)(s)+(A\wedge A)(s)$, i.e.

$$F_\nabla = d(A) + A\wedge A.$$

ii) For a line bundle this calculation yields $F_\nabla = d(A)$. In this case, the curvature is an ordinary two-form.

For $a\in\mathcal{A}^1(M,\mathrm{End}(E))$ the two-form $a\wedge a\in\mathcal{A}^2(M,\mathrm{End}(E))$ is given by exterior product in the form part and composition in $\mathrm{End}(E)$. Using this, the example is easily generalized to

Lemma 4.3.4 *Let ∇ be a connection on a vector bundle E and let $a\in\mathcal{A}^1(M,\mathrm{End}(E))$. Then $F_{\nabla+a} = F_\nabla + \nabla(a) + a\wedge a$.* □

Any connection ∇ on a vector bundle E induces a natural connection on $\mathrm{End}(E)$ which will also be called ∇. In particular, this connection can be applied to the curvature $F_\nabla\in\mathcal{A}^2(M,\mathrm{End}(E))$ of the original connection on E. Here is the next remarkable property of the curvature:

Lemma 4.3.5 (Bianchi identity) *If $F_\nabla\in\mathcal{A}^2(M,\mathrm{End}(E))$ is the curvature of a connection ∇ on a vector bundle E, then*

$$0 = \nabla(F_\nabla)\in\mathcal{A}^3(M,\mathrm{End}(E)).$$

Proof. This follows from $\nabla(F_\nabla)(s) = \nabla(F_\nabla(s)) - F_\nabla(\nabla(s)) = \nabla(\nabla^2(s)) - \nabla^2(\nabla(s)) = 0$. Here we use Exercise 4.3.1. □

Example 4.3.6 For the connection $\nabla = d + A$ on the trivial bundle the Bianchi identity becomes $dF_\nabla = F_\nabla\wedge A - A\wedge F_\nabla$.

The curvature of induced connections on associated bundles can usually be expressed in terms of the curvature of the given connections. For the most frequent associated bundles they are given by the following proposition.

Proposition 4.3.7 *Let* E_1, E_2 *be vector bundles endowed with connections* ∇_1 *and* ∇_2, *respectively.*

i) *The curvature of the induced connection on the direct sum* $E_1 \oplus E_2$ *is given by*

$$F = F_{\nabla_1} \oplus F_{\nabla_2}.$$

ii) *On the tensor product* $E_1 \otimes E_2$ *the curvature is given by*

$$F_{\nabla_1} \otimes 1 + 1 \otimes F_{\nabla_2}.$$

iii) *For the induced connection* ∇^* *on the dual bundle* E^* *one has*

$$F_{\nabla^*} = -F_{\nabla}^{\mathrm{t}}.$$

iv) *The curvature of the pull-back connection* $f^*\nabla$ *of a connection* ∇ *under a differentiable map* $f : M \to N$ *is*

$$F_{f^*\nabla} = f^* F_{\nabla}.$$

Proof. Let us prove ii). This is the following straightforward calculation

$$\begin{aligned}
& F_{\nabla}(s_1 \otimes s_2) \\
&= \nabla(\nabla(s_1 \otimes s_2)) = \nabla(\nabla_1(s_1) \otimes s_2 + s_1 \otimes \nabla_2(s_2)) \\
&= \nabla_1^2(s_1) \otimes s_2 - \nabla_1(s_1) \otimes \nabla_2(s_2) + \nabla_1(s_1) \otimes \nabla_2(s_2) + s_1 \otimes \nabla_2^2(s_2) \\
&= F_{\nabla_1}(s_1) \otimes s_2 + s_1 \otimes F_{\nabla_2}(s_2).
\end{aligned}$$

The sign appears, because ∇ is applied to the one-form $\nabla_1(s_1) \otimes s_2$. We leave i) and iii) to the reader (cf. Exercise 4.3.2).

iv) follows from the local situation, where ∇ is given as $d + A$. Then $F_{f^*\nabla} = F_{d+f^*A} = d(f^*A) + f^*(A) \wedge f^*(A) = f^*(d(A) + A \wedge A) = f^* F_{\nabla}$. □

Next we will study the curvature of the special connections introduced in Section 4.2.

Proposition 4.3.8 i) *The curvature of an hermitian connection* ∇ *on an hermitian vector bundle* (E, h) *satisfies* $h(F_{\nabla}(s_1), s_2) + h(s_1, F_{\nabla}(s_2)) = 0$, *i.e.*

$$F_{\nabla} \in \mathcal{A}^2(M, \mathrm{End}(E, h)).$$

ii) *The curvature* F_{∇} *of a connection* ∇ *on a holomorphic vector bundle* E *over a complex manifold* X *with* $\nabla^{0,1} = \bar{\partial}$ *has no* $(0,2)$*-part, i.e.*

$$F_{\nabla} \in (\mathcal{A}^{2,0} \oplus \mathcal{A}^{1,1})(X, \mathrm{End}(E)).$$

iii) *Let* E *be a holomorphic bundle endowed with an hermitian structure* h. *The curvature of the Chern connection* ∇ *is of type* $(1,1)$, *real, and skew-hermitian, i.e.* $F_{\nabla} \in \mathcal{A}_{\mathbb{R}}^{1,1}(X, \mathrm{End}(E, h))$. *(Recall that* $\mathrm{End}(E, h)$ *is only a real vector bundle.)*

Proof. i) A local argument goes as follows: Choose a trivialization such that (E, h) is isomorphic to the trivial bundle $M \times \mathbb{C}^r$ endowed with the constant standard hermitian product. Then, $\nabla = d + A$ with $\bar{A}^{\mathrm{t}} = -A$. For its curvature $F_\nabla = d(A) + A \wedge A$ one obtains

$$\begin{aligned}\bar{F}_\nabla^{\mathrm{t}} &= d(\bar{A}^{\mathrm{t}}) + (\bar{A} \wedge \bar{A})^{\mathrm{t}} = d(\bar{A}^{\mathrm{t}}) - \bar{A}^{\mathrm{t}} \wedge \bar{A}^{\mathrm{t}} \\ &= d(-A) - (-A) \wedge (-A) = -F_\nabla.\end{aligned}$$

For a global argument one first observes that the assumption that ∇ is hermitian yields for form-valued sections $s_i \in \mathcal{A}^{k_i}(E)$ the equation

$$dh(s_1, s_2) = h(\nabla(s_1), s_2) + (-1)^{k_1} h(s_1, \nabla(s_2)).$$

Recall that $h(\alpha_1 \otimes t_1, \alpha_2 \otimes t_2) = (\alpha_1 \wedge \bar{\alpha}_2) h(t_1, t_2)$ for local forms α_1, α_2 and sections t_1, t_2.

Hence, for $s_1, s_2 \in \mathcal{A}^0(E)$ one has

$$\begin{aligned}dh(\nabla(s_1), s_2) &= h(F_\nabla(s_1), s_2) - h(\nabla(s_1), \nabla(s_2)) \\ dh(s_1, \nabla(s_2)) &= h(\nabla(s_1), \nabla(s_2)) + h(s_1, F_\nabla(s_2))\end{aligned}$$

and on the other hand

$$dh(\nabla(s_1), s_2)) + dh(s_1, \nabla(s_2)) = d(dh(s_1, s_2)) = 0.$$

This yields the assertion.

ii) Here, one first observes that the extension $\nabla : \mathcal{A}^k(E) \to \mathcal{A}^{k+1}(E)$ splits into a $(1,0)$-part and a $(0,1)$-part, the latter of which is $\bar{\partial}$. Then one computes $\nabla^2 = (\nabla^{1,0})^2 + \nabla^{1,0} \circ \bar{\partial} + \bar{\partial} \circ \nabla^{1,0}$, as $\bar{\partial}^2 = 0$. Hence, $F_\nabla(s) \in (\mathcal{A}^{2,0} \oplus \mathcal{A}^{1,1})(E)$ for all $s \in \mathcal{A}^0(E)$.

Locally one could argue as follows: Since $\nabla = d + A$ with A of type $(1,0)$, the curvature $d(A) + A \wedge A = \bar{\partial}(A) + (\partial A + A \wedge A)$ is a sum of a $(1,1)$-form and a $(2,0)$-form.

iii) Combine i) and ii). By comparing the bidegree of F_∇^{t} and F_∇ in local coordinates we find that F_∇ is of type $(1,1)$.

More globally, due to ii) one knows that $h(F_\nabla(s_1), s_2)$ and $h(s_1, F_\nabla(s_2))$ are of bidegree $(2,0) + (1,1)$ respectively $(1,1) + (0,2)$. Recall the convention $h(s_1, \alpha_2 \otimes s_2) = \bar{\alpha}_2 h(s_1, s_2)$. Using i), i.e. $h(F_\nabla(s_1), s_2) + h(s_1, F_\nabla(s_2)) = 0$, and comparing the bidegree shows that $h(F_\nabla(s_1), s_2)$ has trivial $(2,0)$-part for all sections s_1, s_2. Hence, F_∇ is of type $(1,1)$. ☐

Examples 4.3.9 i) Suppose E is the trivial vector bundle $M \times \mathbb{C}^r$ with the constant standard hermitian structure. If $\nabla = d + A$ is an hermitian connection, then i) says $d(A + \bar{A}^{\mathrm{t}}) + (A \wedge A + \overline{(A \wedge A)}^{\mathrm{t}}) = 0$. For $r = 1$ this means that the real part of A is constant.

ii) If (L, h) is an hermitian holomorphic line bundle, then the curvature F_∇ of its Chern connection is a section of $\mathcal{A}_{\mathbb{R}}^{1,1}(X, \mathrm{End}(L, h))$, which can be identified with the imaginary $(1,1)$-forms on X. Indeed, $\mathrm{End}(L, h)$ is the purely imaginary line bundle $i \cdot \mathbb{R} \times X$ (cf. page 176).

iii) If the hermitian structure on the holomorphic vector bundle E is locally given by the matrix H, then the Chern connection is of the form $d+\bar{H}^{-1}\partial(\bar{H})$. Hence, the curvature is

$$F = \bar{\partial}(\bar{H}^{-1}\partial(\bar{H})).$$

Indeed, a priori $F = \bar{\partial}(\bar{H}^{-1}\partial(\bar{H})) + \partial(\bar{H}^{-1}\partial(\bar{H}) + (\bar{H}^{-1}\partial(\bar{H})) \wedge (\bar{H}^{-1}\partial(\bar{H}))$, but the sum of the last two terms must vanish, as both are of type $(2,0)$.

If E is a line bundle, then the hermitian matrix is just a positive real function h. In this case one writes $F = \bar{\partial}\partial\log(h)$. Once again, we see that F can be considered as a purely imaginary two-form

iv) Let (X,g) be an hermitian manifold. Then the tangent bundle is naturally endowed with an hermitian structure. The curvature of the Chern connection on $\mathcal{T}_X$ is called the *curvature of the hermitian manifold* (X,g). In Section 4.A we shall see that the curvature of a Kähler manifold (X,g) is nothing but the usual curvature of the underlying Riemannian manifold.

For the Chern connection on a holomorphic hermitian bundle the Bianchi identity yields

$$0 = (\nabla(F_\nabla))^{1,2} = \bar{\partial}(F_\nabla),$$

i.e. F_∇ as an element of $\mathcal{A}^{1,1}(X, \mathrm{End}(E))$ is $\bar{\partial}$-closed. Thus, in this case the curvature yields a natural Dolbeault cohomology class $[F_\nabla] \in H^1(X, \Omega_X \otimes \mathrm{End}(E))$ for any holomorphic vector bundle E. A priori, this cohomology class might depend on the chosen hermitian structure or, equivalently, on the connection. That this is not the case is an immediate consequence of the following description of it as the Atiyah class of E.

Proposition 4.3.10 *For the curvature F_∇ of the Chern connection on an hermitian holomorphic vector bundle (E,h) one has*

$$[F_\nabla] = A(E) \in H^1(X, \Omega_X \otimes \mathrm{End}(E)).$$

Proof. The comparison of Dolbeault and Čech cohomology can be done by chasing through the following commutative diagram of sheaves:

$$\begin{tikzcd}
\Omega_X \otimes \mathrm{End}(E) \arrow[r] \arrow[d] & \mathcal{C}^0(\{U_i\}, \Omega_X \otimes \mathrm{End}(E)) \arrow[r] \arrow[d] & \mathcal{C}^1(\{U_i\}, \Omega_X \otimes \mathrm{End}(E)) \arrow[d, "i"] \\
\mathcal{A}^{1,0}(\mathrm{End}(E)) \arrow[r] \arrow[d] & \mathcal{C}^0(\{U_i\}, \mathcal{A}^{1,0}(\mathrm{End}(E))) \arrow[r, "\delta_1"] \arrow[d, "\bar{\partial}"] & \mathcal{C}^1(\{U_i\}, \mathcal{A}^{1,0}(\mathrm{End}(E))) \\
\mathcal{A}^{1,1}(\mathrm{End}(E)) \arrow[r, "\delta_0"] & \mathcal{C}^0(\{U_i\}, \mathcal{A}^{1,1}(\mathrm{End}(E))) &
\end{tikzcd}$$

Here, $X = \bigcup U_i$ is an open covering of X trivializing E via $\psi_i : E|_{U_i} \cong U_i \times \mathbb{C}^r$. With respect to ψ_i the hermitian structure h on U_i is given by an hermitian matrix H_i. Then the curvature F_∇ of the Chern connection on the holomorphic bundle E on U_i is given by $F_\nabla|_{U_i} = \psi^{-1}(\bar\partial(\bar H_i^{-1}\partial \bar H_i))\psi_i$. Thus,

$$\begin{aligned}\delta_0(F_\nabla) &= \{U_i, \psi_i^{-1}\circ(\bar\partial(\bar H_i^{-1}\partial\bar H_i))\circ\psi_i\}\\ &= \bar\partial\{U_i, \psi_i^{-1}\circ(\bar H_i^{-1}\partial\bar H_i)\circ\psi_i\},\end{aligned}$$

as the maps ψ_i are holomorphic trivializations.

Hence, it suffices to show that

$$i\{U_{ij}, \psi_j^{-1}\circ(\psi_{ij}^{-1}d\psi_{ij})\circ\psi_j\} = \delta_1\{U_i, \psi_i^{-1}\circ(\bar H_i^{-1}\partial\bar H_i)\circ\psi_i\},$$

because the cocycle $\{U_i, \psi_i^{-1}\circ(\psi_{ij}^{-1}d\psi_{ij})\circ\psi_j\}$ represents by definition the Atiyah class of E. Using the definition of δ_1 one shows that the term on the right hand side equals

$$\{U_{ij}, \psi_j^{-1}\circ(\bar H_j^{-1}\partial\bar H_j)\circ\psi_j - \psi_i^{-1}\circ(\bar H_i^{-1}\partial\bar H_i)\circ\psi_i)\}.$$

Since

$$\begin{aligned}&\psi_j^{-1}\circ(\bar H_j^{-1}\partial\bar H_j)\circ\psi_j - \psi_i^{-1}\circ(\bar H_i^{-1}\partial\bar H_i)\circ\psi_i\\ &= \psi_j^{-1}\circ(\bar H_j^{-1}\partial\bar H_j - \psi_{ij}^{-1}\circ(\bar H_i^{-1}\partial\bar H_i)\circ\psi_{ij})\circ\psi_j,\end{aligned}$$

it suffices to prove

$$\bar H_j^{-1}\partial\bar H_j - \psi_{ij}^{-1}\circ(\bar H_i^{-1}\partial\bar H_i)\circ\psi_{ij} = \psi_{ij}^{-1}\partial\psi_{ij}.$$

The latter is a consequence of the compatibility $\psi_{ij}^{\mathrm t}H_i\bar\psi_{ij} = H_j$ or, equivalently, $\bar\psi_{ij}^{\mathrm t}\bar H_i\psi_{ij} = \bar H_j$ and the chain rule

$$\begin{aligned}\bar H_j^{-1}\partial\bar H_j &= \psi_{ij}^{-1}\bar H_i^{-1}(\bar\psi_{ij}^{\mathrm t})^{-1}\left(\bar\psi_{ij}^{\mathrm t}(\partial\bar H_i)\psi_{ij} + \bar\psi_{ij}^{\mathrm t}\bar H_i\partial\psi_{ij}\right)\\ &= \psi_{ij}^{-1}(\bar H_i^{-1}\partial\bar H_i)\psi_{ij} + \psi_{ij}^{-1}\partial\psi_{ij},\end{aligned}$$

where we have used $\partial\bar\psi_{ij} = 0$. □

Remark 4.3.11 Here is a more direct argument to see that $[F_\nabla]$ does not depend on the connection ∇. Indeed, any other connection is of the form $\nabla + a$ and $F_{\nabla+a} = F_\nabla + \nabla(a) + a\wedge a$. If both connections ∇ and $\nabla + a$ are Chern connections with respect to certain hermitian structures, then F_∇ and $F_{\nabla+a}$ are $(1,1)$-forms and $a \in \mathcal{A}^{1,0}(\mathrm{End}(E))$. Thus, $a\wedge a \in \mathcal{A}^{2,0}(\mathrm{End}(E))$ and, therefore, $\nabla(a) + a\wedge a = (\nabla(a) + a\wedge a)^{1,1} = \nabla(a)^{1,1} = \bar\partial(a)$, i.e. $F_{\nabla+a} = F_\nabla + \bar\partial(a)$ and hence

$$[F_{\nabla+a}] = [F_\nabla].$$

We have used here that the induced connection on the endomorphism bundle is again compatible with the holomorphic structure.

Example 4.3.12 Let us consider the standard homogeneous linear coordinates $z_0, \ldots, z_n$ on $\mathbb{P}^n$ as sections of $\mathcal{O}(1)$. According to Example 4.1.2 one associates with them a natural hermitian metric $h(t) = |\psi(t)|^2/(\sum |\psi(z_i)|^2)$ on $\mathcal{O}(1)$.

We claim that the curvature F of the Chern connection on the holomorphic line bundle $\mathcal{O}(1)$ endowed with this hermitian metric is

$$\frac{i}{2\pi}F = \omega_{\mathrm{FS}},$$

where ω_{FS} is the Fubini–Study Kähler form (see Example 3.1.9, i)).

This can be verified locally. On a standard open subset $U_i \subset \mathbb{P}^n$ one has $\omega_{\mathrm{FS}} = \frac{i}{2\pi}\partial\bar\partial\log(1+\sum|w_i|^2)$.

The hermitian structure of $\mathcal{O}(1)|_{U_i}$ with respect to the natural trivialization is given by the scalar function $h = (1+\sum|w_i|^2)^{-1}$. By Example iii) in 4.3.9 we have $F = \bar\partial\partial\log(h) = \partial\bar\partial\log(1+\sum|w_i|^2)$.

Remark 4.3.13 In the general situation, i.e. of a holomorphic line bundle L on a complex manifold X, the hermitian structure $h_{\{s_i\}}$ induced by globally generating sections $s_0, \ldots, s_n$ is the pull-back of the hermitian structure on $\mathcal{O}(1)$ of the previous example under the induced morphism $\varphi : X \to \mathbb{P}^n$. Thus, for the curvature F_∇ of the Chern connection ∇ on L one has: $(i/2\pi)F_\nabla = \varphi^*\omega_{\mathrm{FS}}$, where ω_{FS} is the Fubini–Study form on $\mathbb{P}^n$.

Suppose now that L is not only holomorphic, but also endowed with an hermitian structure h. What is the relation between h and $h_{\{s_i\}}$? In general, they are not related at all, but if the sections $s_0, \ldots, s_n$ are chosen such that they form an orthonormal base of $H^0(X, L)$ then one might hope to approximate h by $h_{\{s_i\}}$. (Here, $H^0(X, L)$ is equipped with the hermitian product defined in 4.1.11.) This circle of questions is intensively studied at the moment and there are many open questions.

Definition 4.3.14 A real $(1,1)$-form α is called *(semi-)positive* if for all holomorphic tangent vectors $0 \neq v \in T^{1,0}X$ one has

$$-i\alpha(v, \bar v) > 0 \text{ (resp. } \geq).$$

At a point $x \in X$ any semi-positive $(1,1)$-form is a positive linear combination of forms of the type $i\beta\wedge\bar\beta$, where β is a $(1,0)$-form. The standard example of a positive form is provided by a Kähler form $\omega = \frac{i}{2}\sum h_{ij}dz_i \wedge d\bar z_j$. In this case (h_{ij}) is a positive hermitian matrix and thus $v^{\mathrm{t}}(h_{ij})\bar v > 0$ for all non-zero holomorphic tangent vectors. Together with Example 4.3.12 this shows that iF_∇ of the Chern connection ∇ on $\mathcal{O}(1)$ (with the standard hermitian structure) is positive.

Clearly, the pull-back of a semi-positive form is again semi-positive. For the curvature of a globally generated line bundle L this implies

$$F_\nabla(v, \bar v) \geq 0.$$

We next wish to generalize this observation to the higher rank case. Let (E, h) be an hermitian vector bundle over a complex manifold X and let ∇ be an hermitian connection that satisfies $F_\nabla \in \mathcal{A}^{1,1}(X, \mathrm{End}(E))$.

Definition 4.3.15 The curvature F_∇ is (Griffiths-)*positive* if for any $0 \neq s \in E$ one has

$$h(F_\nabla(s), s)(v, \bar{v}) > 0$$

for all non-trivial holomorphic tangent vectors v. Semi-positivity (negativity, semi-negativity) is defined analogously.

Remark 4.3.16 Let L be an hermitian holomorphic line bundle and let ∇ be the Chern connection. Its curvature F_∇ is an imaginary $(1,1)$-form. Then the curvature F_∇ is positive in the sense of Definition 4.3.15 if and only if the real $(1,1)$-form iF_∇ is positive in the sense of Definition 4.3.14. The extra factor i is likely to cause confusion at certain points, but these two concepts of positivity (and others) are met frequently in the literature.

Before proving the semi-positivity of the curvature of any globally generated vector bundle, we need to relate the curvature and the second fundamental forms of a split vector bundle $E = E_1 \oplus E_2$. Let ∇ be a connection on E. We denote the induced connections by ∇_i and the second fundamental forms by b_i, $i = 1, 2$. Thus,

$$\nabla = \begin{pmatrix} \nabla_1 & b_2 \\ b_1 & \nabla_2 \end{pmatrix}$$

which immediately shows

Lemma 4.3.17 *The curvature of the induced connection ∇_1 on E_1 is given by $F_{\nabla_1} = \mathrm{pr}_1 \circ F_\nabla - b_2 \circ b_1$.* □

Now let E_1 be a holomorphic subbundle of the trivial holomorphic vector bundle $E = \mathcal{O}^{\oplus r}$ endowed with the trivial constant hermitian structure. The curvature of the Chern connection ∇ on E is trivial, as ∇ is just the exterior differential. Hence, $F_{\nabla_1} = -b_2 \circ b_1$. This leads to

Proposition 4.3.18 *The curvature F_{∇_1} of the Chern connection ∇_1 of a subbundle $E_1 \subset E = \mathcal{O}^{\oplus r}$ (with the induced hermitian structure) is semi-negative.*

Proof. By the previous lemma we have $F_{\nabla_1} = -b_2 \circ b_1$. Thus, if h_2 is the induced hermitian structure on the quotient E/E_1 then

$$h_1(F_{\nabla_1}(s), s) = -h_1(b_2(b_1(s)), s) = -h_2(b_1(s), b_1(s)).$$

Here we use properties of the second fundamental form proved in Section 4.2.

More precisely, one has

$$\begin{aligned} h_1(b_2(\beta\otimes t),s) &= h_1(-\beta\otimes b_2(t),s) = -\beta h_1(b_2(t),s) \\ &= \beta h_2(t,b_1(s)) = h_2(\beta\otimes t, b_1(s)) \end{aligned}$$

for any one-form β.

Now, it suffices to show that $h(\alpha,\alpha)\geq 0$ for any $\alpha\in\mathcal{A}^{1,0}(E)$. Fix an orthonormal basis s_i of E and write $\alpha=\sum\alpha_i s_i$. Then $h(\alpha,\alpha)=\sum\alpha_i\wedge\bar{\alpha}_i$. But $\alpha_i\wedge\bar{\alpha}_i$ is semi-positive due to

$$(\alpha_i\wedge\bar{\alpha}_i)(v,\bar{v}) = \alpha_i(v)\cdot\bar{\alpha}_i(\bar{v}) = \alpha_i(v)\cdot\overline{\alpha_i(v)}\geq 0.$$

(Note that we did use that b_1 is of type $(1,0)$.) ☐

A holomorphic vector bundle E is *globally generated* if there exist global holomorphic sections $s_1,\ldots,s_r\in H^0(X,E)$ such that for any $x\in X$ the values $s_1(x),\ldots,s_r(x)$ generate the fibre $E(x)$. In other words, the sections $s_1,\ldots,s_r$ induce a surjection $\mathcal{O}^{\oplus r}\twoheadrightarrow E$. The standard constant hermitian structure on $\mathcal{O}^{\oplus r}$ induces via this surjection an hermitian structure on E and dualizing this surjection yields an inclusion of vector bundles $E^*\subset\mathcal{O}^{\oplus r}$.

Using Exercise 4.3.3 the proposition yields

Corollary 4.3.19 *The curvature of a globally generated vector bundle is semi-positive.* ☐

Here, the curvature is the curvature of the Chern connection with respect to a hermitian structure on E defined by the choice of the globally generating holomorphic sections.

Example 4.3.20 The Euler sequence on $\mathbb{P}^n$ twisted by $\mathcal{O}(-1)$ is of the form

$$\begin{tikzcd} 0 \arrow[r] & \mathcal{O}(-1) \arrow[r] & \mathcal{O}^{\oplus n+1} \arrow[r] & \mathcal{T}_{\mathbb{P}^n}(-1) \arrow[r] & 0\,. \end{tikzcd}$$

Hence, $\mathcal{T}_{\mathbb{P}^n}(-1)$ admits an hermitian structure such that the curvature of the Chern connection is semi-positive. Twisting by $\mathcal{O}(1)$ yields a connection on $\mathcal{T}_{\mathbb{P}^n}$ with positive curvature. In fact, this is the curvature of the Fubini–Study metric on $\mathbb{P}^n$. See Example 4.1.5.

Remark 4.3.21 As for line bundles, one could have first studied the universal case. Recall that on the Grassmannian $\mathrm{Gr}_r(V)$ there exists a universal short exact sequence

$$\begin{tikzcd} 0 \arrow[r] & S \arrow[r] & \mathcal{O}\otimes V \arrow[r] & Q \arrow[r] & 0. \end{tikzcd}$$

By definition, the fibre of S over a point of $\mathrm{Gr}(V)$ that corresponds to $W\subset V$ is naturally isomorphic to W. Fixing an hermitian structure on V induces hermitian structures on S and Q (and therefore on the tangent bundle $\mathcal{T}$ of $\mathrm{Gr}_r(V)$, which is $\mathrm{Hom}(S,Q)$).

If E is any holomorphic vector bundle of rank r on a complex manifold X generated by global sections spanning $V \subset H^0(X,E)$, then there exists a morphism $\varphi : X \to \mathrm{Gr}_r(V)$ with $\varphi^*Q = E$ (see Exercise 2.4.11). Again, choosing an hermitian product on V induces an hermitian structure on E which coincides with the pull-back of the hermitian structure on Q under φ. This shows that the curvature of E and Q can be compared, namely $\varphi^*F_Q = F_E$.

Thus, showing the positivity of F_Q proves the semi-positivity for any globally generated vector bundle E. Moreover, if $\varphi : X \to \mathrm{Gr}_r(V)$ is an embedding, then the curvature F_E is positive.

Exercises

4.3.1 Show that $\nabla^2 : \mathcal{A}^k(E) \to \mathcal{A}^{k+2}(E)$ is given by taking the exterior product with the form part of the curvature $F_\nabla \in \mathcal{A}^2(M, \mathrm{End}(E))$ and applying its endomorphism part to E.

4.3.2 Prove i) and iii) of Proposition 4.3.7. Compute the connection and the curvature of the determinant bundle.

4.3.3 Let (E_1, h_1) and (E_2, h_2) be two hermitian holomorphic vector bundles endowed with hermitian connections ∇_1, ∇_2 such that the curvature of both is (semi-)positive. Prove the following assertions.

i) The curvature of the induced connection ∇^* on the dual vector bundle E_1^* is (semi-)negative.

ii) The curvature on $E_1 \otimes E_2$ is (semi-)positive and it is positive if at least one of the two connections has positive curvature.

iii) The curvature on $E_1 \oplus E_2$ is (semi-)positive.

4.3.4 Find an example of two connections ∇_1 and ∇_2 on a vector bundle E, such that F_{∇_1} is positive and F_{∇_2} is negative.

4.3.5 Let L be a holomorphic line bundle on a complex manifold. Suppose L admits an hermitian structure whose Chern connection has positive curvature. Show that X is Kähler. If X is in addition compact prove $\int_X A(L)^n > 0$.

4.3.6 Show that the canonical bundle of $\mathbb{P}^n$ comes along with a natural hermitian structure such that the curvature of the Chern connection is negative.

4.3.7 Show that the curvature of a complex torus $\mathbb{C}^n/\Gamma$ endowed with a constant hermitian structure is trivial. Is this true for any hermitian structure on $\mathbb{C}^n/\Gamma$?

4.3.8 Show that the curvature of a the natural metric on the ball quotient introduced in Example 3.1.9, iv) is negative. The one-dimensional case is a rather easy calculation.

4.3.9 Let X be a compact Kähler manifold with $b_1(X) = 0$. Show that there exists a unique flat connection ∇ on the trivial holomorphic line bundle $\mathcal{O}$ with $\nabla^{0,1} = \bar{\partial}$. Moreover, up to isomorphism $\mathcal{O}$ is the only line bundle with trivial Chern class $c_1 \in H^2(X, \mathbb{Z})$.

4.3.10 Let ∇ be a connection on a (complex) line bundle L on a manifold M. Show that L locally admits trivializing parallel sections if and only if $F_\nabla = 0$.

This is the easiest case of the general fact that a connection on a vector bundle is flat if and only if parallel frames can be found locally. (Frobenius integrability.)

Comments: - Various notions for the positivity of vector bundles can be found in the literature. Usually they all coincide for line bundles, but the exact relations between them is not clear for higher rank vector bundles. Positivity is usually exploited to control higher cohomology groups. This will be illustrated in Section 5.2. We shall also see that, at least for line bundles on projective manifolds, an algebraic description of bundles admitting an hermitian structure whose Chern connection has positive curvature can be given. For a more in depth presentation of the material we refer to [35, 100] and the forthcoming book [83].

- The problem alluded to in Remark 4.3.13 is subtle. See [37, 107].

- The curvature of Kähler manifold will be dealt with in subsequent sections, in particular its comparison with the well-known Riemannian curvature shall be explained in detail.

- In [75, Prop. 1.2.2] one finds a cohomological version of the Bianchi identity in terms of the Atiyah class.

1.2.2. Prove the convergence of Newton's method in the ring of formal power series $\mathbb{C}[[x]]$, where $\phi_n \to 0$ if and only if the degree of its leading term $\to \infty$. Note that this ring is equipped with the x-adic topology, where the ideals (x^N) form a fundamental system of neighborhoods of 0.

1.2.3. Prove that Fermat's curve $x_0^n + x_1^n + x_2^n = 0$ in $\mathbb{P}^2$ is nonsingular.

1.3 Bézout's Theorem

An important feature of the projective plane is that any two lines meet. In fact, it has a much stronger property:

Theorem 1.3.1 (Weak Bézout's theorem). *Any two algebraic curves in* $\mathbb{P}^2$ *intersect.*

We give an elementary classical proof here using resultants. Given two monic polynomials

$$f(y) = y^n + a_{n-1}y^{n-1} + \cdots + a_0 = \prod_{i=1}^{n}(y - r_i),$$

$$g(y) = y^m + b_{m-1}y^{m-1} + \cdots + b_0 = \prod_{j=1}^{m}(y - s_j),$$

their resultant is the expression

$$\mathrm{Res}(f,g) = \prod_{ij}(r_i - s_j).$$

It is obvious that $\mathrm{Res}(f,g) = 0$ if and only if f and g have a common root. From the way we have written it, it is also clear that $\mathrm{Res}(f,g)$ is a polynomial of degree mn in $r_1,\ldots,r_n,s_1,\ldots,s_m$ that is symmetric separately in the r's and s's. So it can be rewritten as a polynomial in the elementary symmetric polynomials in the r's and s's. In other words, $\mathrm{Res}(f,g)$ is a polynomial in the coefficients a_i and b_j. Standard formulas for it can be found, for example, in [76].

Proof. Assume that the curves are given by homogeneous polynomials $F(x,y,z)$ and $G(x,y,z)$ respectively. After translating the line at infinity if necessary, we can assume that the polynomials $f(x,y) = F(x,y,1)$ and $g(x,y) = G(x,y,1)$ are both nonconstant in x and y. Treating these as polynomials in y with coefficients in $\mathbb{C}[x]$, the resultant $\mathrm{Res}(f,g)(x)$ can be regarded as a nonconstant polynomial in x. Since $\mathbb{C}$ is algebraically closed, $\mathrm{Res}(f,g)(x)$ must have a root, say a. Then $f(a,y) = 0$ and $g(a,y) = 0$ have a common solution. $\square$

It is worth noting that this argument is entirely algebraic, and therefore applies to any algebraically closed field, such as the field of algebraic numbers $\overline{\mathbb{Q}}$. So as a bonus, we get the following arithmetic consequence.

Corollary 1.3.2. *If the curves are defined by equations with coefficients in* $\overline{\mathbb{Q}}$*, then the there is a point of intersection with coordinates in* $\overline{\mathbb{Q}}$*.*

Suppose that the curves $C, D \subset \mathbb{P}^2$ are irreducible and distinct. Then it is not difficult to see that $C \cap D$ is finite. We can ask how many points are in the intersection. To get a more refined answer, we can assign a multiplicity to the points of intersection. If the curves are defined by polynomials $f(x,y)$ and $g(x,y)$ with a common isolated zero at the origin $O = (0,0)$, then define the *intersection multiplicity* at O by

$$i_O(C,D) = \dim \mathbb{C}[[x,y]]/(f,g),$$

where $\mathbb{C}[[x,y]]$ is the ring of formal power series in x and y. The ring of convergent power series can be used instead, and it would lead to the same result. The multiplicities can be defined at other points by a similar procedure. While this definition is concise, it does not give us much geometric insight. Here is an alternative: $i_p(D,E)$ is the number of points close to p in the intersection of small perturbations of these curves. More precisely, we have the following:

Lemma 1.3.3. $i_p(D,E)$ *is the number of points in* $\{f(x,y) = \varepsilon\} \cap \{g(x,y) = \eta\} \cap B_\delta(p)$ *for small positive* $|\varepsilon|, |\eta|, \delta$*, where* $B_\delta(p)$ *is a* δ*-ball around* p*.*

Proof. This follows from [42, 1.2.5e]. □

There is another nice interpretation of this number worth mentioning. If $K_1, K_2 \subset S^3$ are disjoint knots, perhaps with several components, their linking number is roughly the number of times one of them passes through the other. A precise definition can be found in any basic book on knot theory (e.g., [98]).

Theorem 1.3.4. *Given a small sphere* S^3 *about* p*,* $i_p(D,E)$ *is the linking number of* $D \cap S^3$ *and* $E \cap S^3$*.*

Proof. See [42, 19.2.4]. □

We can now state the strong form of Bézout's theorem. We will revisit this in Corollary 11.2.7.

Theorem 1.3.5 (Bézout's theorem). *Suppose that* C *and* D *are algebraic curves with no common components. Then the sum of intersection multiplicities at points of* $C \cap D$ *equals the product of degrees* $\deg C \cdot \deg D$*, where* $\deg C$ *and* $\deg D$ *are the degrees of the defining polynomials.*

Corollary 1.3.6. *The cardinality* $\#C \cap D$ *is at most* $\deg C \cdot \deg D$*.*

Exercises

1.3.7. Show that the vector space $\mathbb{C}[[x,y]]/(f,g)$ considered above is finite-dimensional if $f=0$ and $g=0$ have an isolated zero at $(0,0)$.

1.3.8. Suppose that $f=y$. Using the original definition show that $i_O(C,D)$ equals the multiplicity of the root $x=0$ of $g(x,0)$. Now prove Bézout's theorem when C is a line.

1.4 Cubics

We now turn our attention to the very rich subject of cubic curves. In the degenerate case, the polynomial factors into a product of a linear and quadratic polynomial or three linear polynomials. Then the curve is a union of a line with a conic or three lines. So now assume that X (1.1.2) is defined by an irreducible cubic polynomial. It is called an *elliptic curve* because of its relationship to elliptic functions and integrals.

Lemma 1.4.1. *After a projective linear transformation, an irreducible cubic can be transformed into the projective closure of an affine curve of the form $y^2 = p(x)$, where $p(x)$ is a cubic polynomial. This is nonsingular if and only if $p(x)$ has no multiple roots.*

Proof. See [105, III §1]. $\square$

We note that nonsingular cubics are very different from conics, even topologically.

Proposition 1.4.2. *A nonsingular cubic X is homeomorphic to a torus $S^1 \times S^1$.*

There is a standard way to visualize this (see Figure 1.3). Mark four points $a,b,c,d=\infty$ on $\mathbb{P}^1$, where the first three are the roots of $p(x)$. Join a to b and c to d by nonintersecting arcs α and β. The preimage of the complement $Y=\mathbb{P}^1-(\alpha\cup\beta)$ in X should fall into two pieces both of which are homeomorphic to Y. So in other words, we can obtain X by first taking two copies of the sphere, slitting them along α and β, and then gluing them along the slits to obtain a torus.

Perhaps that was not very convincing. Instead, we will use a parameterization by elliptic functions to verify Proposition 1.4.2 and more. By applying a further projective linear transformation, we can put our equation for X into Weierstrass form

$$y^2 = 4x^3 - a_2x - a_3 \tag{1.4.1}$$

with discriminant $a_2^3 - 27a_3^2 \neq 0$. The idea is to parameterize the cubic by the elliptic integral

3.6 Line Bundles on Projective Space

In this section we define and study certain key examples of sheaves that are of fundamental importance in algebraic geometry. Fix a positive integer n. Let k be an algebraically closed field, $\mathbb{P} = \mathbb{P}^n_k$, and $V = k^{n+1}$. Let $R = k[x_0, \ldots, x_n] = \bigoplus R_d$, where R_d is the subspace of homogeneous polynomials of degree d. Given an integer d, define the subsheaf $\mathscr{O}_{\mathbb{P}}(d)$ of the constant sheaf of rational functions on $\mathbb{P}$ by

$$\mathscr{O}_{\mathbb{P}}(d)(U) \cong \left\{ \frac{f}{g} \mid \exists e, g \in R_e, f \in R_{e+d}, g \text{ nowhere zero on } U \right\}. \qquad (3.6.1)$$

Of course, we have $\mathscr{O}_{\mathbb{P}}(0) = \mathscr{O}_{\mathbb{P}}$ immediately from the definition. We have products

$$\mathscr{O}_{\mathbb{P}}(a) \otimes \mathscr{O}_{\mathbb{P}}(b) \to \mathscr{O}_{\mathbb{P}}(a+b).$$

given by

$$\frac{f}{g} \otimes \frac{f'}{g'} \mapsto \frac{ff'}{gg'}.$$

In particular, this shows that $\mathscr{O}_{\mathbb{P}}(d)$ is an $\mathscr{O}_{\mathbb{P}}$-module.

Lemma 3.6.1.

(a) When $d \geq 0$, the space of global sections of $\mathscr{O}_{\mathbb{P}}(d)$ is R_d.
(b) When $d < 0$, $\mathscr{O}_{\mathbb{P}}(d)$ has no nonzero global sections.
(c) Each $\mathscr{O}_{\mathbb{P}}(a)$ is locally free of rank one.
(d) There are natural isomorphisms $\mathscr{O}_{\mathbb{P}}(a) \otimes \mathscr{O}_{\mathbb{P}}(b) \cong \mathscr{O}_{\mathbb{P}}(a+b)$ and $\mathscr{O}_{\mathbb{P}}(a)^* \cong \mathscr{O}_{\mathbb{P}}(-a)$.

Proof. Statements (a) and (b) are immediate consequences of the definition (3.6.1), since the denominator g is necessarily a nonzero constant. From the definition, we can also identify

$$\mathscr{O}_{\mathbb{P}}(d)(U_i) = x_i^d \mathscr{O}_{\mathbb{P}}(U_i), \qquad (3.6.2)$$

where U_i denotes the complement of $x_i = 0$. The remaining statements follows easily from this. ☐

Part of the importance of these sheaves stems from the following fact:

Lemma 3.6.2. *The ideal sheaf of any degree-$d > 0$ hypersurface in $\mathbb{P}$ (see Example 3.5.4) is isomorphic to $\mathscr{O}_{\mathbb{P}}(-d)$.*

Proof. Given a nonzero degree-d homogeneous polynomial $h \in R_d$, we can see from (3.6.1) that we have an embedding $\mathscr{O}_{\mathbb{P}}(-d) \to \mathscr{O}_{\mathbb{P}}$ given by $f/g \mapsto fh/g$. The image is precisely the ideal sheaf defined by h. ☐

We claimed earlier that locally free sheaves arise from vector bundles. We can see this explicitly in these cases. We treat degree -1 here, and the leave the remaining cases as exercises. Recall that the tautological line bundle (Example 2.6.5) on projective space $\mathbb{P}$ is given by

$$L = \{(x,\ell) \in V \times \mathbb{P} \mid x \in \ell\}$$

with its natural projection to $\mathbb{P}$.

Lemma 3.6.3. *$\mathscr{O}_{\mathbb{P}}(-1)$ is isomorphic to the sheaf $\mathscr{L}$ of sections of L.*

Proof. By definition,

$$\mathscr{L}(U) = \{H : U \to k^{n+1} \mid H \text{ is regular and } H(\ell) \in \ell\}.$$

Thus the components h_i of H are regular functions satisfying

$$h_i(x_0,\ldots,x_n) = \lambda(x_0,\ldots,x_n)x_i$$

for some function λ. Rewriting $\lambda = h_i/x_i$, we see that it lies in $\mathscr{O}_{\mathbb{P}}(-1)(U)$. This process can be reversed. $\square$

When $k = \mathbb{C}$, we can pass to the associated complex analytic line bundle associated with L. Instead of trying to mimic equation (3.6.1) in the analytic category, we simply define $\mathscr{O}_{\mathbb{P}_{\mathrm{an}}}(-1)$ as the sheaf of holomorphic sections of L, and

$$\mathscr{O}_{\mathbb{P}_{\mathrm{an}}}(d) = \begin{cases} \mathscr{O}_{\mathbb{P}_{\mathrm{an}}}(-1) \otimes \cdots \otimes \mathscr{O}_{\mathbb{P}_{\mathrm{an}}}(-1) & (|d|\text{-times}) \quad \text{if } d \le 0, \\ \mathscr{O}_{\mathbb{P}_{\mathrm{an}}}(-1)^* \otimes \cdots \otimes \mathscr{O}_{\mathbb{P}_{\mathrm{an}}}(-1)^* & (d\text{-times}) \quad \text{otherwise.} \end{cases}$$

Note that in the sections where we will be working exclusively in the analytic category, we usually suppress the subscript an.

Exercises

3.6.4. Show that $\mathscr{O}_{\mathbb{P}}(a) \cong \mathscr{O}_{\mathbb{P}}(b)$ implies that $a = b$. Using the notation of Exercise 3.5.21, conclude that $\mathbb{Z} \subset \mathrm{Pic}(\mathbb{P})$.

3.6.5. Let $U = \mathbb{P}^{n+1} - \{[0,\ldots,0,1]\}$ and let $\pi : U \to \mathbb{P}$ denote projection. Show that this is a line bundle, and that $\mathscr{O}_{\mathbb{P}}(1)$ is isomorphic to the sheaf of its sections.

3.6.6. Let $v : \mathbb{P} \to \mathbb{P}^N = \mathbb{P}(S^dV)$ denote the degree-d Veronese map. Show that $\{(x,\ell) \in S^dV \times \mathbb{P} \mid x \in v(\ell)\}$ determines a line bundle over $\mathbb{P}$, and that $\mathscr{O}_{\mathbb{P}}(-d)$ is its sheaf of sections.

3.6.7. Choose a point $p \in \mathbb{P}^1$. Prove that there is an exact sequence

$$0 \to \mathscr{O}_{\mathbb{P}^1_{\mathrm{an}}}(d-1) \to \mathscr{O}_{\mathbb{P}^1_{\mathrm{an}}}(d) \to \mathbb{C}_p \to 0,$$

where $\mathbb{C}_p(U) = \mathbb{C}$ if $p \in U$ and 0 otherwise. Use this to prove that $\dim \Gamma(\mathscr{O}_{\mathbb{P}^1_{\mathrm{an}}}(d)) = d+1$ when $d \ge 0$.

3.7 Direct and Inverse Images

It is useful to transfer a sheaf from one topological space to another via a continuous map $f : X \to Y$. In fact, we have already done this in special cases. We start by explaining how to push a sheaf on X down to Y.

Definition 3.7.1. Given a presheaf $\mathscr{F}$ on X, the direct image $f_*\mathscr{F}$ is a presheaf on Y given by $f_*\mathscr{F}(U) = \mathscr{F}(f^{-1}U)$ with restrictions given by

$$\rho_{f^{-1}Uf^{-1}V} : \mathscr{F}(f^{-1}U) \to \mathscr{F}(f^{-1}V).$$

Lemma 3.7.2. *Direct images of sheaves are sheaves.*

Proof. Suppose that $f : X \to Y$ is a continuous map and $\mathscr{F}$ is a sheaf on X. Let $\{U_i\}$ be an open cover of $U \subseteq Y$, and $s_i \in f_*\mathscr{F}(U_i)$ a collection of sections that agree on the intersections. Then $\{f^{-1}U_i\}$ is an open cover of $f^{-1}U$, and we can regard $s_i \in \mathscr{F}(f^{-1}U_i)$ as a compatible collection of sections for it. Thus we can patch s_i to get a uniquely defined $s \in f_*\mathscr{F}(U) = \mathscr{F}(f^{-1}U)$ such that $s|_{U_i} = s_i$. This proves that $f_*\mathscr{F}$ is a sheaf. □

Now we want to consider the opposite direction. Suppose that $\mathscr{G}$ is a sheaf on Y. We would like to pull it back to X. We will denote this by $f^{-1}\mathscr{G}$, since f^* is reserved for something related to be defined later on. Naively, we can simply try to define

$$f^{-1}\mathscr{G}(U) = \mathscr{G}(f(U)).$$

However, this does not yet make sense unless $f(U)$ is open. So as a first step, given any subset $S \subset Y$ of a topological space and a presheaf $\mathscr{G}$, define

$$\mathscr{G}(S) = \varinjlim \mathscr{G}(V) \tag{3.7.1}$$

as V ranges over all open neighborhoods of S. When S is a point, $\mathscr{G}(S)$ is just the stalk. An element of $\mathscr{G}(S)$ can be viewed as germ of a section defined in a neighborhood of S, where two sections define the same germ if their restrictions agree in a common neighborhood. If $S' \subset S$, there is a natural restriction map $\mathscr{G}(S) \to \mathscr{G}(S')$ given by restriction of germs. So our naive attempt can now be made precise.

Definition 3.7.3. If $\mathscr{G}$ is a presheaf on Y, the presheaf inverse image $f^P\mathscr{G}$ is a presheaf on X given by $f^P\mathscr{G}(U) = \mathscr{G}(f(U))$ with restrictions as above. The sheaf inverse image is the sheafification $f^{-1}\mathscr{G} = (f^P\mathscr{G})^+$.

Although the definition of f^{-1} seems much more complicated compared to f_*, it is in fact just as natural. The picture becomes clearer if we view the inverse image in terms of its stalks. We then have

$$(f^{-1}\mathscr{G})_x \cong \mathscr{G}_{f(x)}, \tag{3.7.2}$$

and there is more. As explained in Exercise 3.1.22, the sheaf $\mathscr{G}$ determines the étalé space $\pi : \mathrm{Et}(\mathscr{G}) = \bigcup \mathscr{G}_y \to Y$. The étalé space for $f^{-1}\mathscr{G}$ is the fiber product

$$\mathrm{Et}(f^{-1}\mathscr{G}) = \{(x,g) \in X \times \mathrm{Et}(\mathscr{G}) \mid f(x) = \pi(g)\},$$

so that $f^{-1}\mathscr{G}$ is the sheaf of continuous cross sections of the projection $\mathrm{Et}(f^{-1}\mathscr{G}) \to X$.

If $f : X \to Y$ is the inclusion of a closed set, we also call $f_*\mathscr{F}$ the extension of $\mathscr{F}$ by 0 and $f^{-1}\mathscr{G}$ the restriction of $\mathscr{G}$. We often identify $\mathscr{F}$ with its extension, and denote the restriction by $\mathscr{G}|_X$.

These operations extend to functors $f_* : \mathrm{Ab}(X) \to \mathrm{Ab}(Y)$ and $f^{-1} : \mathrm{Ab}(Y) \to \mathrm{Ab}(X)$ in an obvious way. While these operations are generally not inverses, there is a relationship. There are canonical morphisms, called adjunctions, $\alpha : \mathscr{F} \to f_*f^{-1}\mathscr{F}$ and $\beta : f^{-1}f_*\mathscr{G} \to \mathscr{G}$ induced by the restriction maps

$$\begin{aligned} \mathscr{F}(U) \to \mathscr{F}(f(f^{-1}(U))) = f_*f^P\mathscr{F}(U) \to f_*f^{-1}\mathscr{F}(U), \quad U \subseteq Y, \\ f^Pf_*\mathscr{G}(V) = \mathscr{G}(f^{-1}(f(V))) \to \mathscr{G}(V), \quad V \subseteq X. \end{aligned}$$

Lemma 3.7.4. *There is a natural isomorphism*

$$\mathrm{Hom}_{\mathrm{Ab}(X)}(f^{-1}\mathscr{F}, \mathscr{G}) \cong \mathrm{Hom}_{\mathrm{Ab}(Y)}(\mathscr{F}, f_*\mathscr{G})$$

given by $\eta \mapsto (f_*\eta) \circ \alpha$. *The inverse is given by* $\xi \mapsto \beta \circ (f^{-1}\xi)$.

In the language of category theory, this says that the functor f^{-1} is left adjoint to f_*. The proof will be left as an exercise.

The collection of ringed spaces will form a category. To motivate the definition of morphism, observe that from a morphism F of concrete k-spaces $(X,\mathscr{R}) \to (Y,\mathscr{S})$, we get a morphism of sheaves of rings $\mathscr{S} \to F_*\mathscr{R}$ given by $s \mapsto s \circ F$.

Definition 3.7.5. A morphism of (k-)ringed spaces $(X,\mathscr{R}) \to (Y,\mathscr{S})$ is a continuous map $F : X \to Y$ together with a morphism of sheaves of rings (or algebras) $F' : \mathscr{S} \to F_*\mathscr{R}$.

By Lemma 3.7.4, to give F' is equivalent to giving the adjoint map $F^{-1}\mathscr{S} \to \mathscr{R}$. Therefore we have the induced ring homomorphism $\mathscr{S}_{F(x)} \to \mathscr{R}_x$ for each $x \in X$.

Definition 3.7.6. If $(X,\mathscr{R})$ and $(Y,\mathscr{S})$ are locally ringed, a morphism $F : (X,\mathscr{R}) \to (Y,\mathscr{S})$ is called a morphism of locally ringed spaces if it satisfies the additional requirement that the induced maps $\mathscr{S}_{F(x)} \to \mathscr{R}_x$ be local homomorphisms. A morphism of schemes is simply a morphism of locally ringed spaces

For affine schemes, we have the following description.

Proposition 3.7.7. *Let R and S be affine algebras. There is a bijection*

$$\mathrm{Hom}_{\mathrm{Schemes}}((\mathrm{Spec}_m S, \mathscr{O}_{\mathrm{Spec}_m S}), (\mathrm{Spec}_m R, \mathscr{O}_{\mathrm{Spec}_m R})) \cong \mathrm{Hom}_{k\text{-alg}}(R,S).$$

Therefore there is an antiequivalence between the category of affine schemes and affine algebras.

Proof. Let $X = \mathrm{Spec}_m S$ and $Y = \mathrm{Spec}_m R$. Given a homomorphism $f : R \to S$, we just construct the corresponding morphism $F = f^* : X \to Y$. If $m \subset S$ is a maximal ideal, then $f^{-1}m$ is again a maximal ideal by Hilbert's Nullstellensatz. So we can define $F(m) = f^{-1}m$. It is easy to see that F is continuous. The induced homomorphisms $R[1/r] \to S[1/f(r)]$ yield morphisms $\mathscr{O}_Y \to F_*\mathscr{O}_X$ of sheaves of rings on basic open sets, and therefore on their extensions. The maps on stalks are the induced local homomorphisms $f_m : R_{F(m)} \to S_m$. Therefore F is a morphism of schemes.

In the opposite direction, a morphism $F : X \to Y$ induces a homomorphism $R = \mathscr{O}(Y) \to \mathscr{O}(X) = S$. This yields the inverse. The remaining details will be left as an exercise. □

The simplest example of a scheme that is not a variety is the fat point $\mathrm{Spec}_m k[\varepsilon]/(\varepsilon^2)$. This has the following interesting property.

Lemma 3.7.8. *If X is a scheme, the set of morphisms from $\mathrm{Spec}_m k[\varepsilon]/(\varepsilon^2)$ to X is in one-to-one correspondence with the set of vectors in the disjoint union of tangent spaces $\cup T_x$.*

Proof. The scheme $D = \mathrm{Spec}_m k[\varepsilon]/(\varepsilon^2)$ has a unique point $m = (\varepsilon)$. We show that the set of morphisms $i : D \to X$ with $i(m) = x$ is in one to one correspondence with T_x. To give such a morphism is equivalent to giving a morphism of D to a neighborhood of x. Therefore, we may replace X by an affine scheme $\mathrm{Spec}_m R$. By Proposition 3.7.7, $D \to \mathrm{Spec}_m R$ corresponds to an algebra homomorphism $i^* : R \to k[\varepsilon]/(\varepsilon^2)$ such that $(i^*)^{-1}m = m_x$. The map i^* factors through R/m_x^2. We can see that any homomorphism

$$h : R/m_x^2 = k \oplus m_x/m_x^2 \to k[\varepsilon]/(\varepsilon^2) = k \oplus k\varepsilon$$

is given by $h(a,b) = a + v(b)\varepsilon$ for $v \in T_x = (m_x/m_x^2)^*$. The argument can be reversed to show that conversely, any vector in $v \in T_x$ determines an algebra map $i^* : R \to k[\varepsilon]/(\varepsilon^2)$ for which $(i^*)^{-1}m = m_x$. □

Suppose that $f : (X, \mathscr{R}) \to (Y, \mathscr{S})$ is a morphism of ringed spaces. Given an $\mathscr{R}$-module $\mathscr{M}$, $f_*\mathscr{M}$ is naturally an $f_*\mathscr{R}$-module, and hence an $\mathscr{S}$-module by restriction of scalars via $\mathscr{S} \to f_*\mathscr{R}$. Similarly, given an $\mathscr{S}$-module $\mathscr{N}$, $f^{-1}\mathscr{N}$ is naturally an $f^{-1}\mathscr{S}$-module. We define the $\mathscr{R}$-module

$$f^*\mathscr{N} = \mathscr{R} \otimes_{f^{-1}\mathscr{S}} f^{-1}\mathscr{N},$$

where the $\mathscr{R}$ is regarded as an $f^{-1}\mathscr{S}$-module under the adjoint map $f^{-1}\mathscr{S} \to \mathscr{R}$. When f is injective, we often write $\mathscr{N}|_X$ instead of $f^*\mathscr{N}$.

The inverse image of a locally free sheaf is easily seen to be locally free. This has an interpretation in the context of vector bundles. If $\pi : V \to Y$ is a vector bundle, the pullback $f^*V \to X$ is the vector bundle given set theoretically as the projection

$$f^*V = \{(v,x) \,|\, \pi(v) = f(x)\} \to X.$$

Then

$$f^*(\mathscr{V}) \cong (\text{sheaf of sections of } f^*V). \tag{3.7.3}$$

A special case is that in which $X = \{y\} \to Y$ is the inclusion of a point. Then the fiber $\pi^{-1}y$ can be identified with $f^*(\mathscr{V}) = (\mathscr{R}_y/m_y) \otimes \mathscr{V}_y$.

Exercises

3.7.9. Verify (3.7.2).

3.7.10. Prove Lemma 3.7.4.

3.7.11. Give examples where $\mathscr{F} \to f_*f^{-1}\mathscr{F}$ and $f^{-1}f_*\mathscr{G} \to \mathscr{G}$ are not isomorphisms.

3.7.12. Complete the proof of Proposition 3.7.7.

3.7.13. Given an inclusion of an open set $j : U \to X$ and a sheaf $\mathscr{F}$ on U, define $j_!\mathscr{F}$ to be the sheafification of the presheaf

$$\mathscr{G}(V) = \begin{cases} \mathscr{F}(V) & \text{if } V \subseteq U, \\ 0 & \text{otherwise.} \end{cases}$$

If $\mathscr{S}$ is a sheaf on X, show that this fits into an exact sequence

$$0 \to j_!j^{-1}\mathscr{S} \to \mathscr{S} \to i_*i^{-1}\mathscr{S} \to 0,$$

where $i : X - U \to X$ is the inclusion of the complement.

3.7.14. Generalize Lemma 3.2.5 to show that an exact sequence $0 \to \mathscr{A} \to \mathscr{B} \to \mathscr{C} \to 0$ of sheaves gives rise to an exact sequence $0 \to f_*\mathscr{A} \to f_*\mathscr{B} \to f_*\mathscr{C}$. In other words, f_* is left exact.

3.7.15. Prove that f^{-1} is exact, i.e., that it takes exact sequences to exact sequences.

3.7.16. Verify the assertion given in (3.7.3).

3.7.17. Suppose we have gluing data (R_i, ϕ_{ij}) and (R'_i, ϕ'_{ij}) and homomorphisms $f_i : R_i \to R'_i$ such that $f_i\phi'_{ij} = \phi_{ij}f_j$. Show that there is an induced morphism of glued schemes extending $f_i^* : \mathrm{Spec}_m R'_i \to \mathrm{Spec}_m R_i$. Use this to justify Remark 3.4.11.

3.7.18. Let L_d be obtained by gluing $\mathrm{Spec}_m k[x,y]$ to $\mathrm{Spec}_m k[x^{-1}, x^d y]$. Show that L_d is a line bundle over $\mathbb{P}^1_k$ whose sheaf of sections is isomorphic to $\mathscr{O}(\pm d)$.

3.7.19. Let $f : \mathbb{P}^{n-1}_k \to \mathbb{P}^n_k$ be a linear embedding, given for example by setting $x_n = 0$. Show that $f^*\mathscr{O}_{\mathbb{P}^n}(d) = \mathscr{O}_{\mathbb{P}_{n-1}}(d)$.

3.7.20. Let $v : \mathbb{P}^n_k \to \mathbb{P}^N_k$ be the dth Veronese embedding. Show that $v^*\mathscr{O}_{\mathbb{P}^N}(1) = \mathscr{O}_{\mathbb{P}^n}(d)$.

3.7.21. An n-jet on a scheme X is a morphism from $\operatorname{Spec} k[\varepsilon]/(\varepsilon^{n+1})$ to X. Give an interpretation of these similar to Lemma 3.7.8.

3.8 Differentials

With basic sheaf theory in hand, we can now construct sheaves of differential forms on manifolds and varieties in a unified way. In order to motivate things, let us start with a calculation. Suppose that $X = \mathbb{R}^n$ with coordinates $x_1, \ldots, x_n$. Given a C^∞ function f on X, we can develop a Taylor expansion about $(y_1, \ldots, y_n)$:

$$f(x_1, \ldots, x_n) = f(y_1, \ldots, y_n) + \sum \frac{\partial f}{\partial x_i}(y_1, \ldots, y_n)(x_i - y_i) + O((x_i - y_i)^2).$$

Thus the differential is given by

$$df = f(x_1, \ldots, x_n) - f(y_1, \ldots, y_n) \mod (x_i - y_i)^2.$$

We can view $x_1, \ldots, x_n, y_1, \ldots, y_n$ as coordinates on $X \times X = \mathbb{R}^{2n}$, so that $x_i - y_i = 0$ defines the diagonal Δ. Then df lies in the ideal of Δ modulo its square.

Let X be a C^∞ or complex manifold or an algebraic variety over a field k. We take $k = \mathbb{R}$ or $\mathbb{C}$ in the first two cases. We have a diagonal map $\delta : X \to X \times X$ given by $x \mapsto (x, x)$, and projections $p_i : X \times X \to X$. Let $\mathscr{I}_\Delta$ be the ideal sheaf of the image of δ, and let $\mathscr{I}_\Delta^2 \subseteq \mathscr{I}_\Delta$ be the sub–ideal sheaf locally generated by products of pairs of sections of $\mathscr{I}_\Delta$. Then we define the sheaf of 1-forms by

$$\Omega^1_X = (\mathscr{I}_\Delta / \mathscr{I}_\Delta^2)|_\Delta.$$

This has two different $\mathscr{O}_X$-module structures; we pick the first one, where $\mathscr{O}_X$ acts on $\mathscr{I}_\Delta$ through $p_1^{-1}\mathscr{O}_X \to \mathscr{O}_{X \times X}$. We define the sheaf of p-forms by $\Omega^p_X = \wedge^p \Omega^1_X$. We define a morphism $d : \mathscr{O}_X \to \Omega^1_X$ of sheaves (but not $\mathscr{O}_X$-modules) by $df = p_1^*(f) - p_2^*(f)$. This has the right formal properties because of the following:

Lemma 3.8.1. *d is a k-linear derivation.*

Proof. By direct calculation,

$$d(fg) - fdg - gdf = [p_1^*(f) - p_2^*(f)][p_2^*(g) - p_2^*(g)] \in \mathscr{I}_\Delta^2. \qquad \square$$

Differentials behave contravariantly with respect to morphisms. Given a morphism of manifolds or varieties $f : Y \to X$, we get a morphism $Y \times Y \to X \times X$

Chapter 6
Riemann Surfaces

Riemann surfaces are the same thing as one-dimensional complex manifolds or nonsingular complex curves. Although the basic concept goes back to Riemann, the rigorous definition appears to be due to Weyl [122]. We already considered these briefly in the first chapter. But now we are in a position to make a more thorough study using the geometric and homological tools introduced in the intervening chapters. Nevertheless, we will only scratch the surface of this rich subject. Further details can be found in [5, 20, 49, 38] in addition to Weyl's book.

6.1 Genus

The coarsest classification is topological. A Riemann surface can be regarded as a manifold of real dimension 2. It has a canonical orientation: if we identify the real tangent space at any point with the complex tangent space, then for any nonzero vector v, we declare the ordered basis (v, iv) to be positively oriented. Let us now forget the complex structure and consider the purely topological problem of classifying these surfaces up to homeomorphism.

Given two connected 2-dimensional topological manifolds X and Y with points $x \in X$ and $y \in Y$, we can form a new topological manifold $X\#Y$, called the connected sum. To construct this, choose open disks $D_1 \subset X$ and $D_2 \subset Y$. Then $X\#Y$ is obtained by gluing $X - D_1 \cup S^1 \times [0,1] \cup Y - D_2$ appropriately. The homeomorphism class is independent of the choices made. Figure 6.1 depicts the connected sum of two tori.

Theorem 6.1.1. *A compact connected orientable 2-dimensional topological manifold is classified, up to homeomorphism, by a nonnegative integer called the genus. A genus-*0 *surface is homeomorphic to the 2-sphere* S^2*. A manifold of genus* $g > 0$ *is homeomorphic to a connected sum of the 2-torus and a surface of genus* $g - 1$*.*

Proof. An equivalent formulation is that every such manifold is homeomorphic to a sphere with g handles. A classical reference for this is [99, p. 145]. ☐

D. Arapura, *Algebraic Geometry over the Complex Numbers*, Universitext,
DOI 10.1007/978-1-4614-1809-2_6, © Springer Science+Business Media, LLC 2012

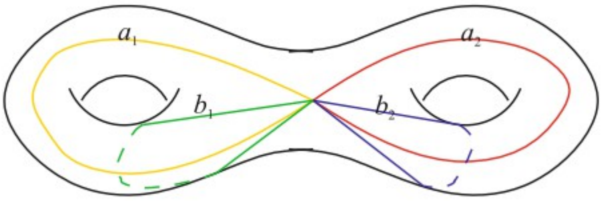

Fig. 6.1 Genus-2 surface.

There is another standard model for these surfaces [99] that is also quite useful (for instance for computing the fundamental group). A genus-g surface can be constructed by gluing the sides of a $2g$-gon. It is probably easier to visualize this in reverse. After cutting the genus-2 surface of Figure 6.1 along the indicated curves, it can be opened up to an octagon (see Figure 6.2).

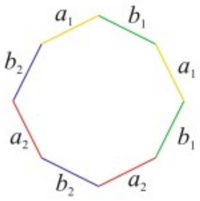

Fig. 6.2 Genus-2 surface cut open.

The topological Euler characteristic of the space X is

$$e(X) = \sum(-1)^i \dim H^i(X,\mathbb{R}).$$

From Exercise 4.5.5, we have the following lemma:

Lemma 6.1.2. *If X is a union of two open sets U and V, then $e(X) = e(U) + e(V) - e(U \cap V)$.*

Corollary 6.1.3. *If X is a manifold of genus g, then $e(X) = 2 - 2g$, and the first Betti number is given by $\dim H^1(X,\mathbb{R}) = 2g$.*

Proof. This will be left for the exercises. □

When $g = 2$, this gives $\dim H^1(X,\mathbb{R}) = 4$. We can find explicit generators by taking the fundamental classes of the curves a_1, a_2, b_1, b_2 in Figure 6.1, after choosing orientations. To see that these generate, $H^1(X,\mathbb{R})$, it suffices to prove that they are linearly independent. For this, consider the pairing

$$(\alpha,\beta) \mapsto \int_X \alpha \wedge \beta$$

on $H^1(X,\mathbb{R})$. This restricts to the intersection pairing on fundamental classes. After orienting the curves suitably, their intersection matrix is

$$\begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix},$$

and this shows independence. A similar basis with intersection matrix

$$\begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}$$

can be found for any g. These basis vectors will generate a lattice inside $H^1(X,\mathbb{R})$ that can be identified with $H^1(X,\mathbb{Z})$.

To answer the obvious question, we show that every genus occurs by direct construction. A much harder question is, what does a typical genus g look like? Many examples of compact Riemann surfaces can be given explicitly as nonsingular projective algebraic curves, and we start with this approach. Later, we will see that all compact Riemann surfaces arise in this way.

Example 6.1.4. Let $f(x,y,z)$ be a homogeneous polynomial of degree d. Suppose that the partials of f have no common zeros in $\mathbb{C}^3$ except $(0,0,0)$. Then the curve $V(f) = \{f(x,y,z) = 0\}$ in $\mathbb{P}^2_{\mathbb{C}}$ is nonsingular. We will see later that the genus is $\frac{(d-1)(d-2)}{2}$. In particular, not every genus occurs for these examples.

Example 6.1.5. Given a collection of homogeneous polynomials $f_i \in \mathbb{C}[x_0,\dots,x_n]$ such that $X = V(f_1, f_2, \dots) \subset \mathbb{P}^n_{\mathbb{C}}$ is a nonsingular algebraic curve, then X will be a complex submanifold of $\mathbb{P}^n_{\mathbb{C}}$ and hence a Riemann surface. By a generic projection argument, $n = 3$ suffices to give all such examples.

Example 6.1.6. Choose $2g+2$ distinct points in $a_i \in \mathbb{C}$. Consider the affine curve $C_1 \subset \mathbb{C}^2$ defined by

$$y^2 = \prod (x - a_i).$$

We can compactify this to obtain a nonsingular projective curve C by taking the projective closure and normalizing. Here is an alternative description of the same curve. Consider the affine curve C_2:

$$Y^2 = \prod (1 - a_i X).$$

Glue this to C_1 by identifying $X = x^{-1}$ and $Y = yx^{-g-1}$. Since C is nonsingular, it can be viewed as a Riemann surface. By construction, C comes equipped with a morphism $f : C \to \mathbb{P}^1_{\mathbb{C}}$ that is 2-to-1 except at the branch points $\{a_i\}$. In the exercises, it will be shown that the genus of X is g. Curves of this form are called hyperelliptic (if $g > 1$), and they are very nice to work with. However, "most" curves are not hyperelliptic.

From a more analytic point of view, we can construct many examples as quotients of $\mathbb{C}$ or the upper half-plane. In fact, the *uniformization theorem* [38] tells us that all examples other than $\mathbb{P}^1$ arise in this way.

Example 6.1.7. Let $L \subset \mathbb{C}$ be a lattice, i.e., an abelian subgroup generated by two $\mathbb{R}$-linearly independent numbers. The quotient $E = \mathbb{C}/L$ can be made into a Riemann surface (Exercise 2.2.20) called an elliptic curve. Since this is topologically a torus, the genus is 1. Conversely, any genus-1 curve is of this form.

The surface $E = \mathbb{C}/L$ can be realized as an algebraic curve in a couple of ways. As we saw in the first chapter, we can embed it into $\mathbb{P}^2$ as the cubic curve

$$zy^2 = 4x^3 - g_2(L)xz^2 - g_3(L)z^3 \tag{6.1.1}$$

by $z \mapsto [\wp(z), \wp'(z), 1]$. Alternatively, $\wp : E \to \mathbb{P}^1$ realizes this directly as a two-sheeted cover branched at four points. We can assume without loss of generality that these are $0, 1, \infty, t$. Then E is given by Legendre's equation

$$y^2z = x(x-z)(x-tz). \tag{6.1.2}$$

Let us now consider quotients of the upper half-plane $H = \{z \mid Im(z) > 0\}$. The group $\mathrm{SL}_2(\mathbb{R})$ acts on H by fractional linear transformations:

$$z \mapsto \frac{az+b}{cz+d}.$$

Note that $-I$ acts trivially, so the action factors through $\mathrm{PSL}_2(\mathbb{R}) = \mathrm{SL}_2(\mathbb{R})/\{\pm I\}$. The action of subgroup $\Gamma \subset \mathrm{SL}_2(\mathbb{R})$ on H is *properly discontinuous* if every point has a neighborhood V such that $\gamma V \cap V \neq \emptyset$ for all but finitely many $\gamma \in \Gamma$. A point $x \in V$ is called a *fixed point* if its stabilizer in $\Gamma/\{\pm I\}$ is nontrivial. The action is *free* if it has no fixed points.

Proposition 6.1.8. *If Γ acts properly discontinuously on H, the quotient $X = H/\Gamma$ becomes a Riemann surface. If $\pi : H \to X$ denotes the projection, the structure sheaf is defined by $f \in \mathscr{O}_X(U)$ if and only if $f \circ \pi \in \mathscr{O}_H(\pi^{-1}U)$.*

When Γ acts freely with compact quotient, then it has genus $g > 1$. The quickest way to see this is by applying the Gauss–Bonnet theorem [56], which says that $e(H/\Gamma) = 2 - 2g$ can be computed by integrating the Gaussian curvature for any Riemannian metric. The hyperbolic metric on H, which descends to the quotient, has negative curvature. A *fundamental domain* for this action is a region $R \subset H$ such that $\cup_\gamma \gamma \bar{R} = H$ and such that two translates of $\bar{R}$ can meet only at their boundaries. The fundamental domain in this case can be chosen to be the interior of a geodesic $2g$-gon.

The modular group $\mathrm{SL}_2(\mathbb{Z})$ is a particularly important example where the action is not free.

Theorem 6.1.9. *The quotient $H/\mathrm{SL}_2(\mathbb{Z})$ is isomorphic to $\mathbb{C}$, and its points correspond to isomorphism classes of elliptic curves (which are genus-one curves with a distinguished point).*

Proof. We sketch the idea. The details can be found in [32, 106] or [103]. A fundamental domain for the action is given in Figure 6.3. The marked points in the diagram are $\rho = e^{2\pi\imath/3}, i$, and $\rho + 1$.

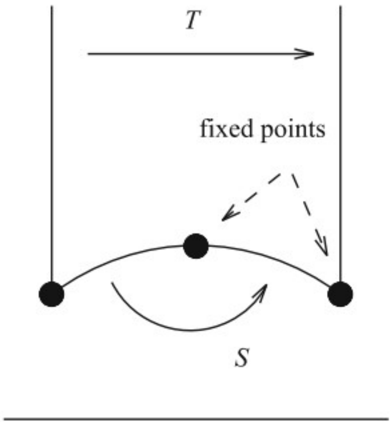

Fig. 6.3 Fundamental domain of $\mathrm{SL}_2(\mathbb{Z})$.

After identifying the sides of the domain by the transformations

$$S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad T = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix},$$

as indicated in the diagram, one sees that that the quotient $H/\mathrm{SL}_2(\mathbb{Z})$ is homeomorphic to $\mathbb{C}$. By the Riemann mapping theorem, $H/\mathrm{SL}_2(\mathbb{Z})$ is isomorphic to either $\mathbb{C}$ or H. To see that it is $\mathbb{C}$, we show that the one-point compactification $H/\mathrm{SL}_2(\mathbb{Z}) \cup \{*\}$ can also be made into a Riemann surface, necessarily isomorphic to $\mathbb{P}^1$. Any continuous function f defined in a neighborhood of $*$ can be pulled back to an $\mathrm{SL}_2(\mathbb{Z})$-invariant function $\tilde{f}$ on H. Invariance under T implies that $\tilde{f}$ is periodic; hence it can be expanded in a Fourier series

$$\tilde{f}(z) = \sum_{n=-\infty}^{\infty} a_n e^{2\pi i n z}.$$

We declare f to be holomorphic if all the a_n are zero for $n < 0$. To put this another way, $q = e^{2\pi i z}$ is taken as a local analytic coordinate at $*$.

The relation to elliptic curves is given in the exercises. ☐

Exercises

6.1.10. Prove Corollary 6.1.3.

Chapter 11
A Little Algebraic Surface Theory

Let us return to geometry armed with what we have learned so far. We have already looked at Riemann surfaces (which will be referred to as complex curves from now on) in some detail. So we consider the next step up. A nonsingular complex surface is a two-dimensional complex manifold. By an algebraic surface, we will mean a two-dimensional nonsingular projective variety. So in particular, they are Kähler manifolds. In this chapter, we will present a somewhat breezy account of surface theory, concentrating on topics that illustrate the general theorems from the previous chapters.

Much more systematic introductions to algebraic surface theory can be found in the books by Barth, Peters, and Van de Ven [9] and Beauville [10].

11.1 Examples

The basic discrete invariant of a curve is its genus. For algebraic surfaces, there are several numbers that play a similar role. We can use the Hodge numbers. By the symmetry properties considered earlier, there are only three that matter: h^{10}, h^{20}, h^{11}. The first two are traditionally called (and denoted by) the *irregularity* ($q = h^{10}$) and *geometric genus* ($p_g = h^{20}$). The basic topological invariants are the Betti numbers, which by Poincaré duality and the Hodge decomposition theorem can be expressed as

$$b_1 = b_3 = 2q, \quad b_2 = 2p_g + h^{11}.$$

It is also convenient to consider the Euler characteristic,

$$e = b_0 - b_1 + b_2 - b_3 + b_4 = 2 - 4q + 2p_g + h^{11}.$$

Let us now start our tour.

D. Arapura, *Algebraic Geometry over the Complex Numbers*, Universitext,
DOI 10.1007/978-1-4614-1809-2_11, © Springer Science+Business Media, LLC 2012

Example 11.1.1. The most basic example is the projective plane $X = \mathbb{P}^2 = \mathbb{P}^2_{\mathbb{C}}$. We computed the Betti numbers $b_1 = 0, b_2 = 1$ in Section 7.2. Therefore $q = p_g = 0$ and $h^{11} = 1$.

Example 11.1.2. If $X = C_1 \times C_2$ is a product of two nonsingular curves of genus g_1 and g_2, then by Künneth's formula (Theorem 5.3.6 and Corollary 10.2.6),

$$q = h^{10}(X) = h^{10}(C_1)h^{00}(C_2) + h^{00}(C_1)h^{10}(C_2) = g_1 + g_2.$$

Similarly, $p_g = g_1 g_2$ and $h^{11} = 2g_1 g_2 + 2$.

Example 11.1.3. As a special case of the previous example, when we have a product of a curve C with $\mathbb{P}^1$, the invariants are $q = g$, $p_g = 0$, and $h^{11} = 2$. More generally, we can consider ruled surfaces over C, which are $\mathbb{P}^1$-bundles that are locally isomorphic to $U_i \times \mathbb{P}^1$, for a Zariski open cover $\{U_i\}$ of C. (See Section 14.5 for a bit more explanation of what this means.) We will see shortly that the invariants are the same as above, although they are not generally products. When $C = \mathbb{P}^1$, there are, up to isomorphism, countably many ruled surfaces. Here is a simple description. Let $C_n \subset \mathbb{P}^n$ be the closure of $\{(t, t^2, \dots, t^n) \mid t \in \mathbb{C}\}$. Choose a point $p_0 \in \mathbb{P}^n - C_n$. Let F_n be the set of pairs $(q, p) \in \mathbb{P}^n \times C_n$ such that q lies on the line connecting p_0 to q.

Example 11.1.4. Let $X \subset \mathbb{P}^3$ be a smooth surface of degree d. Then $q = 0$. We will list the first few values of the remaining invariants:

d	p_g	h^{11}
2	0	2
3	0	7
4	1	20
5	4	45
6	10	86

These can be calculated using formulas given later (17.3.4).

A method of generating new examples from old is by blowing up. We start by describing the blowup of $\mathbb{C}^2$ at 0:

$$\mathrm{Bl}_0\mathbb{C}^2 = \{(x, \ell) \in \mathbb{C}^2 \times \mathbb{P}^1 \,|\, x \in \ell\}.$$

The projection $p_1 : \mathrm{Bl}_0\mathbb{C}^2 \to \mathbb{C}^2$ is one-to-one away from $0 \in \mathbb{C}^2$. This can be generalized to yield the blowup $\mathrm{Bl}_pX \to X$ of a surface X at the point p. Let $B \subset X$ be a coordinate ball centered at p. After identifying B with a ball in $\mathbb{C}^2$ centered at 0, we can let Bl_0B be the preimage of B in $\mathrm{Bl}_0\mathbb{C}^2$. The boundary of Bl_0B can be identified with the boundary of B. Thus we can glue $X - B \cup \mathrm{Bl}_0B$ to form Bl_pX. When X is algebraic, Bl_pX is again algebraic by Exercise 2.4.23.

Let us compute $H^*(\mathrm{Bl}_pX, \mathbb{Z})$. Set $Y = \mathrm{Bl}_pX$ and compare Mayer–Vietoris sequences:

$$\begin{tikzcd}
H^i(X) \arrow[r] \arrow[d] & H^i(X-B')\oplus H^i(B) \arrow[r] \arrow[d] & H^i(X-B'\cap B) \arrow[d, "="] \\
H^i(Y) \arrow[r] & H^i(Y-\mathrm{Bl}_pB')\oplus H^i(\mathrm{Bl}_pB) \arrow[r] & H^i(Y-\mathrm{Bl}_pB'\cap \mathrm{Bl}_pB)
\end{tikzcd}$$

where $B' \subset B$ is a smaller ball. We thus have the following result:

Lemma 11.1.5. *$H^1(\mathrm{Bl}_pX) \cong H^1(X)$ and $H^2(\mathrm{Bl}_pX) = H^2(X) \oplus \mathbb{Z}$.*

Corollary 11.1.6. *q and p_g are invariant under blowing up. $h^{11}(\mathrm{Bl}_pX) = h^{11}(X)+1$.*

Proof. The lemma implies that $b_1 = 2q$ is invariant and $b_2(Y) = b_1(X)+1$. Since $b_2 = 2p_g + h^{11}$, the only possibilities are $h^{11}(Y) = h^{11}(X)+1$, $p_g(Y) = p_g(X)$, and $p_g(Y) < p_g(X)$. The last inequality means that there is a nonzero holomorphic 2-form on X that vanishes on $X-p$, but this is impossible. ☐

A *birational map* $\kappa : X \dashrightarrow Y$ is simply an isomorphism in the category of varieties and rational maps. In more explicit terms, it is given by an isomorphism of Zariski open sets $X \supset U \cong V \subset Y$. Blowups and their inverses ("blowdowns") are examples of birational maps. Two varieties are birationally equivalent if a birational map exists between them. For example, any two ruled surfaces over $\mathbb{P}^1$ are birationally equivalent to each other and to $\mathbb{P}^2$, because they all contain $\mathbb{A}^2$.

For surfaces, the structure of birational maps is explained by the following theorem:

Theorem 11.1.7 (Castelnuovo). *Any birational map between algebraic surfaces is given by a finite sequence of blowups and blowdowns.*

Proof. See [60, 9]. ☐

Corollary 11.1.8. *The numbers q and p_g depend only on the birational equivalence class of the surface.*

This implies that $p_g = g, q = 0$ for ruled surfaces over a genus-g curve, as claimed above.

Blowing up of singular points figures in the proof of the next important theorem.

Theorem 11.1.9 (Zariski). *Given a singular algebraic surface Y, there exist a nonsingular surface X and a morphism $\pi : X \to Y$, called a resolution of singularities, that is an isomorphism away from the singular points.*

Proof. See [9]. ☐

Corollary 11.1.10 (Zariski). *If $f : X \dashrightarrow V$ is a rational function from an algebraic surface to a variety V, then there is a finite sequence of blowups $Y \to X$ such that f extends to a holomorphic map $f' : Y \to V$.*

Proof. We can construct Y by resolving singularities of the closure of the graph of f. $\square$

Analogues of Zariski's and Castelnuovo's theorems in higher dimensions have been established by Hironaka and Włodarczyk respectively. These are much harder.

An *elliptic surface* is a surface X that admits a surjective morphism $f : X \to C$ to a smooth projective curve such that all nonsingular fibers are elliptic curves.

Example 11.1.11. A simple example of an elliptic surface is given as follows: choose two distinct nonsingular cubics $E_0, E_1 \subset \mathbb{P}^2$ defined by $f_0(x,y,z)$ and $f_1(x,y,z)$. These generate a pencil of cubics $E_t = V(tf_1 + (1-t)f_0)$ with $t \in \mathbb{P}^1$. Define

$$X = \{(p,t) \in \mathbb{P}^2 \times \mathbb{P}^1 \mid p \in E_t\}.$$

Projection to $\mathbb{P}^1$ makes this an elliptic surface. X can be identified with the blowup of $\mathbb{P}^2$ at the nine points $E_0 \cap E_1$. So $q = p_g = 0$ and $h^{11} = 10$.

Example 11.1.12. Consider the family of elliptic curves in Legendre form

$$\mathscr{E} = \{([x,y,z],t) \in \mathbb{P}^2 \times \mathbb{C} - \{0,1\} \mid y^2z - x(x-z)(x-tz) = 0\} \to \mathbb{C}.$$

The above equation is meaningful if $t = 0, 1$, and it defines a rational curve with a single node. By introducing $s = t^{-1}$, we get an equation

$$sy^2z - x(x-z)(sx-z) = 0$$

that defines a union of lines when $s = 0$. In this way, we can extend $\mathscr{E}$ to a surface $\mathscr{E}' \to \mathbb{P}^1$. Unfortunately, $\mathscr{E}'$ is singular, and it is necessary to resolve singularities to get a nonsingular surface $\bar{\mathscr{E}}$ containing $\mathscr{E}$ (we can take the minimal desingularization, which for our purposes means that $b_2(\bar{\mathscr{E}})$ is chosen as small as possible).

Exercises

11.1.13. Finish the proof of Lemma 11.1.5.

11.1.14. Given a ruled surface X over a curve C, check that $e(X) = e(\mathbb{P}^1)e(C)$, and use this to verify that $h^{11}(X) = 2$.

11.1.15. Show that there is a nonsingular quartic $X \subset \mathbb{P}^3$ containing a line ℓ, which we can assume to be $x_2 = x_3 = 0$. Show that the map $\mathbb{P}^3 \dashrightarrow \mathbb{P}^1$ defined by $[x_0, \ldots, x_3] \mapsto [x_0, x_1]$ determines a morphism $X \to \mathbb{P}^1$ that makes it an ellptic surface.

11.1.16. Given a smooth projective curve C, the symmetric product is given by $S^2C = C \times C/\sigma$, where σ is the involution interchanging factors. This has the structure of a smooth algebraic surface such that $H^i(S^2C, \mathbb{Q}) = H^i(C \times C, \mathbb{Q})^\sigma$. Compute the Betti and Hodge numbers for S^2C.

Theorem 1.11.6. *A knot which is the image of a C^1 function is ambient isotopic to a polygonal knot.*

PROOF (SKETCH). We shall describe an isotopy that deforms the knot so that it becomes the set of cone axes. Outside the cones, the isotopy is the identity. Inside each cone, the isotopy behaves on each level disc as indicated in Figure 1.17: the disc is transformed so that the single point of intersection of the knot with the disc is pulled into the centre. ☐

The converse is much easier.

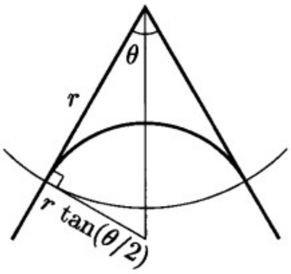

Figure 1.18. A corner can be replaced by a circular arc.

2 A Topologist's Toolkit

Most mathematics texts start from a specified base of mathematical knowledge, add some new ideas, and build on what has been previously studied to develop a familiar topic to a deeper level, or in a new direction. All the stages in the development of the theory are carefully proved and explained with nothing being assumed or hidden. If this pattern were strictly adhered to, knot theory would not be studied at undergraduate level.

To make the study of knot theory mathematically rigorous requires a fair amount of topological sophistication. We have seen that, if we are not careful, our definitions can lead to unexpected results. Trying to understand and exclude wild behaviour was one of the central questions for topologists in the middle of the twentieth century. Many strange spaces and embeddings were created to provide counterexamples to various conjectures. Eventually this work resulted in a firm foundation for geometric topology.

The fact that these foundations have not been studied should not inhibit progress. We shall proceed as working topologists do and just quote the useful results, safe in the knowledge that they have been established elsewhere. Just because we do not understand how a house is constructed that does not mean we cannot live in it.

The results we need are a set of 'tameness' conditions: they provide the reassurance that the topological world behaves as we expect it to. This means imposing a piecewise linear or differentiable structure on our objects of study. Because it is much easier to describe and manipulate piecewise linear objects, we shall work in that category.

With this in mind, this chapter contains a mixture of definitions, examples, facts, and techniques that we shall need throughout the book. The facts are theorems that we shall not prove. Some of them, like the classification of surfaces [71], you may have seen before. The others are topics for your further studies.

2.1 The 3-sphere

Knots and links live in 3-dimensional space. Normally we think of this space as being modelled by $\mathbb{R}^3$. Occasionally, however, we shall find it more convenient to think of links embedded in a compact space and for this we use the 3-dimensional sphere. Here are some descriptions of S^3.

1. Geometrically, the standard 3-sphere is the set of points in $\mathbb{R}^4$ that are one unit away from the origin: $S^3 = \{x \in \mathbb{R}^4 : |x| = 1\}$.

2. The 3-sphere is often thought of as the *1-point compactification* of $\mathbb{R}^3$. This means that we take $\mathbb{R}^3$ and an additional point denoted by ∞ and give it the following topology: a set U in $\mathbb{R}^3 \cup \{\infty\}$ is open if either U is an open set in $\mathbb{R}^3$, or $U = V \cup \{\infty\}$ where V is the complement of a closed and bounded set in $\mathbb{R}^3$.

   To show that $\mathbb{R}^3 \cup \{\infty\}$ is equivalent to the 3-sphere we use stereographic projection (the 2-dimensional case is shown in Figure 2.1). Let $\mathbb{R}^3 \subset \mathbb{R}^4$ be the subspace obtained by setting the fourth coordinate to -1, and let X be the unit 3-sphere in $\mathbb{R}^4$ minus the point $(0,0,0,1)$. There is a homeomorphism $h : \mathbb{R}^3 \longrightarrow X$: the unique line from $(0,0,0,1)$ to a point $p \in \mathbb{R}^3$ cuts X in a single point q and we define $h(p) = q$. We can extend h to a homeomorphism $\mathbb{R}^3 \cup \{\infty\} \longrightarrow S^3$ by setting $h(\infty) = (0,0,0,1)$. Check h is continuous in the given topology.

   If we are working in S^3, pictures of knots in infinite arcs (like the one

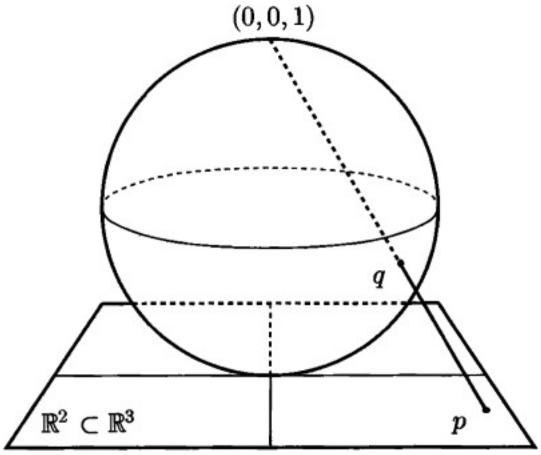

Figure 2.1. Stereographic projection of the plane onto a sphere.

shown in Figure 2.2) also represent loops: the lines extending left and right meet at ∞.

3. The (topological) 3-sphere can be constructed as the union of two balls glued together. This is analogous to the constructions in lower dimensions: a circle (S^1) can be formed by gluing the endpoints of two line segments together; a sphere (S^2) is formed by gluing the boundaries of two discs together.

   This decomposition of S^3 is easily seen through the previous example. The lower hemisphere $\{(x_1, \dots, x_4) \in S^3 \subset \mathbb{R}^4 : x_4 \leqslant 0\}$ is sent by stereographic projection to a 3-ball of radius 2 centred on $(0, 0, 0, -1)$. By symmetry, the upper hemisphere is also (homeomorphic to) a ball.

4. It is possible to construct a piecewise linear 3-sphere. An equilateral triangle is composed of 3 equal line segments meeting 2 at each vertex, and is topologically a circle (S^1). A regular tetrahedron is composed of 4 triangular discs glued edge to edge, meeting 3 at each vertex, and is topologically a sphere (S^2). Proceeding by analogy, we can take 5 solid tetrahedra, glue them face to face with 4 meeting at each vertex: this produces a combinatorial object that is topologically a 3-sphere.

From the topological viewpoint, it does not matter whether we work in $\mathbb{R}^3$ or S^3: a link that passes through ∞ can be moved a little to an isotopic position lying entirely in $\mathbb{R}^3$. However, there are some geometric problems in which differences do show up. In Figure 1.12 we saw that the figure-8 knot can be arranged so that a rigid motion of $\mathbb{R}^3$ (a rotation) carries the knot to its mirror image. In this position, it has an axis of rotation–reflection symmetry where the mirror plane is orthogonal to the axis. For some knots, such a transformation is possible in S^3 but not in $\mathbb{R}^3$. Figure 2.2 shows the oriented knot 8_{17} embedded in S^3 with the line extending left and right to ∞. This oriented knot is not + amphicheiral in S^3 or $\mathbb{R}^3$. However, it is clear from the figure that a 2-fold rotation of S^3 carries the knot to the reverse of its mirror image, showing that it is − amphicheiral. This symmetry can

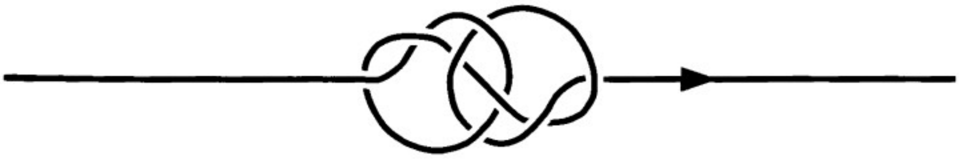

Figure 2.2. The knot 8_{17} is rigidly amphicheiral in S^3 but not in $\mathbb{R}^3$.

be shown topologically in $\mathbb{R}^3$ but it is not possible to demonstrate it using an axis of rotation–reflection in $\mathbb{R}^3$ [21, 70].

2.2 Manifolds

All the topological spaces we are interested in are n-dimensional *manifolds*, usually shortened to n-manifolds. A creature living inside a manifold can not distinguish its environment from the standard space $\mathbb{R}^n$ until it starts to move around. Any neighbourhood looks just like a neighbourhood of $\mathbb{R}^n$; it is only on a global scale that differences between manifolds can be discovered.

The upper half-space in $\mathbb{R}^n$ is the set $\mathbb{R}^n_+ = \{(x_1, \ldots, x_n) \in \mathbb{R}^n : x_n \geqslant 0\}$. Its boundary, the subset given by $x_n = 0$, is a copy of $\mathbb{R}^{n-1}$.

A topological space X is an n-manifold if it is Hausdorff,* has a countable basis, and each point $x \in X$ has a neighbourhood $U \ni x$ which is homeomorphic to $\mathbb{R}^n$ or to $\mathbb{R}^n_+$. If $x \in U$ maps to a point in the boundary of $\mathbb{R}^n_+$ then x is a boundary point of X. The set of all boundary points, denoted by ∂X, is an $(n-1)$-manifold and is called the *boundary* of X.

It is clear that a manifold can be covered with open sets, and that the covering may contain uncountably many sets. A manifold X is *compact* if, when given any covering of X by open sets, we can find a finite subcover. A compact manifold with no boundary, that is $\partial X = \varnothing$, is said to be *closed.*

Up to homeomorphism, there are only four different connected 1-manifolds, and an example of each type is given in Figure 2.3. The real line $\mathbb{R}$ itself is clearly a manifold. It has no boundary and is not compact. The half-line has a single boundary component, the point 0. The edge skeleton of a cube is not a 1-manifold: the vertices do not have the required neighbourhoods.

All the 1-manifolds have natural analogues in all other dimensions. The

Example		Boundary	Compact

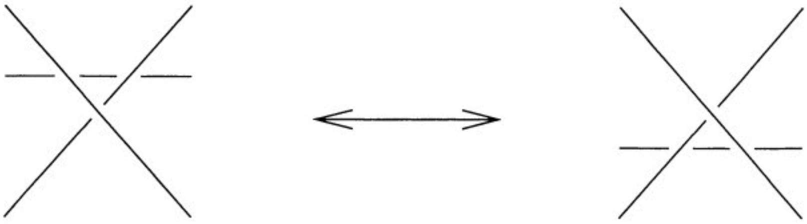

Fig. 2: Reidemeister move of type III

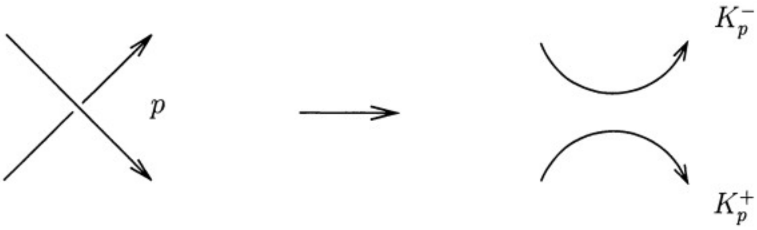
Definition 1.1 A *smoothing* of a crossing p is the procedure



$$i(C,p) := \frac{1}{2\pi i}\oint \frac{1}{z-p}\mathrm{d}z\ .$$

Chapter 1

The space of diagrams

Let pr : $F^2 \times \mathbb{R} \to F^2$ denote the standard projection. A *knot* K is the oriented image of a smooth embedding of S^1 in $F^2 \times \mathbb{R}$. We call K a *diagram* if pr : $K \to F^2$ is an immersion.

Let M_K denote the *space of all diagrams* which are isotopic to a given diagram K. Viewing diagrams as differentiable submanifolds of $F^2 \times \mathbb{R}$ we can introduce a natural topology on M_K. It turns out that this space is never connected. Its connected components consist of diagrams which are isotopic through a smooth sequence of diagrams. This is usually called *regular isotopy*.

As in the case of $\mathrm{F}^2 = \mathbb{R}^2$ two diagrams are regular isotopic if and only if they can be transformed one into the other by finite series of unoriented Reidemeisters moves of type II and III together with isotopies which leave the curve pr(K) fixed. (The proof is the same as in the case of $\mathbb{R}^2$ because Reidemeisters theorem is just the characterization of the generic singularities in a 1-parameter family of diagrams.)

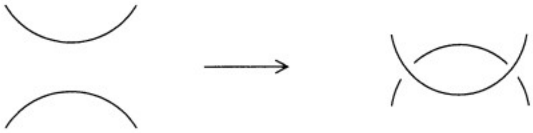


Fig. 1: Reidemeister move of type II

T. Fiedler, *Gauss Diagram Invariants for Knots and Links*
© Springer Science+Business Media Dordrecht 2001

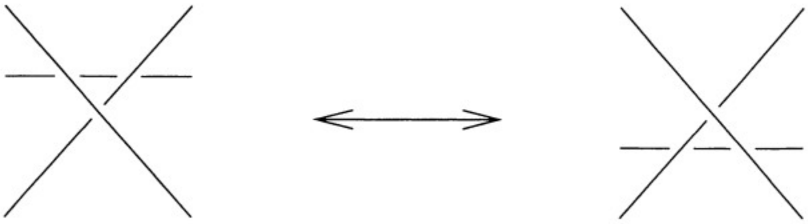

Fig. 2: Reidemeister move of type III

We introduce some basic notions.

Definition 1.1 A *smoothing* of a crossing p is the procedure

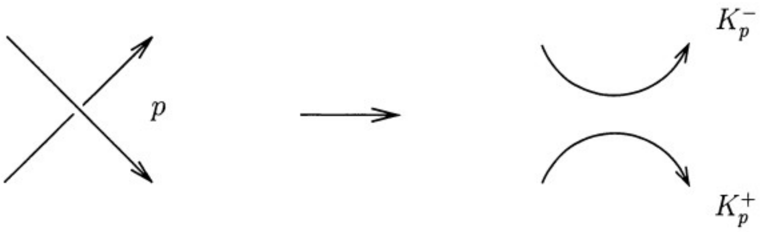

Fig. 3

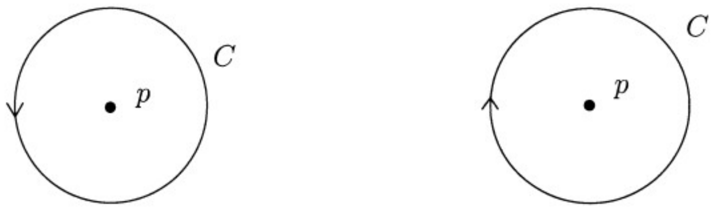
where K_p^+ denotes the component, where the undercrossing is smoothed to the overcrossing.

Note that in addition to the link diagram which results after this operation, we have the trace of p in its complement.

We will characterize the components of M_K only in the special case of planar surfaces, i.e., the surface F^2 is embedded in the oriented plane $\mathbb{R}^2 = \mathbb{C}$. In this case the following notions are well defined:
The *winding index* of a curve $C \subset F^2 \subset \mathbb{C}$ around a point $p \notin C$ is

$$i(C,p) := \frac{1}{2\pi i} \oint \frac{1}{z-p} \mathrm{d}z \ .$$

Pictorially it measures how many times the curve walks around p.



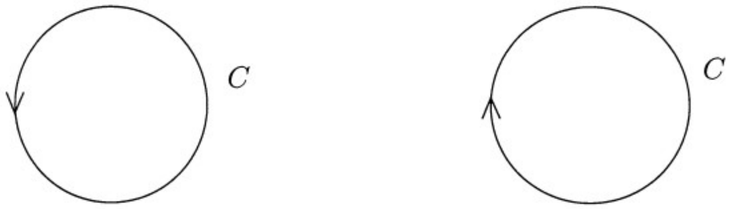
$i(C,p) = +1$ $i(C,p) = -1$

Fig. 4

The *Whitney index* $n(C)$ of a curve C is the degre of the map

$$\frac{C'}{||C'||} \; : \; S^1 \to S^1$$

where C' denotes the vector consisting of the derivatives. The *Whitney index of a diagram* K is the Whitney index of the curve pr(K).

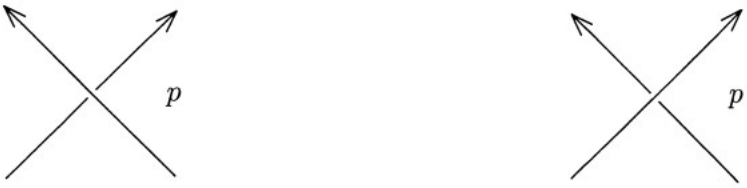


$n(C) = +1$ $n(C) = -1$

Fig. 5

Note that $n(c)$ and $i(C,p)$ are the only invariants of the couple up to regular homotopy $(C, p \notin C)$ if $F^2 = \mathbb{R}^2$ (see [A]).

The *writhe* $w(K)$ of a diagram is the sum of the writhes $w(p)$ of all its crossings p. (This is well defined in the case of *any* oriented surface F^2, because the lines $\mathbb{R}$ are always assumed to be oriented, and the writhe $w(p)$ depends only on the orientation of $F^2 \times \mathbb{R}$.)



$w(p) = -1$ $w(p) = +1$

Fig. 6

The lines $\mathbb{R}$ are always oriented from the sheet of paper to the reader's eye. For each crossing p we define $i_p^{\pm} := i(K_p^{\pm}, p)$, where p means the trace of p as described above. In the following it will be more convenient to use $i_p := i_p^+ + i_p^-$ and $\sigma_p := i_p^+ - i_p^-$ instead of $i_p^{\pm}$.

The following lemma is well known (folklore) but of great importance for us.

Lemma 1.1 *Let F^2 be a planar surface. A diagram K' is in the component M_K if and only if K' is isotopic to K (they represent the same knot type) and $n(K') = n(K)$, $w(K') = w(K)$.*

Proof. Evidently $n(K)$ and $w(K)$ are invariants of M_K. We have to prove that besides the knot type these are the only invariants.

Let K_t, $t \in [0, 1]$, be an isotopy which connectes K with K'. It is a regular isotopy besides for a finite number of values of the parameter t_1,... where a Reidemeister move of type I is performed:

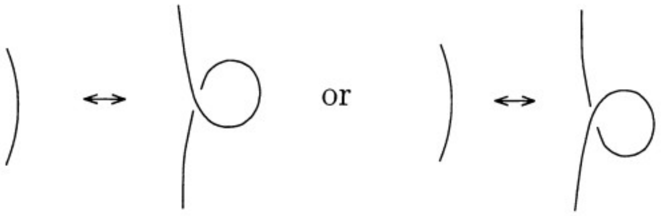


Fig. 7

There are exactly 4 types of oriented moves of type I plus their inverses:

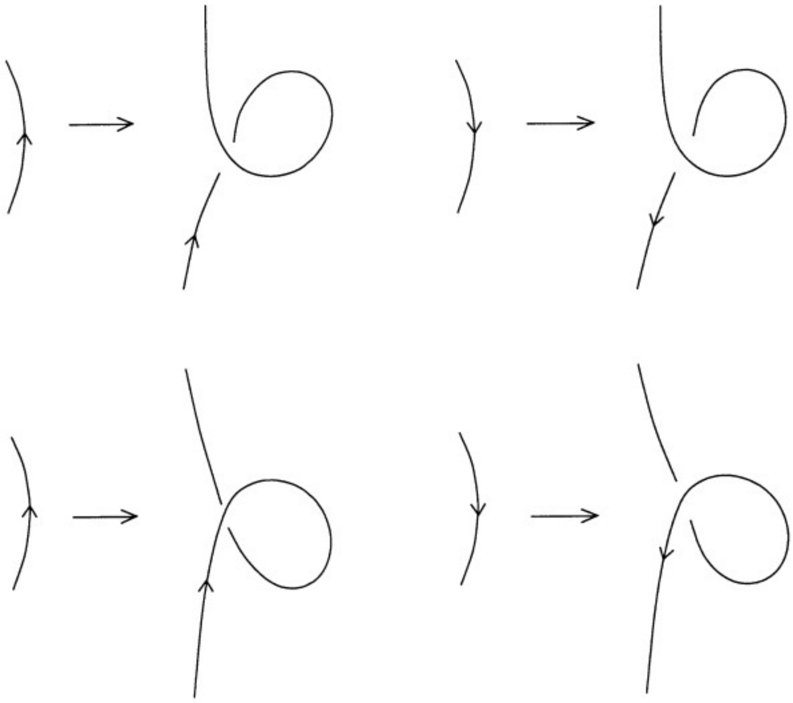

Fig. 8

Note that the four cases are distiguished exactly by the changings of n and w. We replace each of the moves in Fig. 8 by a regular isotopy using the 'Whitney trick' (Fig. 9).

We do not perform all the inverses of the moves in Fig. 8 in our isotopy K_t. We have lots of small curls like in Fig.8 in our isotopy now. They do not disturb the rest of the isotopy, and by moving them along K' we can collect them in a small arc of K. Performing the Whitney trick in the other direction we can cancel them two by two exactly if $n(K') = n(K)$ and $w(K') = w(K)$. ■

From now on M_K will always denote the connected component which contains K. Evidently for each knot K we have $n(K) + w(K) \equiv 1(\text{mod})2$ and perfoming moves as in Fig. 8 we see that this is the only restriction on $n(K)$ and $w(K)$.

Given two diagrams K, K' we add small curls to K' to obtain a diagram

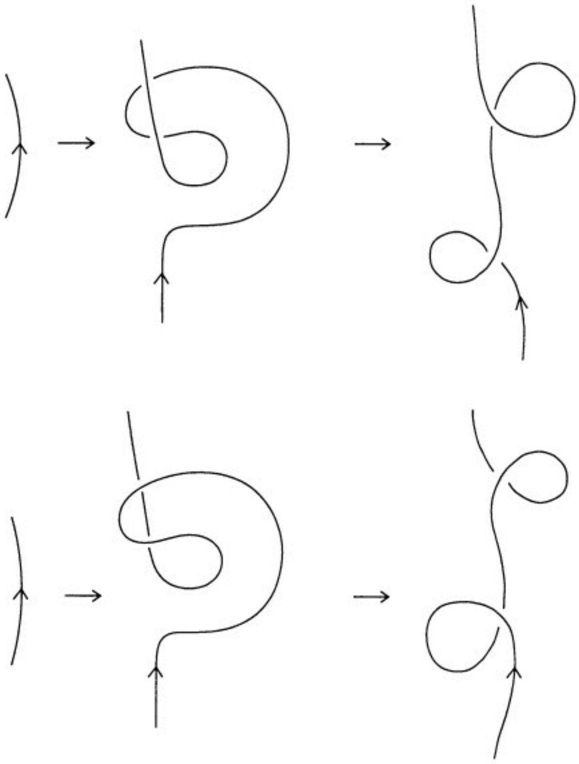

Fig. 9

K'' such that $n(K'') = n(K)$ and $w(K'') = w(K)$. This does not change the knot type. Hence K' is isotopic to K if and only if $K'' \in M_K$. So it is sufficient to find invariants of M_K.

Remark. In the case of a general surface there are two possibilities. Either an invariant does not change by a Reidemeister move of type I; hence each invariant of M_K is a knot invariant; we call these *stable invariants*. Or the invariant changes; it is then only an invariant of regular isotopy, sometimes called an invariant of *framed knots*.

It turns out that our Gauss sums for knots K and their generalizations for families of knots K_t, $t \in S^1$, are a very powerful tool for studying M_K.

Chapter 4
Mechanisms for Generating Conical Curves

Abstract Starting from geometry, the equivalent mechanisms that trace ellipses, hyperbolas, or parabolas are built. These mechanisms are studied structurally, and their kinematic analysis is developed, resulting in relations, successive positions, diagrams, tables, and curves traced. Curves are traced either as trajectories of points or by enveloping. On the basis of projective geometry problems, a new mechanism that traces parabolas by enveloping is presented. Starting from an analytical geometry problem, synthesis of a new equivalent mechanism, which traces parabolas by enveloping, is also created. Next, we study a new mechanism, created on a locus problem, reaching the hyperbolas obtained by enveloping. Another problem in geometry allows the synthesis of the mechanism that traces a hyperbola as a trajectory of a point. A locus problem in 1896 allowed the synthesis of a new mechanism that traces ellipses, parabolas, and hyperbolas.

4.1 Mechanism Ellipsograph

4.1.1 Introduction

Ellipsograph mechanisms have been studied for a long time, being closely linked to the development of the Mechanism and Machine Theory [2, 22]. Scientists, especially mathematicians, have studied various mathematical curves [3, 4, 24]. They have established their geometric properties, and they have drawn it with a ruler and a compass. Afterward, they designed mechanisms to trace them, making models that have verified the correctness of calculations [19]. Taimina studied in detail the evolution of research in the field of the mechanisms generating facet curves [23]. Different mechanisms are described, including conicographs, throughout the evolution of the Theory of Mechanism, from the thirteenth century to the twentieth century. Reuleaux designed and built many mechanisms for curves generating [18, 19]. Artobolevskii also obtained many different mechanisms that draw different mathematical curves, including ellipsographs, parabolographs, and hyperbolographs [1, 2]. All these mechanisms have been designed based on geometrical considerations.

Fig. 4.1 Geometric construction of the pedal Γ of the ellipse C

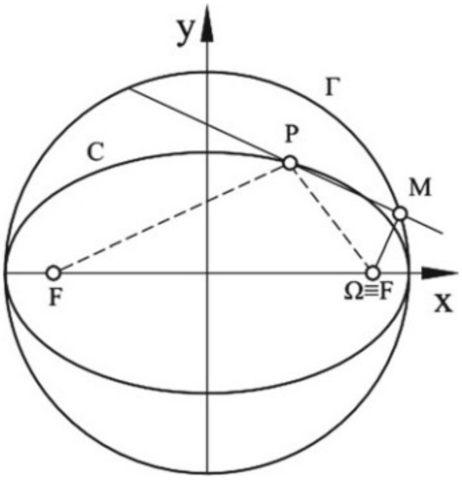

Figure 4.1 [4] shows the pedal of an ellipse with the focal points F and F'. The pedal curve results from the orthogonal projection of a fixed point on the tangent lines of a given curve.

The locus of point M resulted by bringing a perpendicular from F to the ellipse tangent, in point P. The searched pedal is the Γ circle.

4.1.2 The Mechanism Synthesis

Based on the geometric construction of the pedal (Fig. 4.1), we proposed the inverted problem, that is finding an ellipsograph mechanism [17, 20]. In this way, the point M is taken on the Γ circle, then M is joined to F and further MP is constructed perpendicular on FM, which is the envelope of the ellipse.

Figure 4.2 shows the mechanism which is built based on this method.

Chapter 5
Mechanisms for Generating Some Plane Mathematical Curves

Abstract Based on geometrical problems, the synthesis of original mechanisms that trace different mathematical curves is made. Then the structure is analyzed and the calculations are made for the positions of the mechanisms, successive positions, diagrams of the curve generating point coordinates, diagrams of the displacements for some sliders, and the traced curves. Further curves generated by these mechanisms are also studied for different initial input data. In this way, with two original mechanisms, the cissoids (of the circle and of the straight line) are traced, in some cases in particular generating ellipses, parabolas and hyperbolas. Next Berard's curve is studied, where a point of the mechanism traces a branch of the curve, and another point, the other branch. By modifying some dimensions, other curves generated by the mechanism are obtained. We also made the synthesis of a new mechanism that generates egg-shaped curve. Analysis of the mechanism led to the generation of this curve. We changed some data of the mechanism resulting in similar or modified curves, but positioned in different trigonometric quadrants. Another original mechanism, also based on a geometry problem, describes double egg curve. By changing the initial data, similar curves are obtained, some of them being incomplete. Another original mechanism, based on a geometry problem, describes Bernoulli quartic. In this case, an additional kinematic chain is used to provide the midpoint of a straight segment of variable length at the movement of the mechanism. The chapter continues with a mechanism based also on geometrical principles, which traces Maclaurin's trisectrix. By changing some initial data, the mechanism traces completely different curves from the initial ones. There has also been a synthesis of some original mechanisms that trace ophiuride. In this case, other curves are obtained by modifying some dimensions of the mechanism. Finally, an original mechanism that traces the Pascal's snail is studied. Different snails are obtained by changing some dimensions of the mechanism.

5.1 Mechanisms for Generating Cissoids

5.1.1 The Cissoid of a Circle

5.1.1.1 Introduction

On a straight line d, which is the system's ordinate, there are taken two fixed points O and Ω, and on the curve C, it is taken an M point (Fig. 5.1a–c). The locus of point P, where the MΩ secant intersects the perpendicular from O on OM is the cissoid of C curve [1]. The cissoid of a circle is called the cissoid of Diocles.

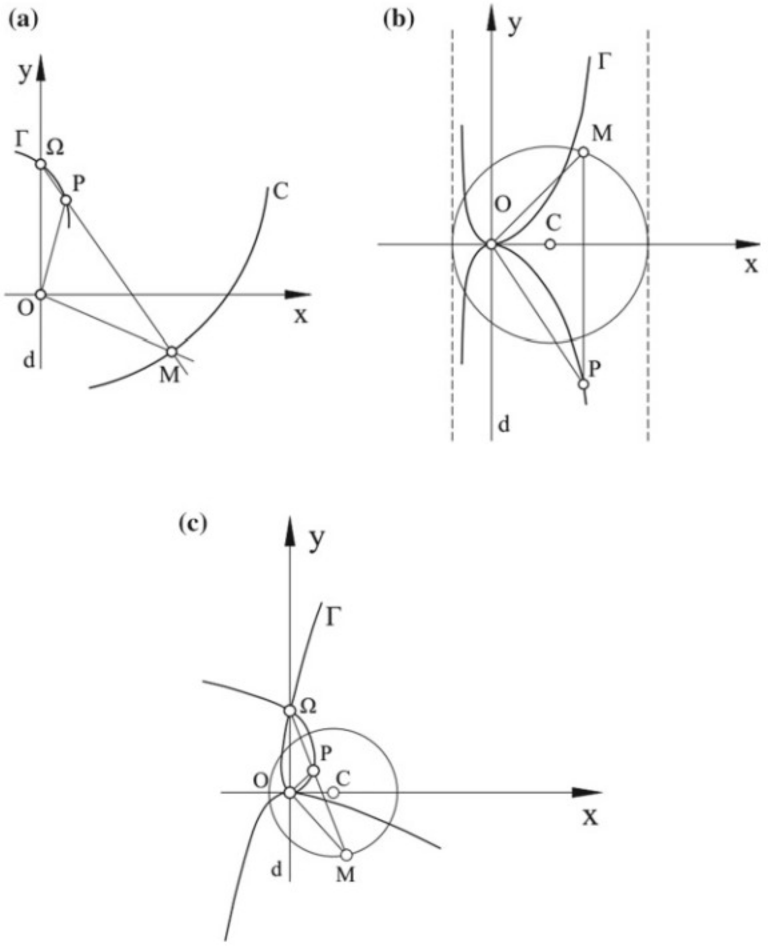

Fig. 5.1 Geometrical construction of the cissoid

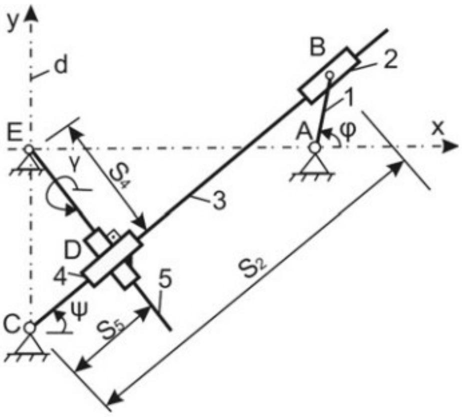

Fig. 5.2 Obtained mechanism

5.1.1.2 The Mechanism Synthesis

In Fig. 5.2, it is presented the mechanism which is constructed based on Fig. 5.1 [2].

Curve C becomes the circle of *AB* radius; the MΩ straight line becomes the *CB* element with variable length, that is why at *B* was mounted slider 2.

Point *O* shown in Fig. 5.1 becomes *E* in Fig. 5.2 and the perpendicular from *E* to *CB* was materialized into two perpendicular welded sliders. The generating point of the cissoid is the point *D*.

5.1.1.3 The Mechanism Analysis

Based on Fig. 5.2, with the contours method, Eqs. (5.1)–(5.5) can be written:

$$x_B = AB\ \cos\varphi + x_A = S_2\ \cos\psi \tag{5.1}$$

$$y_B = AB\ \sin\varphi + y_A = y_C + S_2\ \sin\psi \tag{5.2}$$

$$x_D = S_5\ \cos\psi + x_C = S_4\ \cos\gamma + x_E \tag{5.3}$$

$$y_D = y_C + S_5 \sin\psi = S_4 \sin\gamma + y_E \tag{5.4}$$

$$\gamma = \psi + 270 \tag{5.5}$$

from which the unknowns S_2, S_4, S_5, ψ are calculated.

5.1.1.4 Results Obtained

We used the following initial data: $XA = 40$, $AB = 40$, $YC = -50$; $XC = \mathrm{XE} = 0$ (mm). The mechanism for one position is given in Fig. 5.3. The mechanism for different positions is shown in Fig. 5.4.

It is seen from Fig. 5.4a that, although B makes a complete rotation, the EDC area is situated under the x-axis, and the generating point D is not passing above the x-axis. Because of this, the mechanism draws only a branch of the cissoid (Fig. 5.5a), by taking $YC = -120$ mm.

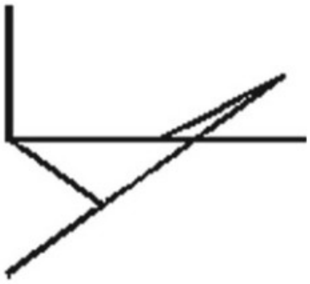

Fig. 5.3 Mechanism for a given position

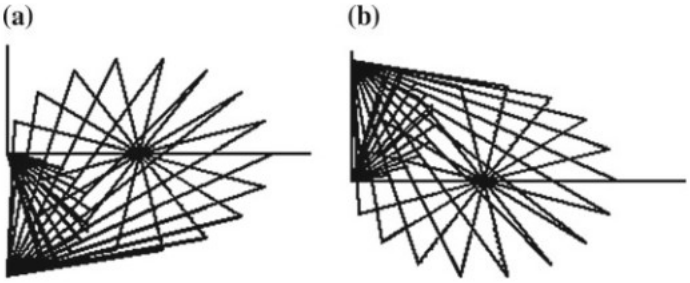

Fig. 5.4 Mechanism for different positions

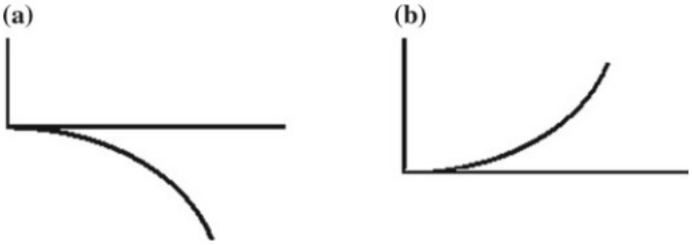

Fig. 5.5 Different branches of the cissoid

If it is assumed $YC = +120$ mm, then the other branch of the cissoid (Fig. 5.5b) is obtained. The successive positions are given in Fig. 5.4b.

5.1.2 The Straight Line Cissoid

5.1.2.1 Introduction

When the C curve of Fig. 5.1a is a straight line Δ, then the cissoid is a conic curve: an ellipse (Fig. 5.6a), a parabola (Fig. 5.6b), and a hyperbola (Fig. 5.6c) [3]. The ellipse is obtained when M is on the right side of Δ, the parabola when M is on Δ, the hyperbola when M is between Δ and OY, respectively.

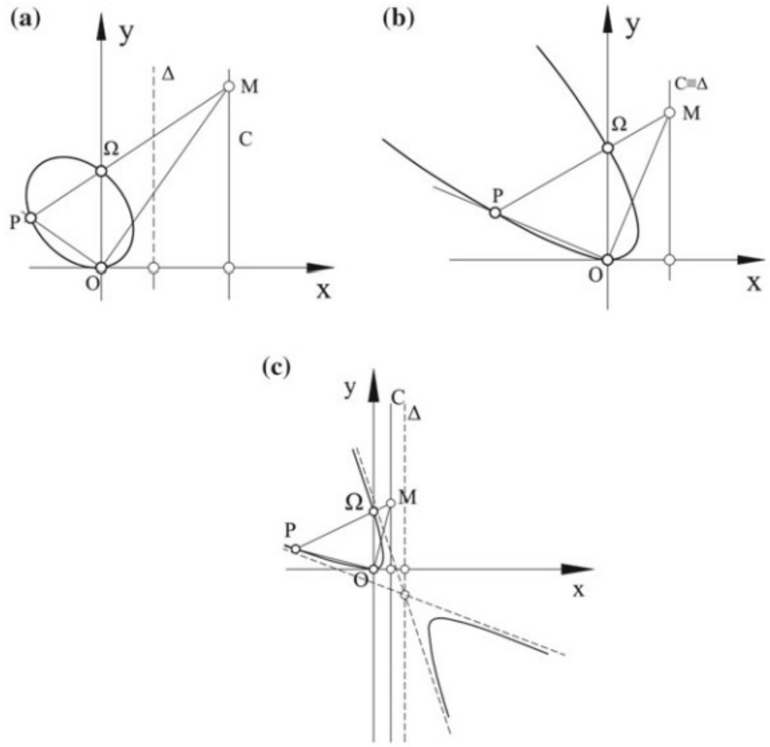

Fig. 5.6 Geometrical constructions of straight line cissoids

3- > = "

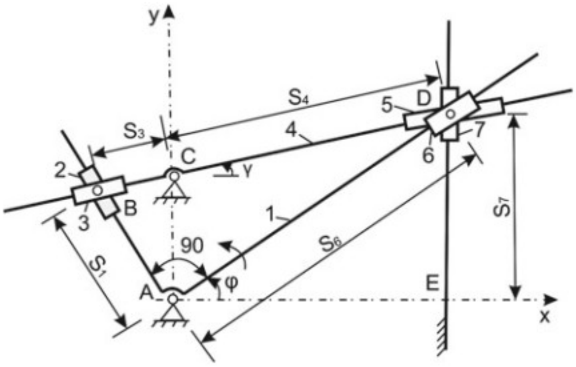

Fig. 5.7 Mechanism obtained

5.1.2.2 The Mechanism Synthesis

The mechanism that undergoes these conditions was found by synthesis, and given in Fig. 5.7 [4]. The element 1 has the BAD angle of 90°, the Δ straight line is noted as *ED*, which is defined with *XE*. At *E*, there are three sliders moving on the elements 4, 1, 0. At *B* there are two sliders which are connected by a torque in such way that between the elements 1 and 4 exists a rotational movement.

5.1.2.3 The Mechanism Analysis

In order to analyze the positions, based on the contours method we write the Eqs. (5.6)–(5.13):

$$x_D = S_6 \cos\varphi = x_E = \text{const.} \tag{5.6}$$

$$y_D = S_6 \sin\varphi = S_7 \tag{5.7}$$

$$x_B = S_1 \cos(\varphi + 90) \tag{5.8}$$

$$y_B = S_1 \sin(\varphi + 90) \tag{5.9}$$

$$x_C + S_4 \cos\gamma = x_D \tag{5.10}$$

$$y_C + S_4 \sin\gamma = y_D \tag{5.11}$$

$$x_B + S_3 \cos\gamma = x_C \tag{5.12}$$

$$y_B + S_3 \sin\gamma = y_C \tag{5.13}$$

5.1.2.4 Results Obtained

The values for *YC* and *XE* are given as input data. For the values of $YC = 50$ mm and $XE = 80$ mm the mechanism was obtained in one position, which is given in Fig. 5.8. The generating ellipse can be observed in Fig. 5.9 and the successive positions of the mechanism are given in Fig. 5.10.

Referring to Fig. 5.11, it is shown that *XB* varies by a sinusoid type curve, it also moves to the left of *y*-axis and *YB* is always positive.

For the computer program a jump instruction was provided for the cases when *S*7 advances above 200 mm, because it went beyond the drawing borders, which is

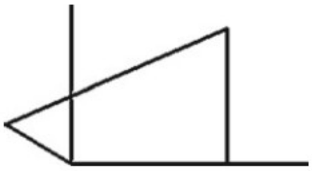

Fig. 5.8 Mechanism in one position

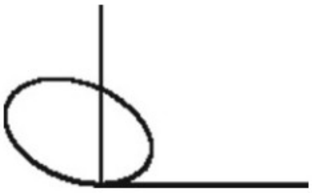

Fig. 5.9 Resulting ellipse

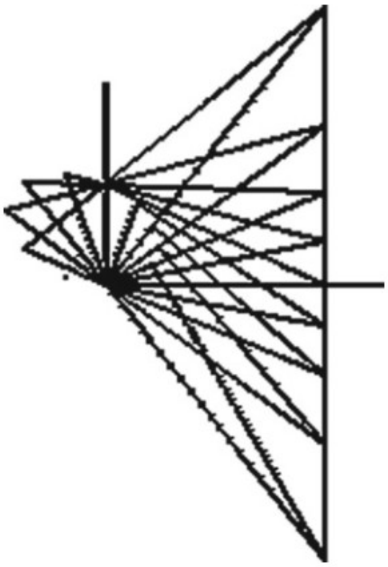

Fig. 5.10 Successive positions of the mechanism

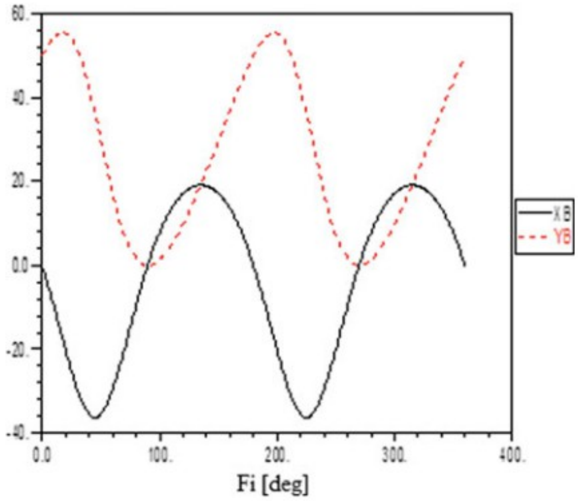
Fig. 5.11 Variations of the coordinates y_B, x_B

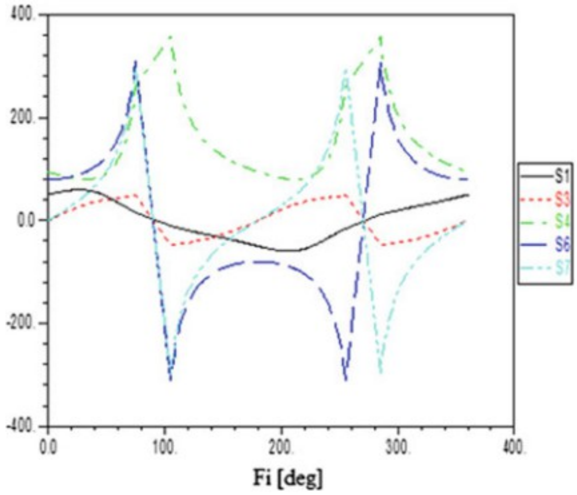


found in Fig. 5.12 where jumps occur at $S7$ and $S6$, for φ around values of 90° and 270°.

There were obtained ellipses (Fig. 5.13) for other sets of values, as follows:

1. for $YC = 100$ mm, $XE = 100$ mm;
2. for $YC = -50$ mm, $XE = 50$ mm;
3. for $YC = 50$ mm, $XE = -50$ mm;
4. for $YC = 100$ mm, $XE = -100$ mm;
5. for $YC = 80$ mm, $XE = 50$ mm.

Fig. 5.12 Curves of the displacements $S4$, $S6$, $S1$, $S7$, $S3$



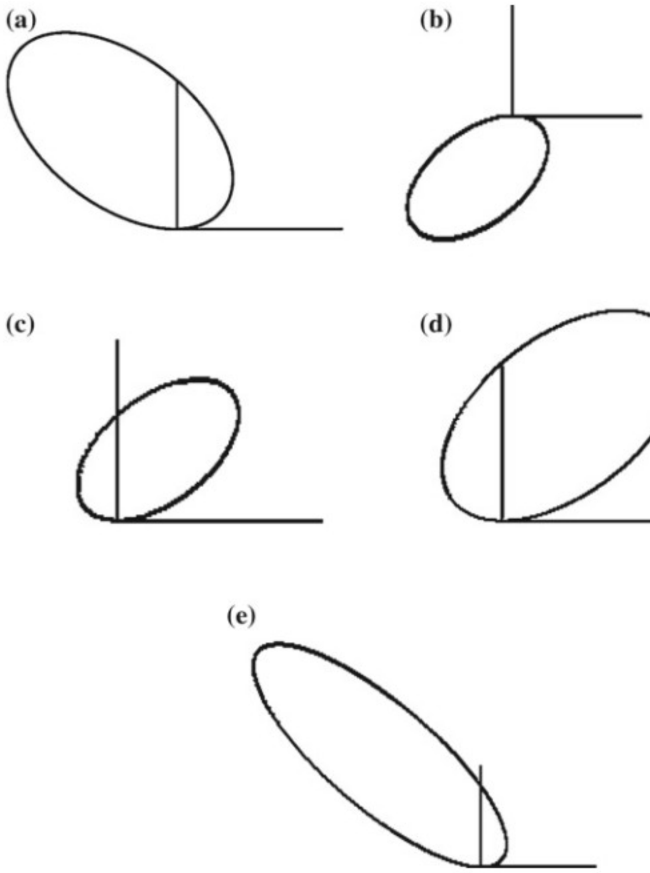


Fig. 5.13 Resulting ellipses

Changing the initial data led to resizing the ellipses dimensions and their axis orientation. When $YC < 0$, the ellipse is in quadrant III, and for $XE < 0$, the axis of the ellipse is placed in quadrant I.

We have also obtained the parabolas in Fig. 5.14:

1. for $YC = 100$ mm, $XE = 40$ mm;
2. for $YC = 100$ mm, $XE = -50$ mm.

For $YC = 80$ mm, $XE = -45$ mm, it resulted the ellipse in Fig. 5.15

In Fig. 5.16 there are presented the generating hyperbolas, for the values:

1. $YC = 100$ mm, $XE = 30$ mm;
2. $YC = 80$ mm, $XE = 25$ mm.

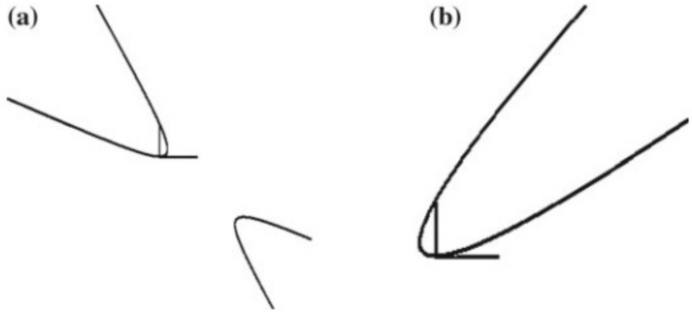

Fig. 5.14 Generated parabolas

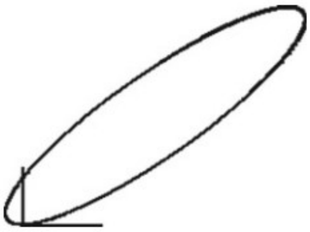

Fig. 5.15 Elipse for $y_C = 80$ mm, $x_E = –45$ mm

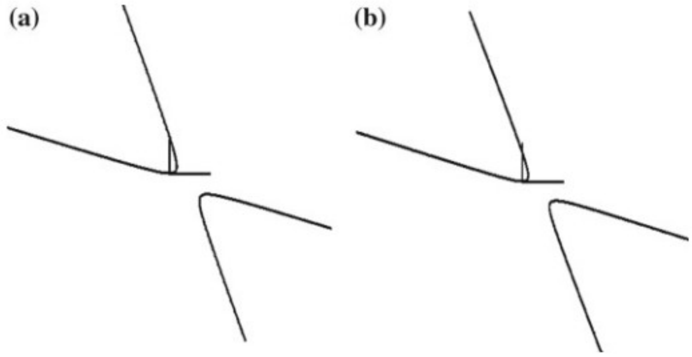

Fig. 5.16 Generated hyperbolas

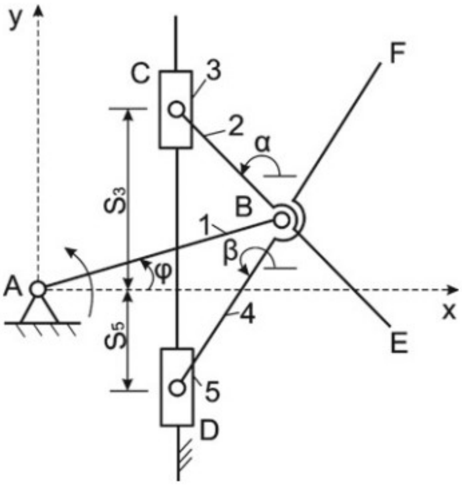
5.2 Mechanism for Generating Berard's Curve

5.2.1 The Mechanism Synthesis

The rod curves of the rod-crank mechanism were studied by mathematicians since the invention of the steam engine [5]. Thus, in 1820, Bérard obtained such curves.

Fig. 5.17 Mechanism obtained



Bérard has obtained and defined them as locus of points which are situated on a straight line that goes from one end on a circle and the other end on another straight line. In [6] are given the equations and the particular cases of these curves. The movement of some straight lines is also designed, obtaining particular curves.

On the basis of these geometric considerations, the mechanism of Fig. 5.17 was conceived, which, by the *E* and *F* points, describes trajectories which are connected to each other, forming the curves of Berard. Structurally, the mechanism is R-RRP-RRP [7].

5.2.2 The Mechanism Analysis

On the basis of Fig. 5.17, Eqs. (5.14)–(5.23) are written:

$$x_B = AB\cos\varphi \tag{5.14}$$

$$y_B = AB\sin\varphi \tag{5.15}$$

$$x_C = AB\cos\varphi + BC\cos\alpha = \text{const.} \tag{5.16}$$

$$y_C = AB\sin\varphi + BC\sin\alpha = S_3 \tag{5.17}$$

$$x_E = x_B + BE\cos(\alpha + \pi) \tag{5.18}$$

$$y_E = y_B + BE\sin(\alpha + \pi) \tag{5.19}$$

The Geometry of Curves

1.1 Introduction

The world of Euclidean geometry is inhabited by lines and planes. If we wish to go beyond this flat world to a universe of curvature, we need to understand more general types of curves and surfaces. This chapter is devoted to exploring curves. Later we shall see that a basic understanding of the geometry of curves is essential to understanding the nature of surfaces as well.

A *curve* in 3-space $\mathbb{R}^3$ is a continuous mapping $\alpha\colon I \to \mathbb{R}^3$ where I is some type of interval (e.g., $(0, 1)$, (a, b), $[a, b]$, $(-\infty, a]$, $[0, 1]$ etc.) on the real line $\mathbb{R}$. Because the range of α is $\mathbb{R}^3$, α's output has three coordinates. We then write, for $t \in I$, a *parametrization* for α,

$$\alpha(t) = (\alpha^1(t),\ \alpha^2(t),\ \alpha^3(t))$$

where the α^i are themselves functions $\alpha^i\colon I \to \mathbb{R}$. A useful way to think about curves is to consider t to be time and $\alpha(t)$ to be the path of a particle in space. We say α is *differentiable* or *smooth* if each coordinate function α^i is differentiable as an ordinary real-valued function of $\mathbb{R}$. In fact, later, in order to define curvature and torsion, we will need each α^i to be at least 3-times differentiable. In practice, we will not find this condition to be much of a constraint.

The *velocity vector* of α at t_0 is defined to be

$$\alpha'(t_0) = \left(\left.\frac{d\alpha^1}{dt}\right|_{t=t_0},\ \left.\frac{d\alpha^2}{dt}\right|_{t=t_0},\ \left.\frac{d\alpha^3}{dt}\right|_{t=t_0} \right)$$

where $d\alpha^i/dt$ is the ordinary derivative and $|_{t=t_0}$ denotes evaluation of the derivative at $t = t_0$. We shall also write $\frac{d\alpha^i}{dt}(t_0)$ for this evaluation when it is convenient. In order to interpret α' geometrically, we introduce the

Example 1.1.1 (First Example of a Curve: a Line in $\mathbb{R}^3$).
We know that two points determine a line. In the plane $\mathbb{R}^2$, this leads to the usual slope-intercept equation which gives an algebraic description of the line. Unfortunately, in $\mathbb{R}^3$ we don't have a good notion of slope, so we can't expect exactly the same type of algebraic description to work.

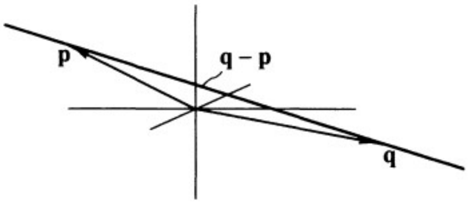

Figure 1.1. A parametrized line

For two points, **p** and **q**, the line l joining them may be described as follows. To attain the line, add the vector **p**. To travel along the line, use the direction vector $\mathbf{q} - \mathbf{p}$ since this is the direction from **p** to **q**. A *parameter* t tells exactly how far along $\mathbf{q} - \mathbf{p}$ to go. Putting these steps together produces a curve which is a *parametrized line* (see Figure 1.1) in $\mathbb{R}^3$,

$$\alpha(t) = \mathbf{p} + t(\mathbf{q} - \mathbf{p}).$$

For instance, if $\mathbf{p} = (1, 2, 3)$ and $\mathbf{q} = (-1, 4, -7)$, then $\mathbf{q} - \mathbf{p} = (-2, 2, -10)$, so the line through **p** and **q** is given by the curve

$$\begin{aligned} \alpha(t) &= (1, 2, 3) + t(-2, 2, -10) \\ &= (1 - 2t, 2 + 2t, 3 - 10t). \end{aligned}$$

Exercise* 1.1.2. What is the parametrization of the line through $(-1, 0, 5)$ and $(3, -1, -2)$?

Exercise* 1.1.3. In $\mathbb{R}^4$, what is the parametrization of the line through $(-1, 6, 5, 0)$ and $(0, 1, -3, 9)$?

So we see that, given a line $\alpha(t) = \mathbf{p} + t(\mathbf{q} - \mathbf{p})$, $\alpha'(t) = \mathbf{q} - \mathbf{p}$. Since this *direction vector* $\mathbf{q} - \mathbf{p}$ is then the velocity vector, we often write

$$\alpha(t) = \mathbf{p} + t\mathbf{v}.$$

Now that we understand lines, we can ask what the picture of the velocity vector is for any curve $\alpha(t)$? The definitions give

$$\begin{aligned} \alpha'(t_0) &= \left(\left.\frac{d\alpha^1}{dt}\right|_{t=t_0}, \left.\frac{d\alpha^2}{dt}\right|_{t=t_0}, \left.\frac{d\alpha^3}{dt}\right|_{t=t_0} \right) \\ &= \left(\lim_{t\to t_0} \frac{\alpha^1(t) - \alpha^1(t_0)}{t - t_0}, \lim_{t\to t_0} \frac{\alpha^2(t) - \alpha^2(t_0)}{t - t_0}, \lim_{t\to t_0} \frac{\alpha^3(t) - \alpha^3(t_0)}{t - t_0} \right) \\ &= \lim_{t\to t_0} \left(\frac{\left(\alpha^1(t), \alpha^2(t), \alpha^3(t)\right) - \left(\alpha^1(t_0), \alpha^2(t_0), \alpha^3(t_0)\right)}{t - t_0} \right) \\ &= \lim_{t\to t_0} \frac{\alpha(t) - \alpha(t_0)}{t - t_0}. \end{aligned}$$

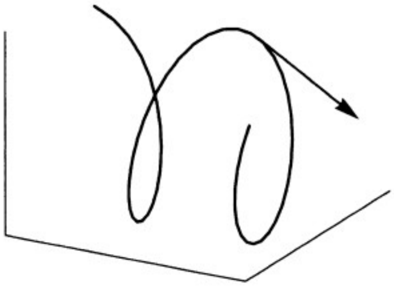

Figure 1.2. A curve with tangent vector

This looks much like our usual "slope" definition of the derivative. Note that the approximating vectors inside the limit always point in the direction of increasing t. For $t < t_0$, this follows since $t - t_0$ is negative. Now, $t \to t_0$, so the vector moves closer and closer to being a tangent vector (see Figure 1.2) to the curve at $\alpha(t_0)$. Hence, the velocity vector $\alpha'(t_0)$ to α at t_0 is a tangent vector to α at $\alpha(t_0)$. Notice that we obtain a vector with a precise length, not a line. Remember that a vector $\mathbf{v} = (v^1, v^2, v^3) \in \mathbb{R}^3$, has a *length* given by the Pythagorean theorem,

$$|\mathbf{v}| = \sqrt{(v^1)^2 + (v^2)^2 + (v^3)^2}.$$

Exercise∗ 1.1.4. Show that $|\mathbf{v}|$ is the distance of (v^1, v^2, v^3) from $(0, 0, 0)$ by two applications of the Pythagorean theorem.

A curve $\alpha(t)$ is *regular* if $\alpha'(t) \neq 0$ for all $t \in I$. In general, if a curve is not regular, then we split it into regular pieces and consider each of these separately. The assumption of regularity ensures that we keep going in the same direction along the curve. This will be important when we consider arclength shortly.

Example 1.1.5 (The Cusp $\alpha(t) = (t^2, t^3)$).
Note that $x = t^2$, $y = t^3$, so $y = \pm x^{3/2}$ with $\alpha'(t) = (2t, 3t^2)$ and $\alpha'(0) = (0, 0)$. Thus α is *not* regular, but the pieces above and below the x-axis *are* regular.

In our situation, $|\alpha'(t)| = \sqrt{(d\alpha^1/dt)^2 + (d\alpha^2/dt)^2 + (d\alpha^3/dt)^2}$ is simply the *speed* of α. Again, thinking of α as the path of a particle and t as time, we see that the length of the velocity vector is precisely the speed of the particle at the given time. For a line, $\alpha(t) = \mathbf{p} + t\mathbf{v}$, the speed is simply $|\mathbf{v}|$, the length of the direction vector. Note that we have taken lines to have constant speed $\mathbf{v}$. We will see later that every *regular* curve can be re-parametrized to have constant speed, so this is no real restriction. However, a given parametrization may disguise the fact that the underlying curve is a line until re-parametrized to have constant speed. We will keep our convention that lines are parametrized with constant speed because we want to characterize them by Proposition 1.1.7.

If $\alpha(t) = \big(\alpha^1(t), \alpha^2(t), \alpha^3(t)\big)$ is a curve in $\mathbb{R}^3$, then its acceleration vector is given by

$$\alpha''(t) = \left(\frac{d^2}{dt^2}\alpha^1(t),\ \frac{d^2}{dt^2}\alpha^2(t),\ \frac{d^2}{dt^2}\alpha^3(t)\right).$$

Exercise⁎ 1.1.6. Newton asked the question, what is the curve which, when revolved about an axis, gives a surface offering the least resistance to motion through a "rare" fluid (e.g., air)? Newton's answer is the following curve (see Chapter 7).

$$(x(t), y(t)) = \left(\frac{\lambda}{2}\left[\frac{1}{t} + 2t + t^3\right], \frac{\lambda}{2}\left[\ln\left(\frac{1}{t}\right) + t^2 + \frac{3}{4}t^4\right] - \frac{7}{8}\lambda\right),$$

where λ is a positive constant and $x \geq 2\lambda$. Graph this curve and compute its velocity and acceleration vectors. What angle does the curve make with the x-axis at the intersection point $(2\lambda, 0)$?

We now come to the first (and simplest nontrivial) instance of calculus imposing a constraint on the geometry of a curve. In a real sense, this is what the differential geometry of curves is all about and we will see many more examples of it later.

Proposition 1.1.7. *The curve α is a (constant speed) straight line if and only if $\alpha'' = 0$.*

Proof. If $\alpha(t) = \mathbf{p} + t\mathbf{v}$ is a line, then $\alpha'(t) = \mathbf{v}$ (which is a constant vector), so $\alpha''(t) = 0$.

If $\alpha''(t) = 0$ for all t, then $d^2\alpha^i(t)/dt^2 = 0$, for each coordinate function $\alpha^i(t)$. But a zero 2nd derivative simply means that $d\alpha^i(t)/dt = v^i$ is a constant. We may integrate with respect to t to obtain $\alpha^i(t) = p^i + v^i t$ where p^i is a constant of integration. Then

$$\alpha(t) = (p^1 + tv^1, p^2 + tv^2, p^3 + tv^3) = p + t\mathbf{v}$$

with $\mathbf{p} = (p^1, p^2, p^3)$ and $\mathbf{v} = (v^1, v^2, v^3)$. Hence the curve α may be parametrized as a line. □

This easy result indicates how we will use calculus to detect geometric properties. Just to see how far we can get using these elementary ideas, let's consider the following question. What is the shortest distance between two points $\mathbf{p}$ and $\mathbf{q}$ in $\mathbb{R}^3$? We have been taught since we were children that the answer is a line, but now we can see why our intuition is correct. Calculus tells us that distance is simply the integral of speed. Therefore, the integral

$$L(\alpha) = \int_a^b |\alpha'(t)|\, dt$$

calculates the *arclength* (i.e., the distance travelled) of a regular curve $\alpha\colon [a, b] \to \mathbb{R}^3$ from $\alpha(a)$ to $\alpha(b)$. In order to see this, consider a small piece (i.e., "an infinitesimal piece") of arclength approximated as in Figure 1.3. The Pythagorean theorem then says that the hypotenuse of the right triangle with sides dx and dy has length $l = \sqrt{dx^2 + dy^2}$. Suppose both x and y are parametrized by t. Then $\alpha(t) = (x(t), y(t))$ and $dx^2 = (dx/dt)^2\, dt^2$ and $dy^2 = (dy/dt)^2\, dt^2$. Finally, we have

$$l = \sqrt{\left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2}\, dt$$

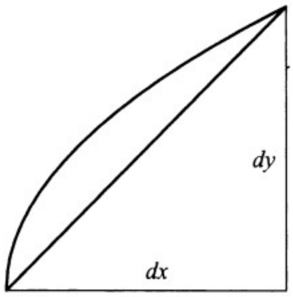

Figure 1.3. An infinitesimal piece of curve

expressing the relation, distance equals rate times time. Now we add up all the small pieces of the curve by integration to get,

$$\begin{aligned} L(\alpha) &= \int_a^b \sqrt{\left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2}\, dt \\ &= \int_a^b \left|\alpha'(t)\right| \, dt. \end{aligned}$$

The three-dimensional version of this intuitive description simply uses our earlier exercise on the Pythagorean theorem in three dimensions. Now, the length of the vector $\mathbf{v}$, $|\mathbf{v}|$, may be written $\sqrt{\mathbf{v} \cdot \mathbf{v}}$, where $\cdot$ denotes the *dot product* of vectors. Recall that, in general, $\mathbf{v} \cdot \mathbf{w} = v^1 w^1 + v^2 w^2 + v^3 w^3$, for $\mathbf{v} = (v^1, v^2, v^3)$ and $\mathbf{w} = (w^1, w^2, w^3)$. We also have the following

Proposition 1.1.8. *The dot product* $\mathbf{v} \cdot \mathbf{w}$ *may be calculated by* $\mathbf{v} \cdot \mathbf{w} = |\mathbf{v}|\,|\mathbf{w}| \cos\theta$, *where* θ *is the angle between the vectors* $\mathbf{v}$ *and* $\mathbf{w}$.

Proof. From Figure 1.4, we see that the usual properties of vectors give $\mathbf{u} = \mathbf{v} - \mathbf{w}$. Hence

$$\begin{aligned} |\mathbf{u}|^2 &= \mathbf{u} \cdot \mathbf{u} = (\mathbf{v} - \mathbf{w}) \cdot (\mathbf{v} - \mathbf{w}) \\ &= \mathbf{v} \cdot \mathbf{v} - 2\mathbf{v} \cdot \mathbf{w} + \mathbf{w} \cdot \mathbf{w} \\ &= |\mathbf{v}|^2 + |\mathbf{w}|^2 - 2\mathbf{v} \cdot \mathbf{w}. \end{aligned}$$

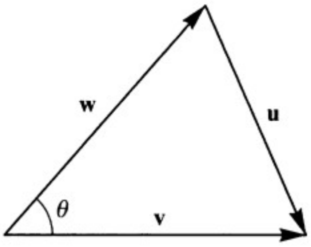

Figure 1.4.

But the Law of Cosines for this triangle says $|\mathbf{u}|^2 = |\mathbf{v}|^2 + |\mathbf{w}|^2 - 2|\mathbf{v}|\,|\mathbf{w}|\,\cos\theta$. Equating the two right-hand sides and eliminating like terms produces

$$\mathbf{v} \cdot \mathbf{w} = |\mathbf{v}|\,|\mathbf{w}| \cos\theta.$$

□

Corollary 1.1.9 (Schwarz's Inequality). *The dot product obeys the inequality,*

$$|\mathbf{v} \cdot \mathbf{w}| \leq |\mathbf{v}|\,|\mathbf{w}|.$$

Proof. Simply note that $|\cos\theta| \leq 1$. □

We note here that, with respect to the derivative, the dot product behaves just as ordinary multiplication — namely, the Leibniz (or product) rule holds. In particular,

Proposition 1.1.10. *If $\alpha(t)$ and $\beta(t)$ are two curves in $\mathbb{R}^3$, then*

$$\frac{d(\alpha \cdot \beta)}{dt} = \frac{d\alpha}{dt} \cdot \beta + \alpha \cdot \frac{d\beta}{dt}.$$

Proof. We use the ordinary product rule on the component functions,

$$\begin{aligned}
\frac{d(\alpha \cdot \beta)}{dt} &= \frac{d}{dt}(\alpha^1\beta^1 + \alpha^2\beta^2 + \alpha^3\beta^3) \\
&= \sum_i \left(\frac{d\alpha^i}{dt}\beta^i + \alpha^i\frac{d\beta^i}{dt}\right) \\
&= \sum_i \left(\frac{d\alpha^i}{dt}\beta^i + \sum_i \alpha^i\frac{d\beta^i}{dt}\right) \\
&= \frac{d\alpha}{dt} \cdot \beta + \alpha \cdot \frac{d\beta}{dt}.
\end{aligned}$$

□

When the parameter t is understood, we will write the product rule as $(\alpha \cdot \beta)' = \alpha' \cdot \beta + \alpha \cdot \beta'$. We are now able to answer the question of which (smooth) path between two points gives the shortest distance.

Theorem 1.1.11. *In $\mathbb{R}^3$, a line is the curve of least arclength between two points.*

Proof. Consider two points $\mathbf{p}, \mathbf{q} \in \mathbb{R}^3$. The line between them may be parametrized by $l(t) = \mathbf{p} + t(\mathbf{q} - \mathbf{p})$, where $\mathbf{q} - \mathbf{p}$ is the vector in the direction from $\mathbf{p}$ to $\mathbf{q}$. Then $l'(t) = \mathbf{q} - \mathbf{p}$ and $|l'(t)| = |\mathbf{q} - \mathbf{p}|$, a constant. Therefore,

$$L(l) = \int_0^1 |l'(t)|\,dt = |\mathbf{q} - \mathbf{p}| \int_0^1 dt = |\mathbf{q} - \mathbf{p}|$$

3- > = - G * " "

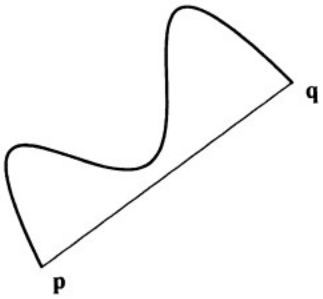

Figure 1.5. Line and comparison curve

and the length of the line segment (or direction vector) from **p** to **q** is the distance from **p** to **q** (as of course we expected). Now consider another curve α which joins **p** and **q** (see Figure 1.5).

We want to show that $L(\alpha) > L(l)$ and, since α is arbitrary, this will say that the straight line minimizes distance. Now, why should α be longer than l? One intuitive explanation is to say that α starts off in the wrong direction. That is, $\alpha'(a)$ is not "pointing toward" **q**. How can we measure this deviation? The angle between the unit vector in the direction of $\mathbf{q}-\mathbf{p}$, $\mathbf{u} = (\mathbf{q}-\mathbf{p})/|\mathbf{q}-\mathbf{p}|$, and $\alpha'(a)$, the tangent vector of α at **p**, may be determined using the dot product $\alpha'(a)\cdot\mathbf{u}$. The total deviation may be added up by integration to give us an idea of why $L(\alpha) > L(l)$ should hold. Precisely, we compute $\int_a^b \alpha'(t)\cdot\mathbf{u}\,dt$ in two ways to obtain the inequality. Now, we have $(\alpha(t)\cdot\mathbf{u})' = \alpha'(t)\cdot\mathbf{u} + \alpha(t)\cdot\mathbf{u}' = \alpha'(t)\cdot\mathbf{u}$ since **u** is a constant vector. Also, the Fundamental Theorem of Calculus gives $\int_a^b df/dt\,dt = f(b) - f(a)$, so

$$\begin{aligned}
\int_a^b \alpha'(t)\cdot\mathbf{u}\,dt &= \int_a^b (\alpha(t)\cdot\mathbf{u})'\,dt = \alpha(b)\cdot\mathbf{u} - \alpha(a)\cdot\mathbf{u} \\
&= \mathbf{q}\cdot\mathbf{u} - \mathbf{p}\cdot\mathbf{u} \qquad \text{since } \alpha(a) = \mathbf{p},\ \alpha(b) = \mathbf{q} \\
&= (\mathbf{q}-\mathbf{p})\cdot\mathbf{u} \\
&= \frac{(\mathbf{q}-\mathbf{p})\cdot(\mathbf{q}-\mathbf{p})}{|\mathbf{q}-\mathbf{p}|} \\
&= \frac{|\mathbf{q}-\mathbf{p}|^2}{|\mathbf{q}-\mathbf{p}|} \\
&= |\mathbf{q}-\mathbf{p}| \\
&= L(l),
\end{aligned} \tag{1}$$

the straight line distance from **p** to **q**. We also have,

$$\begin{aligned}
\int_a^b \alpha'(t)\cdot\mathbf{u}\,dt &\le \int_a^b |\alpha'(t)|\cdot|\mathbf{u}|\,dt \qquad \text{by the Schwarz inequality} \\
&= \int_a^b |\alpha'(t)|\,dt \qquad \text{since } |\mathbf{u}| = 1 \\
&= L(\alpha).
\end{aligned} \tag{2}$$

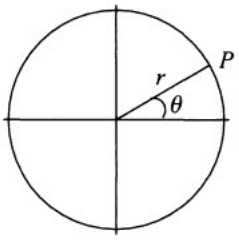

Figure 1.6. Circle of radius r

Combining (1) and (2), we have $L(l) \leq L(\alpha)$. Note also that $\alpha'(t) \cdot \mathbf{u} = |\alpha'(t)| \cdot |\mathbf{u}|$ only when $\cos\theta = 1$, or $\theta = 0$. That is, $\alpha'(t)$ must be parallel to $\mathbf{q} - \mathbf{p}$ for all t. In this case α is the line from $\mathbf{p}$ to $\mathbf{q}$. Therefore, we have the strict inequality $L(l) < L(\alpha)$ unless α is a line. ☐

So, using the first notions of calculus, we have seen how to identify lines in $\mathbb{R}^3$ and to determine exactly why lines give the shortest distance between two points. Of course, $\mathbb{R}^3$ is governed by Euclidean Geometry. One of the main goals of differential geometry is to develop analogous techniques for curved geometries as well.

While curves described parametrically may be defined at the whim of the definer, in fact they often arise from geometric or physical considerations. Several of the examples below illustrate this.

Example 1.1.12 (The Circle of Radius r Centered at $(0, 0)$).
The circle is one of the most useful and familiar curves in geometry. Of course, the question is, how can such a curve be parametrized? The definitions of $\sin\theta$ and $\cos\theta$ as the vertical and horizontal sides of the right triangle with angle θ formed by dropping a vertical line from P to the horizontal axis give us a way of assigning coordinates to the point P when $r = 1$. Namely, the point P has coordinates $(\cos\theta,\ \sin\theta)$ (see Figure 1.6). For a circle of radius r, by the fundamental property of similar triangles, the vertical and horizontal sides of the triangle must be $r\sin\theta$ and $r\cos\theta$ respectively. Hence, the coordinates of the point on the circle are $(r\cos\theta,\ r\sin\theta)$. Therefore, the circle may be parametrized by the angle θ. Again thinking of the circle as the path of a particle, we write

$$\alpha(t) = (r\cos t,\ r\sin t), \qquad \text{for } 0 \leq t < 2\pi.$$

There are two important observations to remember. First, we have $\alpha'(t) = (-r\sin t, r\cos t)$, so $\alpha(t) \cdot \alpha'(t) = 0$ for all t. In other words, the tangent vector is perpendicular to the radius. Second, $\alpha''(t) = (-r\cos t,\ -r\sin t) = -\alpha(t)$, so the acceleration vector points toward the center of the circle. Finally, we can compute the arclength (i.e., circumference) of the circle,

$$\begin{aligned} L(\alpha) &= \int_0^{2\pi} |\alpha'(t)|\, dt = \int_0^{2\pi} \sqrt{r^2\sin^2 t + r^2\cos^2 t}\, dt \\ &= \int_0^{2\pi} r\sqrt{\sin^2 t + \cos^2 t}\, dt = \int_0^{2\pi} r\, dt \\ &= r\,t\,\Big|_0^{2\pi} = 2\pi\, r. \end{aligned}$$

3- 1 "

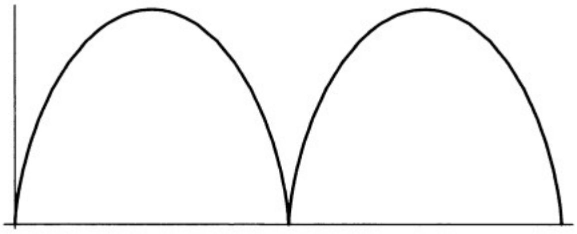

Figure 1.7. A cycloid

Exercise 1.1.13. Suppose a circle of radius a sits on the x-axis making contact at $(0, 0)$. Let the circle roll along the positive x-axis. Show that the path α followed by the point originally in contact with the x-axis is given by

$$\alpha(t) = (a\,(t - \sin t),\ a\,(1 - \cos t))$$

where t is the angle formed by the (new) point of contact with the axis, the center and the original point of contact. This curve is called a *cycloid* (see Figure 1.7) and we will meet it again in Chapter 7. Hints: Recall that $s = a\,t$ where s is arclength. Draw a picture after the circle has rolled s units. Where is the old point of contact?

Exercise 1.1.14. Consider a cycloid of the form

$$(x(t), y(t)) = (A + a\,(t - \sin t),\ B - a\,(1 - \cos t)).$$

Graph this cycloid to see that it is an inverted form of the one found in the previous exercise. Suppose a unit mass particle starts at rest at a point $(\bar{x}, \bar{y})$ on the cycloid corresponding to an angle $\bar{t}$ in the parametrization above. Under the influence of gravity (and assuming no friction), show that, no matter what initial $\bar{t}$ is chosen, it always takes a time of

$$T = \sqrt{\frac{a}{g}}\,\pi\,, \qquad \text{where } g \text{ is the gravitational constant}$$

for the particle to slide down to the bottom of the cycloid (i.e., $t = \pi$). This property was used by C. Huygens to make clocks without pendula (which he hoped would allow for accurate timekeeping on ships at sea and, thereby, improve navigation). He named the cycloid the *tautochrone* since the latter means "same time". We will revisit the cycloid in Chapter 7 where we will see it has yet another intriguing property and name. Hints: potential energy is turned into kinetic energy by $v^2/2 = g(\bar{y} - y)$. Time equals distance divided by speed, so

$$\begin{aligned} T &= \frac{1}{\sqrt{2g}} \int_{\bar{x}}^{x_{bot}} \frac{\sqrt{1 + y'^2}}{\sqrt{\bar{y} - y}}\,dx \\ &= \sqrt{\frac{a}{g}} \int_{\bar{t}}^{\pi} \sqrt{\frac{1 - \cos t}{\cos \bar{t} - \cos t}}\,dt \\ &= \sqrt{\frac{a}{g}} \left(-2 \arcsin\left[\frac{\sqrt{2}\cos\frac{t}{2}}{\sqrt{1 + \cos \bar{t}}} \right] \right) \Bigg|_{\bar{t}}^{\pi} \end{aligned}$$

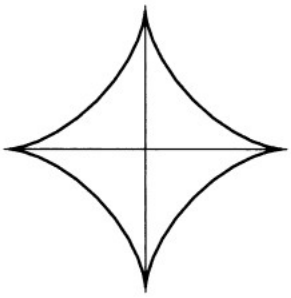

Figure 1.8. An astroid

using $y' = (dy/dt)\big/(dx/dt) = -\sin t/(1-\cos t)$, $\bar{y} = B - a(1-\cos\bar{t})$, $y = B - a(1-\cos t)$ and simplifying. Verify the final step by differentiation and compute T. Now see Section 1.7 for a Maple approach.

Example 1.1.15 (The Astroid).
Consider the astroid $\alpha(t) = (a\cos^3 t,\ a\sin^3 t)$ for $0 \leq t \leq 2\pi$ (see Figure 1.8). The definition of the astroid (which was discovered by people searching for the best form of gear teeth) is very similar to that of the cycloid. For the astroid, however, a circle is rolled, not on a line, but inside another circle. More precisely, let a circle of radius $a/4$ roll inside a large circle of radius a (centered at $(0,0)$ say). For concreteness, suppose we start the little circle at $(a, 0)$ and follow the path of the point originally in contact with $(a, 0)$ as the circle rolls up. Roll the circle a little bit and notice that a piece of arclength s is used up. The key to understanding this situation is the fact that, for t, the angle from the center of the large circle to the new contact point and θ, the angle through which the small circle has rolled (measured from the point of contact), we have $s = at$ and $s = a\theta/4$. Hence, $\theta = 4t$.

Now we can do two things to parametrize the path of the rolling point. First, we can parametrize the path *with respect to the center of the little circle*. This is easy because we are just moving an angle θ around a circle. There is a small problem because we measure θ from the point of contact, but this is handled easily as in Figure 1.9. Note that we make real use of the relation $\theta = 4t$ here. The coordinates with respect to the center then become $x = (a/4)\cos 3t$ and $y = (a/4)\sin 3t$.

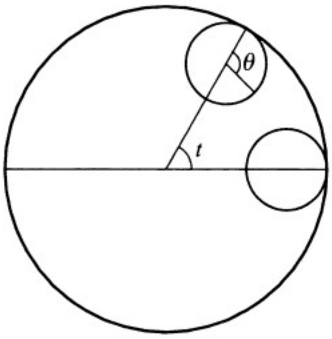

Figure 1.9.

3- 0 " " C T C 0* .. , (
* $$ $ $,$ C * .. , (

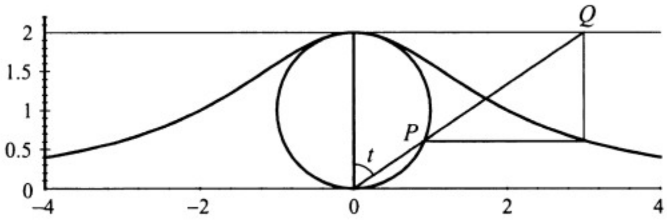

Figure 1.10. The Witch of Agnesi

Secondly, the center of the little circle always remains on the circle of radius $3a/4$ centered at $(0, 0)$, so that the center has moved to $((3a/4)\cos t, (3a/4)\sin t)$. Hence, with respect to the origin $(0, 0)$, the rolling point has moved to

$$\alpha(t) = \left(\frac{3a}{4}\cos t + \frac{a}{4}\cos 3t,\ \frac{3a}{4}\sin t - \frac{a}{4}\sin 3t\right).$$

Exercise 1.1.16. Verify the statements above and show that the formula for the astroid may be reduced to

$$\alpha(t) = (a\cos^3 t,\ a\sin^3 t)$$

with implicit form $x^{2/3} + y^{2/3} = a^{2/3}$.

Exercise 1.1.17. From the origin draw a line through any point P of the circle of radius a centered at $(0, a)$. Find the intersection Q of this line with the horizontal line $y = 2a$. Drop a vertical line from Q and intersect it with a horizontal line passing through P. This intersection is a point on the curve known as the *witch of Agnesi*.[1] See Figure 1.10. Let t denote the angle between the vertical axis and the line through $(0, 0)$, P and Q. Show that the witch $W(t)$ is given in terms of t by

$$W(t) = \left(2a\tan t,\ 2a\cos^2 t\right).$$

Example 1.1.18 (The Helix).
Consider the parametrization $\alpha(t) = (a\cos t,\ a\sin t,\ bt)$, for $0 \leq t < \infty$. Notice that the the first two coordinates provide circular motion while the third coordinate lifts the curve out of the plane. The resulting *helix* is then seen in Figure 1.11. We calculate $\alpha'(t) = (-a\sin t, a\cos t, b)$ and $\alpha''(t) = (-a\cos t, -a\sin t, 0)$. Note that $\alpha''(t)$ points toward the z-axis.

Example 1.1.19 (The Suspension Bridge).
Consider the diagram of a suspension bridge (Figure 1.12) where the cable supports a uniformly distributed load. This means that, over any interval $[a, b]$, the weight supported is given by

---

[1] The 'witch' was named by Maria Agnesi in the middle 1700s — apparently as the result of a mistranslation! The curve had been studied previously by Grandi who had used the Italian word "versorio", meaning "free to move in any direction", in connection with it. Agnesi mistakenly thought Grandi had used the Italian "versiera", which means "Devil's wife" or "witch" and so Agnesi's witch got "her" name [Yat74].

```

Exercise 1.7.10. Recreate the rectifying curves of Theorem 1.5.11. Hint: take, say, $\kappa = s^2 + 2s$ and $\tau = s$.

We have seen in the re-creation of curves above how Maple's "dsolve" command can be used to numerically solve differential equations. In fact, however, "dsolve" can often provide explicit solutions also. Let's look at an example where we see how the Laplace transform can be used to determine the tautochrone of Exercise 1.1.14, the curve having the property that a bead sliding (without friction) to the bottom arrives in the same time no matter where it starts on the curve. Write the curve as $x = x(y)$ since the potential due to gravity involves y. Suppose that the bead begins at a point (x_1, y_1) on the curve and the bottom is at $(0, 0)$. Conservation of energy says that we have $mg\,y_1 = mv^2/2 + mg\,y$ at any point (x, y) along the slide, so the bead's speed is given by $v = \sqrt{2g(y_1 - y)}$. The arclength along an infinitesimal portion of the curve is given by $ds = \sqrt{(\frac{dx}{dy})^2 + 1}\,dy$ and $D = R\,T$, so the total time it takes to the bottom is given by $T = \int_{y_1}^{0} \sqrt{(\frac{dx}{dy})^2 + 1}/\sqrt{2g(y_1 - y)}\,dy$. We want this to be a constant independent of y_1. Write

$$\sqrt{2g}\,T = \int_{y_1}^{0} \frac{\sqrt{(\frac{dx}{dy})^2 + 1}}{\sqrt{y_1 - y}}\,dy,$$

$f(y_1) = 1/\sqrt{y_1}$ and $h(y_1) = \sqrt{(\frac{dx}{dy_1})^2 + 1}$. This means that the integral is a convolution integral of f and h, so $\sqrt{2g}\,T = -f(y) * h(y)$, where we have switched the variable to y for convenience. We will now apply the Laplace transform to both sides, ending up with the transform of $h(y)$ alone. We will then use the inverse transform to find a condition on h which will determine the curve $x = x(y)$. The necessary Maple package is "inttrans" which stands for "integral transform".

```
>  with(inttrans):
```

Sometimes we have to tell Maple certain things to assume about a problem. Here is how to do that.

```
>  assume(T,constant); additionally(g,constant);
> laplace(sqrt(2*g)*T,y,s);
```

$$\frac{\sqrt{2}\,\sqrt{g}\,T}{s}$$

```
> f:=1/sqrt(y);
```

$$f := \frac{1}{\sqrt{y}}$$

It is fortunate that Maple knows how to take this Laplace transform, because it very difficult by hand. Indeed, it involves the Γ function and its properties.

```
> laplace(f,y,s);
```

$$\sqrt{\frac{\pi}{s}}$$

Since $\sqrt{2\,g}\,L(T) = -L(f)\,L(h)$, we can find $L(h)$ by dividing as follows.

```
> Lh:= simplify(laplace(sqrt(2*g)*T,y,s)/laplace(f,y,s),
symbolic);
```

$$Lh := \frac{\sqrt{2}\,\sqrt{g}\,T}{\sqrt{\pi}\,\sqrt{s}}$$

Therefore, h(y) can be found using the inverse laplace transform.

```
> h:=simplify(invlaplace(Lh,s,y),symbolic);
```

$$h := \frac{\sqrt{2}\,\sqrt{g}\,T}{\pi\,\sqrt{y}}$$

But we know that $h(y) = \sqrt{(\frac{dx}{dy})^2 + 1}$, so this gives us a differential equation for $x = x(y)$. Here is how to solve for $x = x(y)$.

```
> solve(sqrt(diff(x(y),y)^2+1)=
2^(1/2)*g^(1/2)*T/Pi/y^(1/2),diff(x(y),y));
```

$$\frac{\sqrt{-y\,(\pi^2\,y - 2\,g\,T^2)}}{\pi\,y},\ -\frac{\sqrt{-y\,(\pi^2\,y - 2\,g\,T^2)}}{\pi\,y}$$

```
> simplify(1/Pi/y*(-y*(Pi^2*y-2*g*T^2))^(1/2), symbolic);
```

$$\frac{\sqrt{\pi^2\,y - 2\,g\,T^2}\,I}{\pi\,\sqrt{y}}$$

Note that Maple simplifies by introducing the complex number $I = \sqrt{-1}$. This is just notation however. We now use "dsolve" to solve the differential equation.

```
> dsolve(diff(x(y),y)=1/Pi/sqrt(y)*
(-(Pi^2*y-2*g*T^2))^(1/2),x(y));
```

$$x(y) = \frac{\sqrt{-\pi^2 y + 2 g T^2}\,\sqrt{y}}{\pi} + \frac{g T^2 \sqrt{(-\pi^2 y + 2 g T^2)\, y} \cdot \arctan\left(\frac{\pi \left(y - \frac{g T^2}{\pi^2}\right)}{\sqrt{-\pi^2 y^2 + 2 y g T^2}}\right)}{\pi^2 \sqrt{-\pi^2 y + 2 g T^2}\,\sqrt{y}} + \_C1$$

This doesn't give much information, so we substitute cleverly to see what is going on.

```
> x(y)=Int(1/Pi/y^(1/2)* (2*g*T^2-Pi^2*y)^(1/2),y=0..y1);
```

$$x(y) = \int_0^{y1} \frac{\sqrt{-\pi^2 y + 2 g T^2}}{\pi \sqrt{y}}\, dy$$

In order to change variables in an integral easily, we need to use the "student" package.

```
> with(student):
> x(y)=changevar(y=2*g*T^2/Pi^2*sin(w)^2,
Int(1/Pi/y^(1/2)*(2*g*T^2-Pi^2*y)^(1/2),y=0..y1),w);
```

$$x(y) = \int_0^{\arcsin\left(\frac{\sqrt{2}\,\pi \sqrt{\frac{y1}{g T^2}}}{2}\right)} \frac{2\sqrt{2}\sqrt{-2 g T^2 \sin(w)^2 + 2 g T^2}\; g T^2 \sin(w)\cos(w)}{\pi^3 \sqrt{\frac{g T^2 \sin(w)^2}{\pi^2}}}\, dw$$

Let's try to simplify the integrand.

```
> simplify(2/Pi^3*2^(1/2)/(g*T^2/Pi^2* sin(w)^2)^(1/2)*
(-2*g*T^2*sin(w)^2+2*g*T^2)^(1/2)*g*T^2*sin(w)*cos(w),trig);
```

$$\frac{4\sqrt{g T^2 \cos(w)^2}\; g T^2 \sin(w)\cos(w)}{\pi^2 \sqrt{-g T^2 (-1 + \cos(w)^2)}}$$

Now, Maple is never perfect at simplifying. As humans, we can see that certain trigonometric identities hold, but Maple doesn't always recognize them. We also note that $\cos(w)$ is positive here, but Maple won't take the square root without us telling it to do so explicitly. In practice, we must use our own skills with Maple's to achieve the best results in simplification.

```
> x(y)=int(4*g*T^2*cos(w)^2/Pi^2,w);
```

$$\mathrm{x}(y) = \frac{4\,g\,T^2\left(\frac{1}{2}\cos(w)\sin(w) + \frac{w}{2}\right)}{\pi^2}$$

```
> x(y)=combine(4*g*T^2/Pi^2* (1/2*cos(w)*sin(w)+1/2*w),w);
```

$$\mathrm{x}(y) = \frac{g\,T^2\sin(2\,w) + 2\,g\,T^2\,w}{\pi^2}$$

Therefore, we have a parametric description of the curve $x = \mathrm{x}(y)$ in terms of the parameter w (recall that $y = 2\,g\,T^2\sin(w)^2/\pi^2$ and that the half angle formula simplifies this to $y = g\,T^2\,(1 - \cos(2\,w))/\pi^2$. Substitute $2\,w = \theta$.

```
> xtheta:=(g*T^2/Pi^2)*(sin(theta)+theta);
ytheta:=(g*T^2/Pi^2)*(1-cos(theta));
```

$$xtheta := \frac{g\,T^2\,(\sin(\theta) + \theta)}{\pi^2}$$

$$ytheta := \frac{g\,T^2\,(1 - \cos(\theta))}{\pi^2}$$

This is a cycloid! So Maple (with a little human intervention) discovers the tautochrone to be a cycloid. Let's forget about the constant factors and plot the parametric curve in Figure 1.37 and Figure 1.38.

```
> plot([theta+sin(theta),1-cos(theta), theta=0..4*Pi],
scaling=constrained,view=[0..12,0..2],color=blue);
> plot([theta+sin(theta),1-cos(theta), theta=Pi..2*Pi],
scaling=constrained,view=[3..6.3,0..2],color=magenta,
ytickmarks=4);
```

Now let's change course a bit by plotting and analyzing Viviani's curve from Exercise 1.3.26.

```
> viv:=<a*(1+cos(t))|a*sin(t)|a*2*sin(t/2)>;
```

$$viv := \left[a\,(1 + \cos(t)),\ a\sin(t),\ 2\,a\sin\left(\frac{t}{2}\right)\right]$$

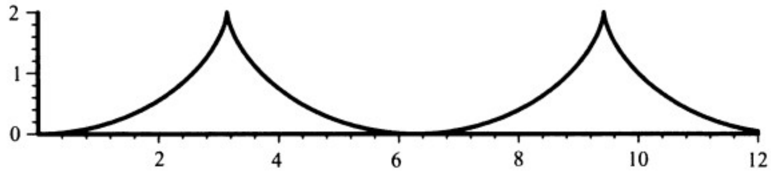

Figure 1.37. The tautochrone

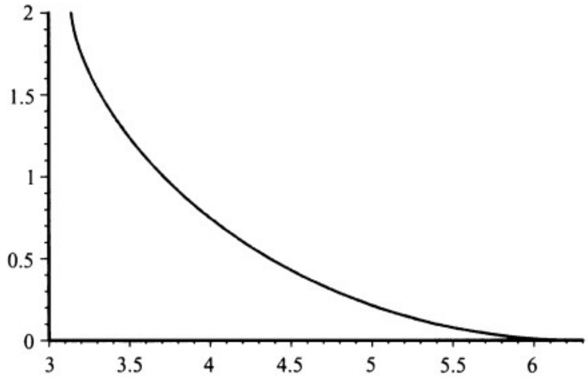

Figure 1.38. The tautochrone: a closer view

We can plot the curve in two ways. Again, we can save plots and display them all at once. We take Viviani's curve, a sphere and an intersecting cylinder. Viviani is the intersection!

```
> viv1:=spacecurve(convert(subs(a=1,viv), list),t=-Pi..Pi,
color=black):
> viv2:=tubeplot(convert(subs(a=1,viv),list), t=-2*Pi..2*Pi,
radius=0.05,color=black):
> sphere:=plot3d([2*cos(u)*cos(v), 2*sin(u)*cos(v),
2*sin(v)],u=0..2*Pi,v=-Pi/2..Pi/2,shading=XY,lightmodel
=light2):
> cyl:=plot3d([cos(u)+1,sin(u),v], u=0..2*Pi,v=-2..2,
shading=Z,lightmodel=light1):
```

Now we display the plots. Note that we use viv2 because "tubeplot" allows us to see the curve of intersection better. See Figure 1.39.

```
> display({viv2,sphere,cyl },scaling=constrained,
orientation= [-27,69]);
```

Now let's verify that Viviani's curve is a spherical curve. We use the criterion for spherical curves given in Exercise 1.3.23–Exercise 1.3.26.

```
> kk:=curv(viv);tt:=tor(viv);
```

$$kk := \frac{1}{2}\,\frac{\sqrt{3\cos\left(\frac{t}{2}\right)^2+5}}{a\left(1+\cos\left(\frac{t}{2}\right)^2\right)^{(3/2)}}$$

$$tt := \frac{3\cos\left(\frac{t}{2}\right)}{\left(3\cos\left(\frac{t}{2}\right)^2+5\right)a}$$

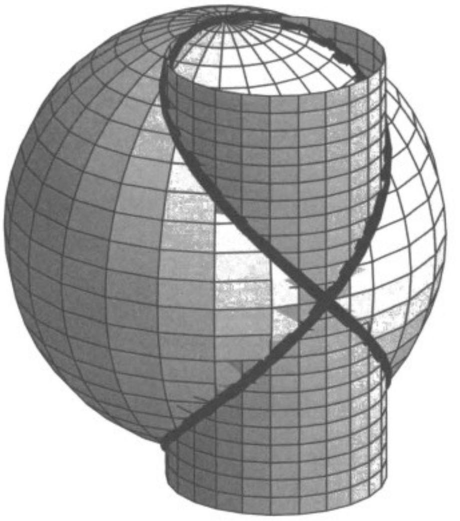

Figure 1.39. Viviani's curve as the intersection of sphere and cylinder

We now check the criterion. We need the following to be a constant.

```
> zz:=simplify(1/kk^2+(1/tt^2)* diff(1/kk,t)^2/Norm(
map(diff,viv,t),Euclidean,conjugate=false)^2,symbolic);
```

$$zz := 4\,a^2$$
